**Figure 39.1.** Components of TBI and various pathophysiologic mechanisms. *CPP,* Cerebral perfusion pressure; *DAI,* diffuse axonal injury; *ICP,* intracranial pressure; *SDH,* subdural hematoma. *(From Maas AIR, Stocchetti N, Bullock R. Moderate and severe traumatic brain injury in adults.* Lancet Neurol. *2008;7:728–741.)*

short and long time to echo (TE) acquisitions are the most commonly used techniques. MRS provides a noninvasive analysis of brain metabolites and biochemical changes. Decreased N-acetyl aspartate (NAA) has been correlated with abnormal neuropsychologic function in TBI. Significant lactate elevations have been correlated with a poor prognosis.[10]

### Nuclear Imaging Modalities

Single-photon emission CT (SPECT) can detect abnormalities in cerebral blood flow, but these alterations are not always associated with traumatic lesions on imaging. However, a negative initial SPECT scan after trauma is a strong predictor of favorable clinical outcome. A worse prognosis is associated with large and/or multiple lesions, as well as lesions located in the brainstem, basal ganglia, and temporal or parietal lobes.

Positron emission tomography (PET) measures the cerebral metabolism of various substrates (see Chapter 25). Fluorodeoxyglucose, the primary substrate used in the measurement of glucose metabolism, correlates to neuronal viability. Although rarely used in children, PET can be used in DAI to determine damage extent, predict prognosis, and determine lesion reversibility. The major limitation of PET is its inability to distinguish functional abnormalities from structural damage.

## CLASSIFICATION AND MECHANISMS OF HEAD INJURY

The sequelae of head trauma can be classified into direct injury from impact loading forces and indirect injury from acceleration/deceleration and rotational forces. Brain injury may result from direct (coup) or indirect (contrecoup) impact. The most common sequelae of direct head injury are scalp hematoma, skull fracture, brain contusion, laceration of the brain parenchyma, subarachnoid hemorrhage (SAH), and epidural or subdural hematomas beneath the site of impact. Nonimpact (acceleration/deceleration) injuries are the result of linear translational forces, acceleration/deceleration, and rotational acceleration causing shear-strain on axons, neurons, and blood vessels. These injuries include contusions, DAI, deep gray matter injury, brainstem injuries, and intraparenchymal and extraaxial hematomas. Brain axons are the most vulnerable, and blood vessels are the most resistant to injury from acceleration/deceleration forces (Fig. 39.1).[11]

Based on the GCS, head injuries are classified as mild (GCS score 13 to 15), moderate (GCS score 9 to 12), and severe (GCS score 3 to 8). Most head trauma results in mild injury with a nearly 0% risk of death in children. Moderate pediatric head injury has a similar occurrence rate as in adults, but a lower mortality rate. Severe pediatric head injury occurs less frequently than in adults, but has a significantly lower mortality rate. The exception is in infants under 2 years who have a higher rate due to severe head injuries from NAT.[12]

### Scalp Hematoma

Scalp contusions and hematomas usually resolve without complications with the exception of subgaleal hematomas in infants, which may pose the risk of life-threatening hypovolemia. When evaluating pediatric scalp contusions, size, location, and patient age are important factors because large scalp hematomas (particularly in infants under 12 months) are associated with an increased risk of fractures and intracranial injury.

### Skull Fractures

The likelihood of intracranial injury in children increases significantly when a skull fracture is present. However, the absence of a skull fracture does not preclude intracranial injury and has little prognostic significance in children. Younger children have thinner, more pliable skulls than adults. Therefore children have a higher incidence of traumatic intracranial injury without the presence of a fracture, particularly in children age 6 to 24 months. Falls and motor vehicle accidents account for most skull fractures in children.

Fractures in infants may be linear, depressed, diastatic, compound (stellate), "ping pong" (buckled), or penetrating. In this age group, fractures are often the result of being dropped by a caregiver or an object striking the head. Fractures tend to course toward a suture, synchondrosis, foramen, or canal. As the calvarium becomes more mature, comminuted fractures may occur.

Linear calvarial fractures are more frequent in all age groups, followed by depressed or comminuted calvarial and basilar fractures. Linear fractures usually heal without complication. Complex fractures, in which the dura mater is torn, may be complicated by herniation of arachnoid layers, creating a leptomeningeal cyst. CSF pulsations cause progressive erosion of fracture margins, known as a "growing fracture," which appears as a lytic skull lesion with scalloped margins (see Chapter 23). Underlying brain contusion is common.

Depressed fractures occur when osseous fragments are displaced inward and usually result from blunt force trauma. These fractures may result in increased intracranial pressure (ICP), epidural hematoma, parenchymal contusion, and/or laceration. Depressed fractures are treated surgically for cosmetic reasons and to prevent complications. Those involving the dural sinuses are treated conservatively due to the risk of fatal hemorrhage with intervention (e-Fig. 39.2). Depressed fractures are categorized as compound when associated with a scalp laceration and as penetrating when an underlying dural tear is present. Pneumocephalus indicates a compound fracture (e-Fig. 39.3). CSF leaks and infection are a concern with compound fractures that have visible contamination, a meningeal tear, and delayed treatment for more than 8 hours after the initial injury.

Diastatic skull fractures (sutures >2 mm) most frequently involve the lambdoid sutures of newborns and infants, but may occur at any age. However, asymmetric sutures, even those less than 2 mm, should raise suspicion for a diastatic fracture.

Skull base fractures are associated with increased risk of vascular or cranial nerve injury. Basilar fractures involving the temporal bone may cause bleeding into the middle ear and mastoid air cells. Temporal bone fractures are classified according to their orientation (longitudinal or transverse) and the portion of the temporal bone involved (petrous or squamous). These classifications are helpful in determining the risk of complications. Although longitudinal fractures are more common (70%–90%), transverse fractures are at higher risk of permanent injury to the facial and vestibulocochlear nerves, cochlear disruption, facial paralysis, sensorineural hearing loss, and perilymph fistula. Temporal bone fractures involving the petrous apex or the carotid canal are associated with increased risk of carotid artery and/or jugular vein injury.

Studies report sensitivities between 94% and 99% for detection of skull fractures on plain radiographs. These radiographs are routinely obtained in suspected cases of NAT as part of the skeletal survey. Previously, axial CT has had a lower sensitivity for detection of linear fractures parallel to the imaging plane. However, reconstructed planes and 3D CT are often diagnostic in difficult cases. CT is sensitive for the detection of depressed and basilar skull fractures, fractures of the facial bones, sinuses, and orbits. In children, skull fractures heal in 6 to 8 weeks, but may remain radiographically visible for 1 year.

## Extraaxial and Intraventricular Hemorrhage

### Epidural Hematoma

Epidural hematomas are uncommon in infants and increase in incidence with age, peaking in adulthood. The etiology of epidural hematomas in children differs from adults. Venous epidural hematomas usually occur in younger children due to tearing of a dural venous sinus, an emissary or diploic vein. Venous epidural hematomas occur in the posterior fossa and occipital region from laceration of the transverse or sigmoid sinus. Middle cranial fossa and parasagittal hematomas result from injuries of the sphenoparietal sinus and superior sagittal sinus, respectively. In older children and adolescents, arterial epidural hematomas are more common. They often involve injuries to the meningeal artery with hematomas accumulating over the temporal or parietal convexities (Fig. 39.4). Fractures associated with epidural hematomas are slightly less frequent in children than adults (83% vs. 93%).

The presentation of epidural hematomas in children may include a loss of consciousness at the time of injury, with a lucid interval in the first 24 hours. Factors associated with a poor outcome in children with epidural hematomas include absence of an immediate lucid period, the presence of additional intracranial injuries, a delayed diagnosis, and surgical intervention.

Epidural collections do not cross suture lines, but do extend over the falx and tentorium. Posterior fossa epidural hematomas may extend into the supratentorial compartment, whereas subdural hematomas are confined to one compartment. Moreover, frontal epidural collections may cross the midline along the superior sagittal sinus, whereas subdural hematomas accumulate along the falx. These features are much more reliable than lentiform versus biconvex shape at differentiating epidural from subdural hematomas. Venous epidural hematomas are frequently concave in the posterior fossa, are often larger, and carry an overall worse prognosis than arterial epidural hematomas because of their delayed presentation.

On CT, acute epidural hematomas are hyperattenuated with progression to intermediate attenuation in the subacute phase and hypoattenuation, possibly with membranes, in the chronic phase. Mixed attenuation may represent active bleeding, hypercoagulable states, a dural tear with mixed CSF and blood in the epidural space, or layering serum as a result of clot retraction. Mixed attenuation hyperacute hematomas (active hemorrhage) occur in the hours after an injury and have frequent associated severe brain injury, edema, and mass effect.

On MRI, the signal characteristics of extraaxial collections are more variable than on CT and depend on several factors such as the patient's hematocrit, local partial pressure of oxygen, pH level, protein concentration, presence of an associated dural tear with CSF mixing, and the magnetic field strength. Signal changes over time of intracranial hematomas have been mainly studied in adults with parenchymal, not subdural, hemorrhages. Because of this, the age of intraaxial, but not extraaxial, blood products can be reliably dated with MRI. Although aging of extraaxial hematomas based on MRI signal characteristics have not been validated in children, signal patterns are similar to parenchymal blood (Table 39.1).

MRI is useful in distinguishing small epidural from subdural hematomas, in which the displaced dura in an epidural hematoma is visualized as a thin, uniform line of hypointense signal on intermediate and T2-weighted sequences. The inner membrane of a subacute or chronic subdural hematoma may have a similar appearance, but the membrane is thicker and more irregular.

### Subdural Hematoma

Subdural hematomas are more common in infants than in older children and adolescents. They may result from shear-strain forces disrupting small veins that traverse the potential subdural space. In infants, up to 85% of subdural hematomas are bilateral. Trauma is the most common cause of subdural hematomas, both accidental and NAT. Most subdural hematomas in infants under 2 years are caused by NAT. Other findings suggestive of NAT include interhemispheric location of subdural hematomas, multilayered subdural hematomas containing blood at different stages of degradation, and associated parenchymal contusions. Retinal hemorrhages are also suggestive of NAT and usually found on funduscopic examination.

Infants with subdural hematomas have various presentations ranging from asymptomatic to vomiting, poor feeding, irritability, a bulging fontanelle, or an increasing head circumference. Older children more commonly present with the signs of raised ICP, headache, altered level of consciousness, systemic hypertension, decreased heart rate, irregular respiration, asymmetric pupils, and hemiparesis. Large subdural hematomas may cause anemia due to blood loss, especially in infants.

(C) A hyperacute mixed attenuation (actively bleeding) left frontal subdural hematoma extending to the left occipital lobe is shown *(arrows).* (D) A skull fracture parallel to the image plane is noted *(arrow).* (E) An acute epidural hematoma adjacent to the fracture *(arrow)* in the same patient as *D*. (F) The poorly visualized fracture on axial images is well demonstrated on 3D volume rendering *(arrow).*

**TABLE 39.1** MRI of Blood at Different Stages at 1.5 Tesla

| Age of Blood | T1 | T2 | GRE |
|---|---|---|---|
| Hyperacute (4–6 hours) | Isointense | Hyperintense | Hypointense |
| Acute (7–72 hours) | Isointense | Central hypointense and peripheral hyperintense | Hypointense |
| Early subacute (4–7 days) | Peripheral hyperintensity and central isointense | Hypointense with some central hyperintense | Hypointense |
| Late subacute (1–4 weeks) | Hyperintense | Hyperintense | Hypointense |
| Early chronic (months) | Peripheral isointensity to hypointensity and central hyperintensity | Peripheral hypointense and central hyperintense | Hypointense |
| Late chronic (months to years) | Hypointense | Hypointense | Hypointense |

*GRE,* Gradient echo.

Subdural hematomas are most commonly located over the frontal, parietal, and temporal lobes. Posterior fossa subdurals, approximately 10% of cases, may result from tearing of the dural sinuses or tentorium. Subdural hematomas cross sutures, but do not cross the falx or tentorium. Occasionally, a normal hyperdense falx may mimic a subdural hematoma on CT. The normal falx is distinguished by a thin, smooth, symmetric contour. Conversely, subdural hematomas are asymmetric, are more irregular, and cause thickening of the falx or tentorium.

CT characteristics of subdural hematomas depend on hematoma age. Hyperacute hematomas represent unclotted blood and show mixed attenuation. After a few hours, hyperacute hemorrhage coagulates converting to an acute hematoma, which is homogenously hyperattenuated. The hyperattenuated acute blood may mix with CSF resulting from a tear in the arachnoid (see Fig. 39.4). Within 1 to 3 weeks, subacute hematomas become isodense to brain parenchyma. After 2 to 3 weeks, the attenuation becomes similar to CSF indicating a chronic hematoma. Hematomas that are isointense to brain may be difficult to detect, save for associated mass effect heralding their presence. If the presence of a subacute or chronic hematoma is questionable, intravenous contrast may show enhancing membranes. If the size of the collection increases or if the attenuation is heterogeneous, rebleeding should be suspected. Spontaneous rebleeding is common in subdural hematomas and does not indicate additional trauma. Membranes calcify in under 3% of cases.

MRI is more sensitive than CT for the detection of subdural hematomas, particularly when their attenuation is similar to brain parenchyma or CSF. Proton-density and FLAIR are the most sensitive sequences for detection of subdural hematomas that are isointense to CSF on T1- and T2-weighted images. The signal of subdural hematomas on MRI varies, depending on the phase of blood products and the presence or absence of CSF leakage. The evolution of signal characteristics of subdural hematomas are similar to those previously described for epidural hematomas.

Subdural hygromas are caused by laceration of the arachnoid with accumulation of CSF in the subdural space. They may occur alone or in combination with acute hemorrhage after trauma. Subdural hygromas generally manifest 3 to 5 days after injury and are bilateral in up to 50% of cases. Hygromas are distinguishable from chronic subdural hematomas in that they are isointense to CSF on all sequences, including FLAIR and proton-density.

## Subarachnoid and Intraventricular Hemorrhage

Traumatic SAH is due to damage of pia-arachnoid vessels and associated parenchymal injury. It is seen in 18% to 25% of pediatric closed head injury (CHI) cases. The amount of blood in the subarachnoid space is typically small and rarely persists longer than 1 week. If a large SAH is seen without parenchymal damage or extraaxial hematomas, there may be an underlying aneurysm or arteriovenous malformation. SAH may obstruct normal CSF resorption at the arachnoid granulations resulting in communicating hydrocephalus.

Traumatic intraventricular hemorrhage (IVH) is related to subependymal vein injury or decompression of a parenchymal hematoma into the ventricles. The most common location of subependymal vein injury is along the anterior corpus callosum, posterior fornix, or septum pellucidum.

CT is the imaging modality of choice for acute SAH and IVH, showing increased attenuation within the sulci (Fig. 39.5), or ventricles, respectively. The most common location of traumatic SAH is in the posterior interhemispheric fissure and along the tentorium. On CT, hyperdense SAH is initially detected adjacent to the source of bleeding. With time, it accumulates in the subarachnoid cisterns (particularly the interpeduncular cistern), the Sylvian fissures, over the convexities, and in the occipital horns.

MRI is more sensitive than CT in detecting small amounts of SAH, showing increased signal on FLAIR sequences. Although GRE and SWI sequences are less sensitive than FLAIR, when visible, SAH is hypointense on these sequences. While extensive or recurrent SAH is rare in children, it may lead to superficial siderosis, hemosiderin laden macrophages within the leptomeninges. Vasospasm due to traumatic SAH is rare in children.

## Traumatic Parenchymal Injury

### Contusion and Laceration

Brain contusions invariably involve the cortex, with variable underlying white matter injury. They are twice as common in children as adults. Brain contusions occur at the site of impact (coup), opposite the site of impact (contrecoup), along the rough calvarial surfaces in the anterior temporal and orbitofrontal regions, and against the free margins of falx cerebri, and tentorium. Cerebellar contusions are often associated with occipital fractures, and frequently involve the cerebellar tonsils. Brain edema develops over the first 1 to 2 days, and is maximal 3 to 5 days after the initial injury. Approximately 50% of brain contusions are hemorrhagic. With increasing severity, microhemorrhages may coalesce into focal hematomas. After 1 month, contused areas progress to form areas of cystic encephalomalacia.

On CT, contusions show hypoattenuation with loss of the gray-white differentiation and sulcal effacement. Hemorrhagic contusions show hyperattenuated central foci (see Fig. 39.5). After the contusion, cortical enhancement may occur in 1 to 2 weeks due to proliferation of immature capillaries lacking a blood-brain barrier.

MRI is the most sensitive modality for detection of brain contusions. In particular, DWI sequences are able to detect parenchymal contusions and shear injury in the first hours after an injury. After 1 to 2 days, contused areas become hyperintense on FLAIR and T2-weighted sequences due to edema and hemorrhagic foci (hypointense on T2 GRE or SWI) (e-Fig. 39.6). High signal on T1-weighted images may be seen in the subacute phase, related to methemoglobin. FLAIR is insensitive to parenchymal contusion in infants because of low contrast in the unmyelinated white matter. T2-weighted images are particularly useful in these cases, showing loss of gray-matter differentiation and hyperintensity relative to the normal brain.

Lacerations of brain parenchyma cause cortical hemorrhage with variable extension into the white matter. They result from penetrating and CHI with or without associated fractures (see Fig. 39.5). Posttraumatic hematoma may rapidly increase in size requiring follow-up imaging in the first 24 to 48 hours. Parenchymal lacerations are most common in the inferior frontal and anterior temporal lobes. Corpus callosum and brainstem lacerations may occur in association with DAI.

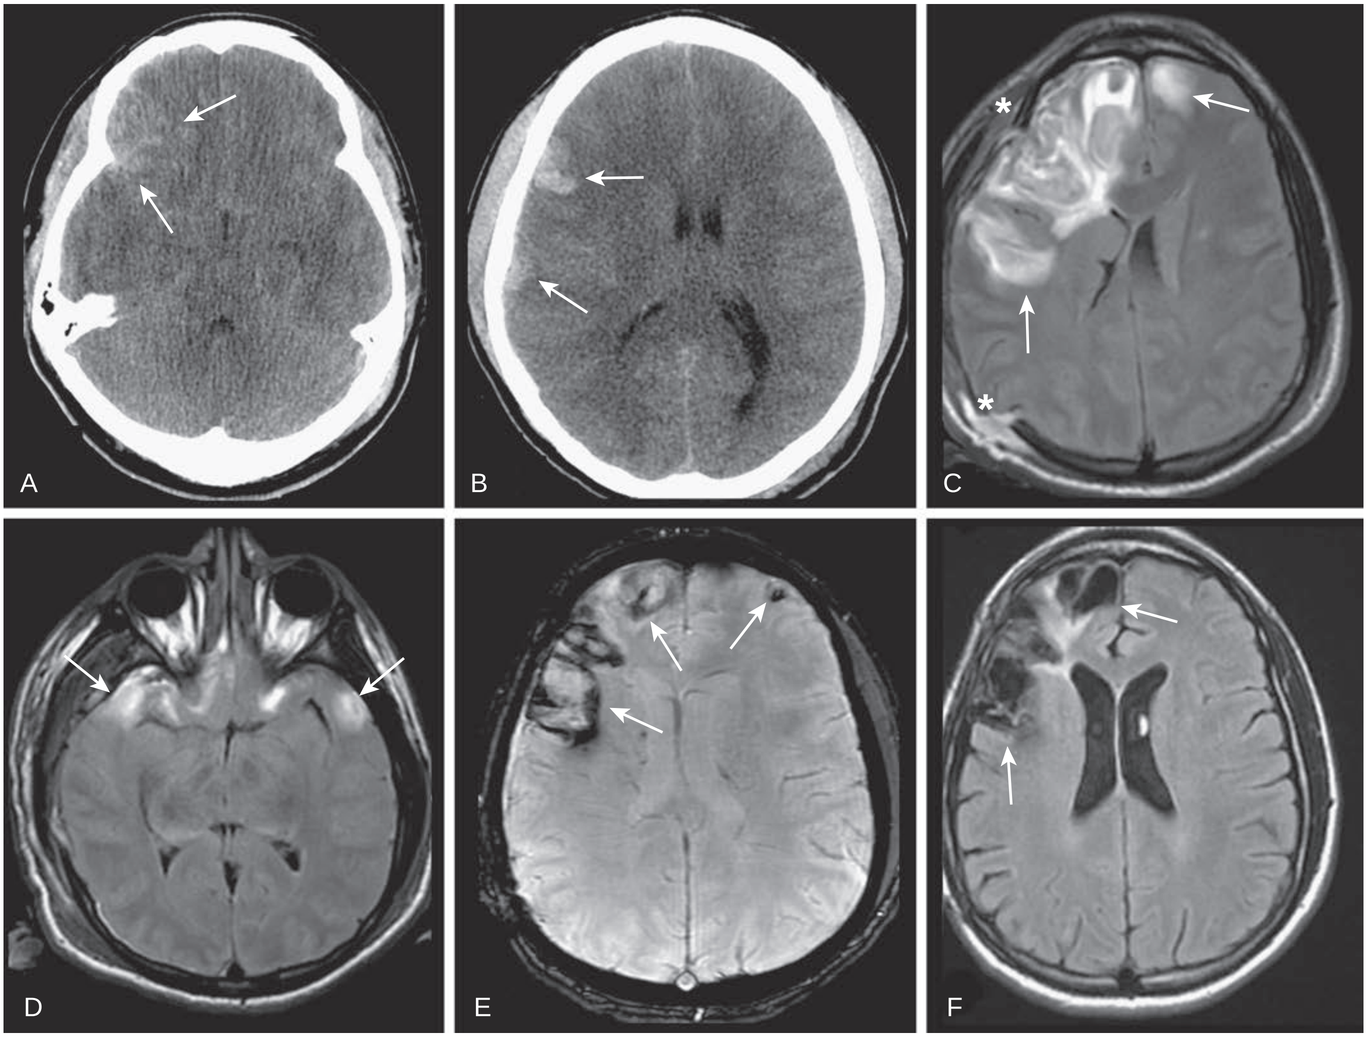
### Diffuse Axonal Injury

DAI is one of the most devastating types of TBI, and is the most common cause of posttraumatic neurologic and cognitive disability. DAI is more common in children than previously recognized, with infants being particularly susceptible. DAI results from rapid acceleration/deceleration resulting in angular and rotational forces that stretch the axons causing damage to their cytoskeleton. Subsequent brain swelling and calcium influx into injured axons is thought to cause further damage.

Children with DAI may present with immediate loss of consciousness and coma. Clinical symptoms are often disproportionate to imaging findings, and CT findings may be normal. Although high-speed motor vehicle accidents are the most common cause of DAI, it may result from any type of head trauma. The mechanism of shear-strain injury in infants younger than 12 months is different from older children and adults. The dominant histologic abnormality in infants is hypoxia, which leads to acute brain swelling, encephalomalacia, volume loss, and potentially death.

Imaging underestimates the extent of DAI, with only 20% to 50% of CT images showing findings initially. Findings of DAI on CT include foci of abnormal attenuation, which are usually bilateral, less than 1 cm, and oriented parallel to white matter tracts. DAI occurs most at the gray-white matter junction of the frontal and temporal lobes, splenium of corpus callosum, and brainstem. An important indirect sign of DAI is intraventricular hemorrhage from adjacent corpus callosum involvement (Fig. 39.7). In infants with severe DAI, CT demonstrates diffuse brain edema. Within 2 to 3 weeks, encephalomalacia and volume loss may also develop.

MRI is more sensitive than CT in detecting shear injuries, and is best performed 3 to 7 days after injury when cellular necrosis and restricted diffusion are maximal. MRI using SWI and GRE sequences detect DAI in 30% of patients with mild head injury and an initially normal CT scan. DAI reveals multiple small, ovoid



**e-Figure 39.6. Progression of imaging characteristics in a parenchymal contusion.** (A and B) Unenhanced CT images demonstrate an acute right frontal contusion *(arrows)* with minimal midline shift. (C and D) A few days later, MRI FLAIR image reveals extensive edema, increasing midline shift, and additional contusions in the left frontal lobe and temporal lobes *(arrows).* Postsurgical findings are related to right hemispherical craniotomy *(asterisks).* (E and F) A few months later, a peripheral rim of susceptibility related to chronic blood products *(arrows)* is seen on SWI sequence (E), and encephalomalacia and volume loss are seen on FLAIR (F).

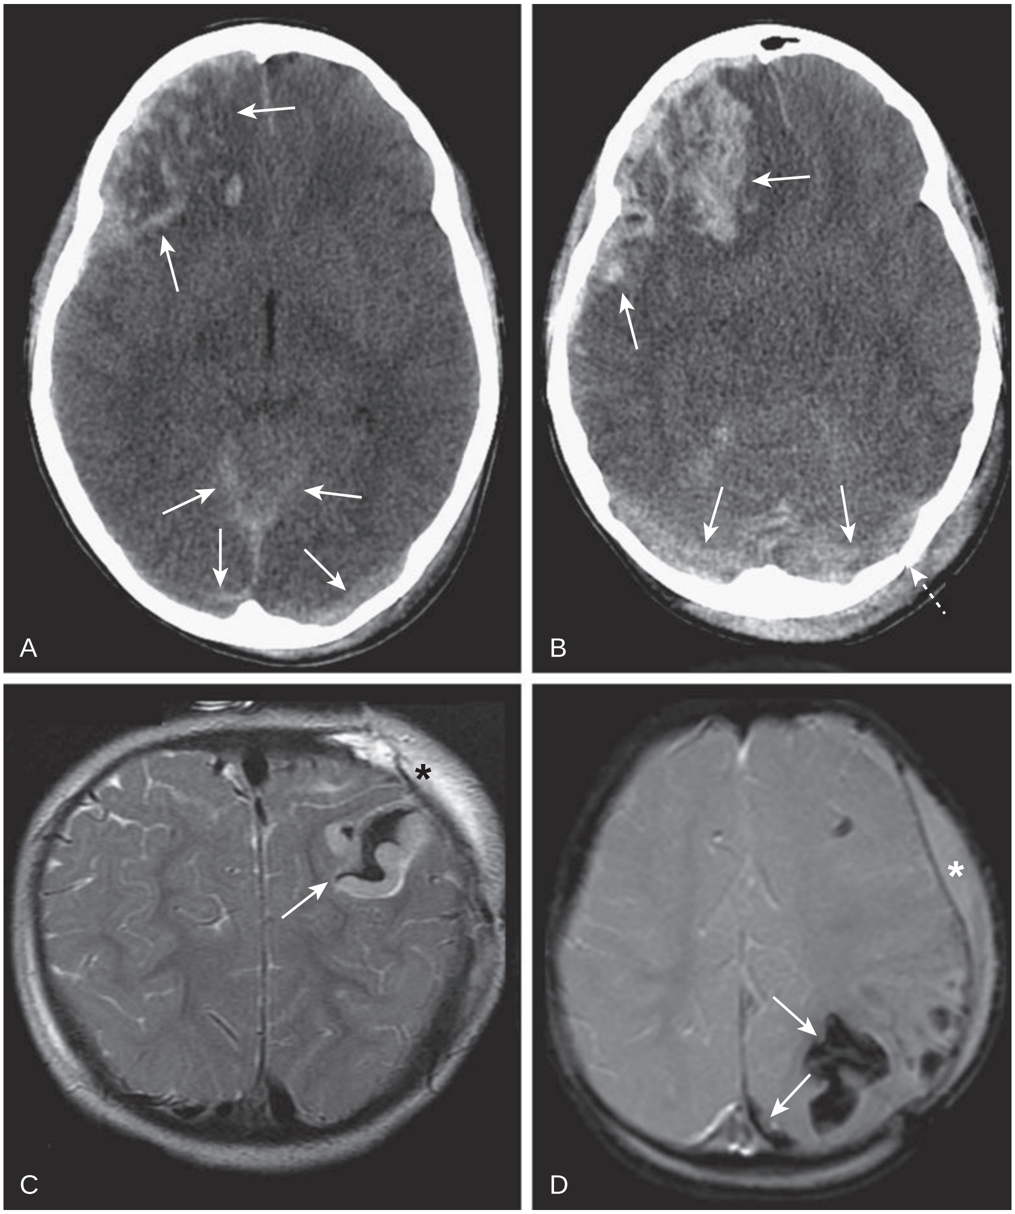


**Figure 39.5. Parenchymal contusion, subarachnoid hemorrhage, and laceration.** Unenhanced CT images (A and B) show a contrecoup right frontal and temporal contusion with associated subarachnoid hemorrhage *(arrows)*. Acute bilateral subdural hematomas are present along with a left occipital fracture and a scalp hematoma *(broken arrow).* MRI T2-weighted (C) and SWI sequence (D) show a parenchymal laceration with a hematoma *(arrows).* Also note postcraniectomy findings *(asterisks).*

areas of decreased T1, increased T2, increased FLAIR, and abnormal DWI signal. Hemorrhagic lesions cause susceptibility effect, with hypointensity on T2* and SWI (see Fig. 39.7). Initial nonhemorrhagic lesions may convert to hemorrhagic foci with time, showing change of signal characteristics of blood, with increasing size due to hemorrhage and edema. DWI depicts additional lesions that exhibit restricted diffusion. ADC values decrease over a longer period of approximately 18 days after injury, which is beyond the usual time frame for cytotoxic edema related to ischemia.[13]

A reduction in fractional anisotropy has been shown with DTI in early imaging after TBI. DTI tractography has shown acute axonal shearing injuries and may have prognostic value for post-traumatic cognitive and neurologic sequelae.

A grading scheme for DAI based on the severity of head trauma and lesion location has been proposed, with mild trauma resulting in more superficial lesions and increasingly severe trauma resulting in involvement of deeper structures. A greater number of lesions correlates with poorer outcomes.

## Deep Gray Matter Injury

Deep gray matter injury, which occurs in severely injured patients, constitutes less than 5% of all primary intraaxial injuries. This type of injury is found in the thalami, basal ganglia, and upper brainstem, from shear-strain forces disrupting small perforating vessels with or without hemorrhage. Surviving patients have profound neurologic deficits. CT is often normal,

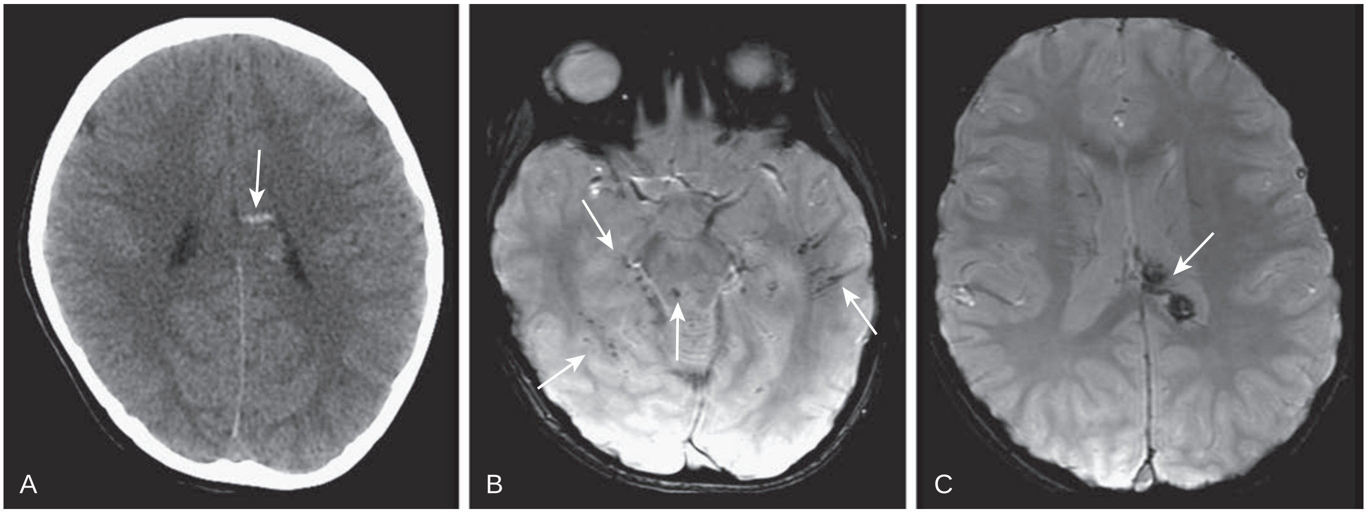

**Figure 39.7. Diffuse axonal injury.** (A) An unenhanced CT image with hyperdense foci in the corpus callosum compatible with a shear injury *(arrow).* (B and C) An MRI SWI sequence shows multiple susceptibility foci of hypointensity/blooming *(arrows)* consistent with parenchymal (B) and intraventricular (C) hemorrhage.

but may show foci of petechial hemorrhage. FLAIR is the most sensitive MRI sequence for nonhemorrhagic deep gray matter injury.

### Brainstem Injury

Although brainstem injury is uncommon in the pediatric population, it is likely underestimated. Clinically, patients with a brainstem injury recover poorly warranting further MRI evaluation.

Injuries include brainstem contusion, shear injury, pontomedullary separation, and hypoxic-ischemic injury. Brainstem injuries cause death in up to 50% of blunt head trauma cases.

Primary brainstem injury can occur from direct or indirect forces characteristically involving the dorsolateral midbrain and superior pons. Indirect forces resulting in brainstem injury can have variable associated DAI in the corpus callosum and deep white matter. Pontomedullary separation is a result of hyperextension forces and is often fatal.

Secondary brainstem injury can result from transtentorial herniation, global hypoxic-ischemic injury, or hypotensive hypoperfusion. If the cause of transtentorial herniation can be treated, its sequelae may be reversible. Prolonged compression of the brainstem and brainstem injury are usually terminal.

### Diffuse Brain Swelling and Hypoperfusion Injury

Diffuse brain swelling has been reported to occur in 21% of pediatric head trauma cases and is 3.5 times more common in this group, particularly in infants and young children.

After a young child sustains a traumatic injury, the immature vasoregulatory system responds with vasodilation and increased blood flow, resulting in a hyperemic state and subsequent diffuse cerebral swelling or edema. In addition, the release of excitatory amines also causes vasodilation and increased blood volume, and the redistribution of intracranial blood from pial to intraparenchymal vessels contributes further to the hyperemic state.

The imaging findings in both conditions primarily affect the cerebrum with loss of the gray-white interface, diffuse decreased attenuation, and effacement of the subarachnoid cisterns and ventricles on CT. The decreased attenuation can cause the circulating blood to erroneously appear hyperdense on CT giving it a “pseudo-SAH” appearance. Further, the cerebellum may be relatively hyperdense compared with the cerebral hemispheres (“white cerebellar sign,” Fig. 39.8).

DWI, MRS, and SWI are helpful in differentiating the two conditions. Increased blood flow and vasogenic edema have increased diffusion on DWI, whereas acute axonal shear injury with cytotoxic edema shows restricted diffusion. MRS shows decreased NAA and increased lactate, choline, and neurotransmitter levels as a result of neuronal injury in acute DAI, with metabolites near normal early in the course of cerebral edema. SWI has a high sensitivity for the detection of hemorrhagic lesions in the setting of DAI.

Progressive edema and increased ICP can result in transtentorial, subfalcine, and tonsillar herniation with subsequent vascular complications and death in 7% of pediatric cases. Overall, these complications occur less frequently in children than adults.

Hypoperfusion injury after trauma may be due to severe cerebral edema, hypotension, and shock. Imaging shows diffuse loss of gray-white interface with relative preservation of extraaxial spaces, subarachnoid cisterns, and ventricle size.

The reversal sign, decreased attenuation of the cerebral cortex compared with the thalami, brainstem, and cerebellum, is a striking CT finding in children with anoxic-ischemic injury. Its presence also portends a poor prognosis.

## SEQUELAE OF TRAUMA

Various clinical and imaging sequelae occur after trauma ranging from neurologic disability and seizures to hydrocephalus and encephalomalacia. Pediatric traumatic vascular injury, such as arterial dissection, may result in infarction (Fig. 39.9). Pseudoaneurysms after skull base fractures, and carotid cavernous fistulas, are less common sequelae after trauma. Venous injury to the dural sinuses is most common after birth trauma and is often associated with fractures, subdural hematomas, or epidural hematomas. Venous sinuses thrombosis can be caused by compression resulting from intracranial bleeding, adjacent fracture, or increased ICP.

CTA is used for imaging vascular injuries such as laceration, occlusion, dissection, pseudoaneurysm, or arteriovenous fistula. CSF leaks can also be evaluated with CT, radionuclide cisternography, and high-resolution long T2-weighted MRI. Infection is an uncommon sequela of penetrating injuries that may present with meningitis, empyema, cerebritis, or intracranial abscess.

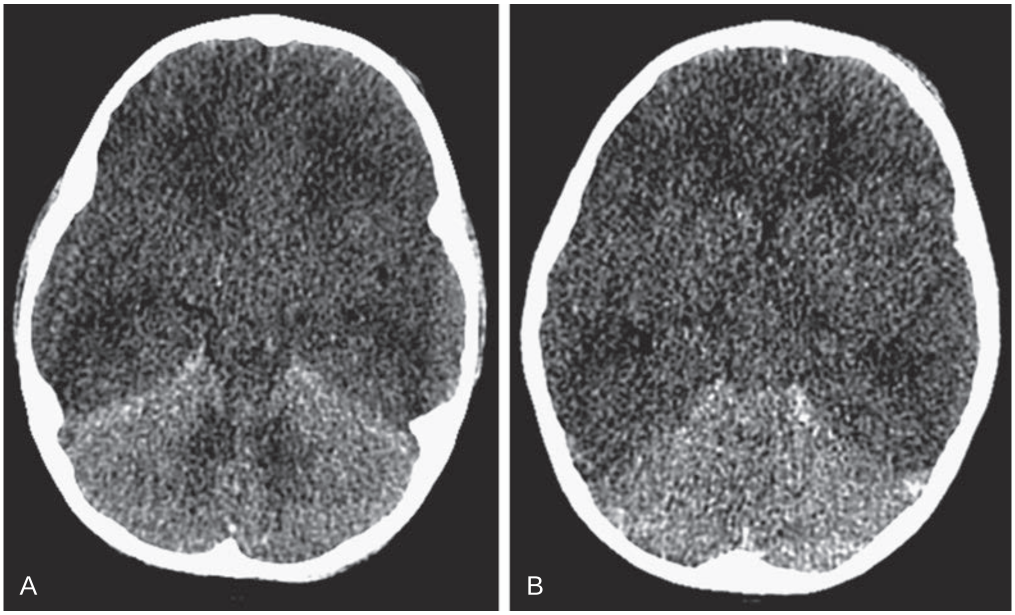

**Figure 39.8. White cerebellum sign.** (A and B) A noncontrast CT image shows diffuse decrease in attenuation of cerebral parenchyma, with increased attenuation of the cerebellum.

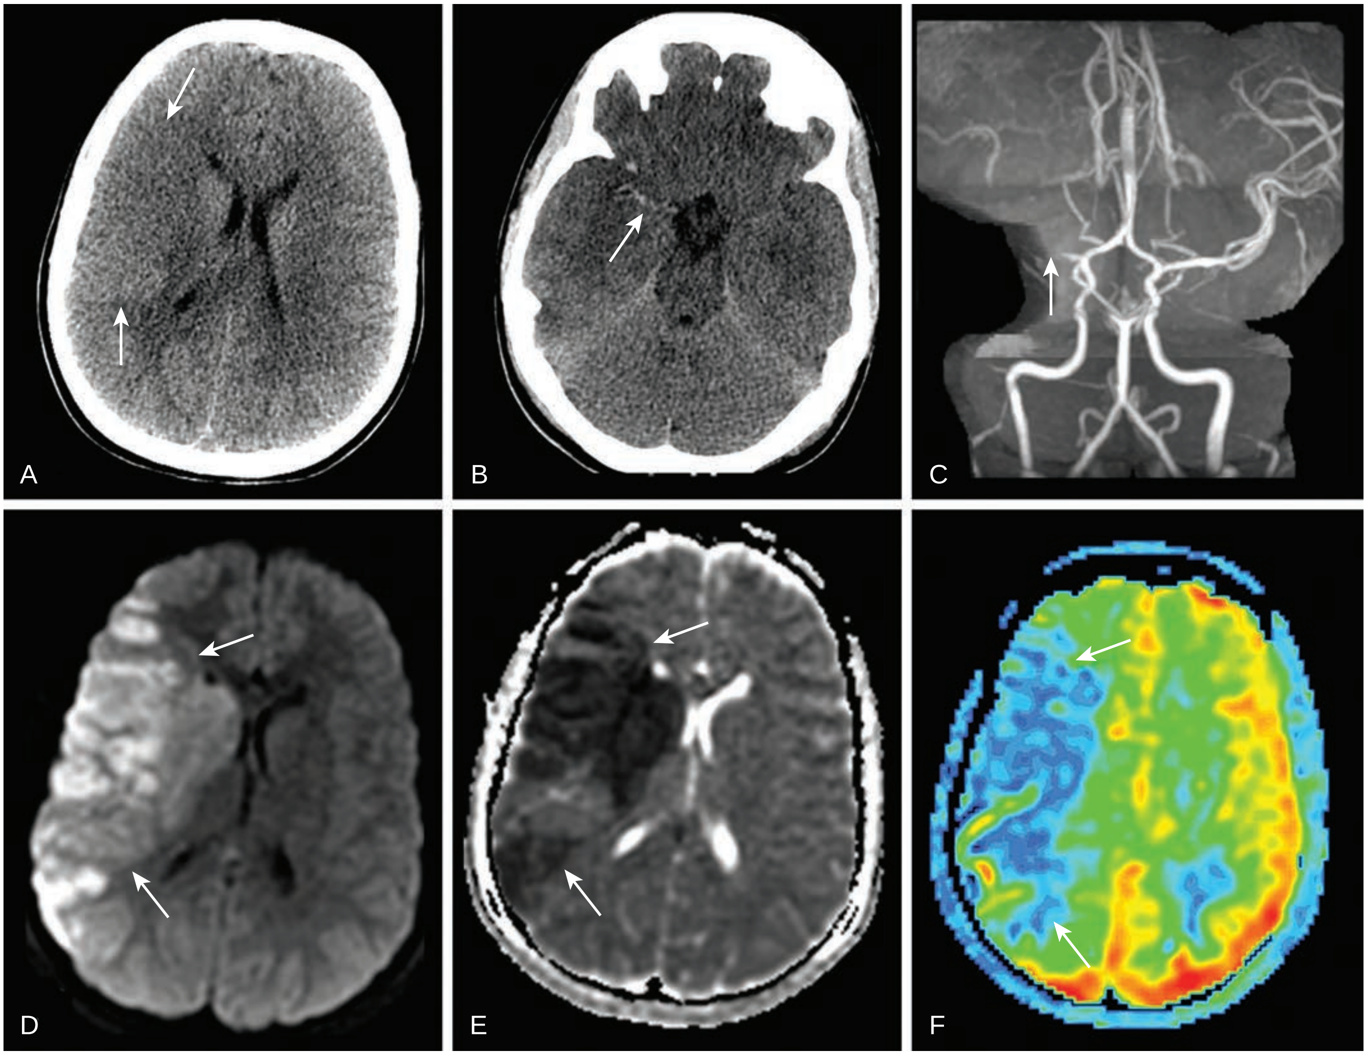

**Figure 39.9. Traumatic dissection of the right middle cerebral artery (MCA).** (A) An unenhanced CT image of the brain demonstrate poor gray-white matter differentiation in the right frontal and temporal lobes *(arrows).* (B) An unenhanced CT image at the level of the circle of Willis and midbrain demonstrates the "hyperdense MCA sign" *(arrow).* (C) Occlusion of the right MCA *(arrow)* on 3D time-of-flight MRA. Nonaccidental trauma.** (A–C) An unenhanced CT image demonstrates multiple areas of loss of gray-white matter differentiation *(asterisks)* and bilateral acute and subacute subdural hematomas *(arrows)*. (D–F) MRI T2-weighted images show the extent of parenchymal injury with multifocal cortical and subcortical injuries *(asterisks).*

## NONACCIDENTAL TRAUMA

Head injury after NAT is one of the leading causes of mortality and morbidity in infants and children. Radiologic findings are an integral part of the workup and diagnosis of NAT (see Chapter 143). Head injuries in these infants and children include skull fractures, intracranial and retinal hemorrhages, and parenchymal brain injury such as contusions, edema, ischemia, and infarction.

The clinical presentation of NAT head trauma is often nonspecific and highly variable ranging from a normal neurologic examination to irritability, lethargy, or seizures. Imaging findings of NAT may provide the first clues to the diagnosis. As in accidental trauma or other causes of acute altered mental status, CT is the initial imaging modality, with MRI used to further define injury extent and assess for possible craniocervical injury.

Intracranial hemorrhages, especially subdural hematomas, are common in NAT. Bleeding into the subarachnoid space may coexist and is seen in the sulci and subarachnoid cisterns. Epidural hemorrhages are uncommon in infants and young children who have sustained NAT. Most acute subdural hematomas are hyperdense on CT, but this finding varies because mixing with CSF from a dural tear may also present.

On MRI, the signal intensity of parenchymal injuries varies with time, and when correlated with other clinical findings, it can be helpful to clinicians and child advocacy services. However, the precise aging of parenchymal lesions and extraaxial hematomas should be undertaken with caution. CT hyperdensity is the only reliable indicator of hemorrhage age (Fig. 39.10). Subdural hematomas in infants under 2 years and subdural hematomas of different ages are highly suspicious for NAT. Although rarely seen on imaging, retinal hemorrhages are a cardinal manifestation of NAT that are best assessed on a dilated funduscopic examination (Fig. 39.11). Their number and severity (multiple, bilateral, multilayered, peripheral extension) correlates with the likelihood of NAT and the severity of associated brain injury.

Mortality and morbidity in children with NAT are often due to parenchymal brain injury. Posttraumatic hypoxic ischemic injury and brain edema are more common than parenchymal contusions and DAI. Hypoxic ischemic injury due to NAT is typically diffuse, and although the exact mechanism is unclear, it is likely related to hypoperfusion. Key imaging findings include diffuse loss of gray-white matter differentiation (brain edema) with sparing of the basal ganglia. Severe insults demonstrate basal ganglia and posterior fossa involvement. Hypoxia after strangulation involves various portions of the anterior circulation bilaterally, with relative sparing of the vertebral circulation. MRI and DWI are useful to delineate the extent and severity of ischemic injury. MRS may show a decrease in NAA, indicating neuronal loss, and an increase in lactate, indicating anaerobic metabolism and a worse prognosis (see Fig. 39.11).

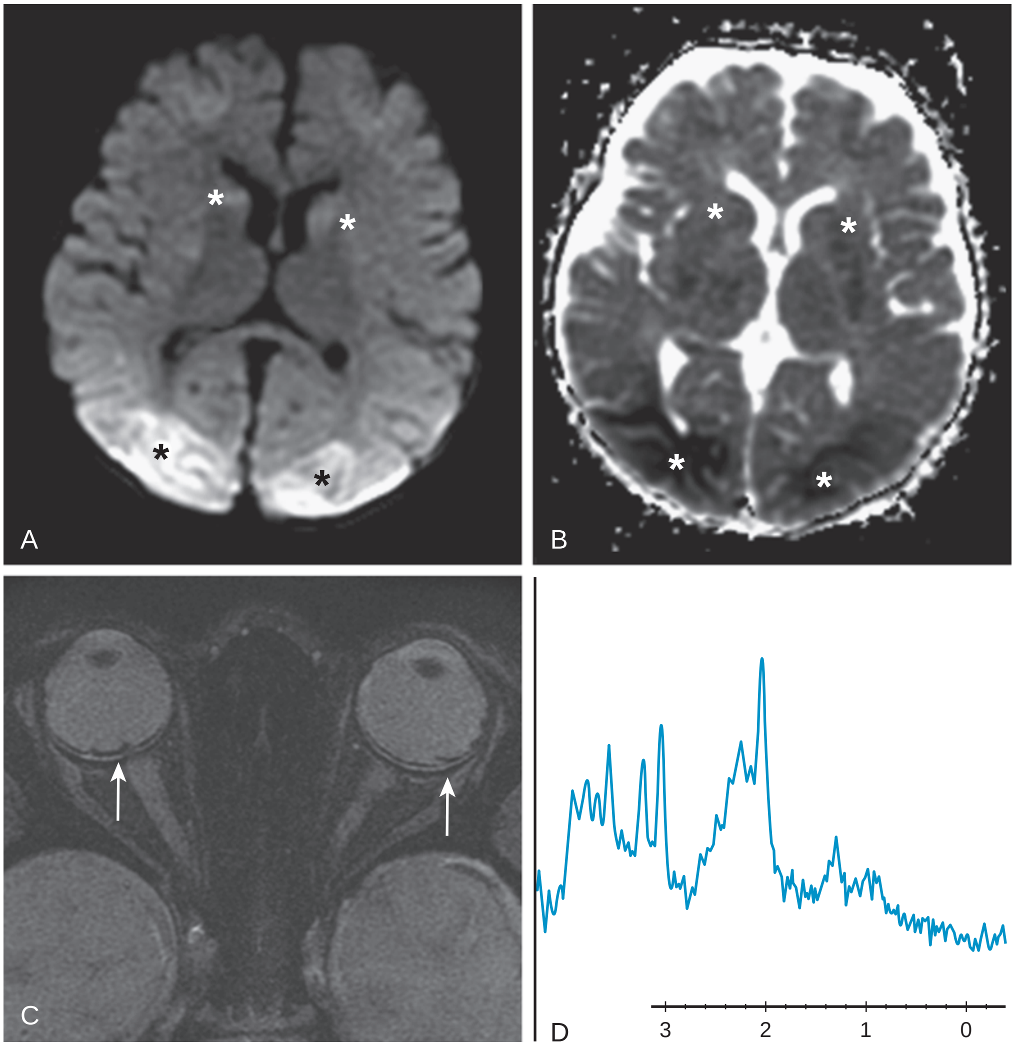

**Figure 39.11. Nonaccidental trauma.** (A and B) MRI diffusion sequences show multiple areas of restriction that are more pronounced in the occipital lobes and caudate nuclei *(asterisks)* (A) and ADC (B). (C) A high-resolution SWI sequence shows susceptibility related to retinal hemorrhages bilaterally *(arrows).* (D) MRS at the level of the occipital lobes demonstrates a decrease in NAA level (2.0 ppm), elevated lactate/lipids (0.8–1.2 ppm), and glutamate/glutamine (2.2–2.4 ppm) levels.

A multidisciplinary approach should be used in the diagnosis of NAT when radiologic findings are suspicious or inconsistent with the clinical history. Radiologists must also consider coagulopathies, severe meningoencephalitis, certain rare metabolic disorders (such as glutaric aciduria type 1) that can present with subdural hematomas, and birth trauma in the differential diagnoses. Intracranial hemorrhage in infants due to birth trauma generally resolves within 4 to 6 weeks.

Vigilance, familiarity with the radiologic findings, communication with the referring physician, relevant clinical history, and recommendation for further imaging to identify or document injuries for evidentiary reasons, if needed, all aid in the workup, diagnosis, and prosecution of NAT.

### Prognosis

Children are more likely than adults to recover from focal brain injury and have a higher likelihood of survival after severe injury. However, children are more vulnerable to long-term cognitive and behavioral dysfunction after diffuse brain injury. Some degree of learning disability is found in 50% of pediatric head trauma survivors. Overall, children under 6 years have the worst prognosis, likely because of the increased risk and prevalence of shear injury in the immature brain. Ultimately, functional outcome depends on injury extent and the ability of existing neurons to recover function.

## SUMMARY

Head trauma is a frequent cause of morbidity and mortality in the pediatric population. A wide spectrum of traumatic head injuries occurs in children, many of which are unique to the pediatric population. The type of injury depends on the mechanism, the force sustained, and patient age. Although CT is the acute imaging modality of choice, various newer imaging techniques such as CTA and MRI with DWI and MRS are useful to better predict recovery and outcome in pediatric patients.

## KEY POINTS

- Head trauma and resulting TBI are the most common causes of morbidity and mortality in children.
- In general, CT is the initial imaging modality used to evaluate patients with known or suspected head trauma.
- The mortality rate from minor head injury in childhood approaches 0%.
- The likelihood of intracranial injury increases when a skull fracture is present, but skull fracture absence does not preclude intracranial injury and has little prognostic significance in pediatric head trauma.
- In younger children, epidural hematomas are more often venous than arterial.
- DAI is one of the most devastating types of TBI and is the most common cause of posttraumatic neurologic and cognitive disability.
- Diffuse brain swelling and hypoperfusion injuries are more common in children and can be differentiated using MRI.
- Children are more likely than adults to recover from focal brain injury and have a higher likelihood of survival after severe injury. However, children are more vulnerable to long-term cognitive and behavioral dysfunction after diffuse brain injury.

## EMBRYOLOGY

The spinal cord forms in three stages beginning in the third gestational week.[1] The first stage, neurulation, involves progression from neural plate to neural tube.[1] The notochord becomes the nucleus pulposus of the intervertebral disks.[2] The second stage, canalization, involves formation of cysts within the caudal cell mass that coalesce and fuse to the distal neural tube forming the primitive spinal cord. The third stage, retrogressive differentiation, involves programmed cell death with regression of the primitive distal cord to form the fetal conus, filum terminale and ventriculus terminalis[1,2] (Fig. 40.1).

The vertebral bodies develop from somites originating from sclerotomes.[3] The caudal and cranial portions of sclerotomes fuse to become single vertebrae. Failure of this process leads to congenital segmentation anomalies such as block and hemivertebrae (Fig. 40.2).[4,5]

## ANATOMY AND PHYSIOLOGY

The spinal cord is largest in the cervical and lumbar regions. Dorsal and ventral nerve roots arise from each level, and the cord is held in place by the lateral dentate ligaments. The distal spinal cord and thecal sac extend to the L2–L3 disc space and the S2 level, respectively.

Although 5% of humans have differing numbers of vertebrae, most have 7 cervical, 12 thoracic, and 5 lumbar segments, as well as 5 sacral and 4 coccygeal segments.[6] Running craniocaudal are the anterior and posterior longitudinal ligaments, supraspinous and interspinous ligaments, and ligamentum flavum.

The arterial supply to the spinal cord is via the anterior spinal and paired posterior spinal arteries. The anterior spinal artery, which originates from branches of the vertebral arteries, courses along the ventral cord. Similarly, the posterior spinal arteries arise from the intradural vertebral arteries and course along the dorsal cord.[7] Radicular artery branches contribute to the cord arterial supply with one particularly large branch, the artery of Adamkiewicz, entering the spinal canal between T9 and T12. It is recognized by its characteristic proximal hairpin turn.[8]

## Normal Findings

The pediatric spine may be imaged with plain radiographs, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). Radiographs and CT are used to screen for osseous anomalies, including acute trauma. In neonates, spine sonography and MRI are the most frequently used modalities. Sonography is used to screen infants younger than 6 months due to its excellent resolution and lack of radiation. It provides sufficient characterization of spinal anomalies to determine if urgent intervention or MRI is required. In older infants and children, MRI is the study of choice for spine evaluation.

Indications for spine sonography include screening neonates with multiple congenital anomalies, dimples with skin stigmata, and infants with soft tissue masses suggesting possible (occult) spinal dysraphism. It is also used to determine the cause of failed lumbar puncture (LP) and localize cerebrospinal fluid (CSF) for reattempts at LP.[9,10] High-risk skin stigmata include atypical dimples (>5 mm) above the gluteal crease (>2.5 cm from the anus), and dimples with skin stigmata such as a hairy patch, hemangioma, mound of soft tissue, skin tag, or tail.[11] Simple sacral dimples do not require imaging.[12] MRI is the study of choice for anomalies requiring surgery and dimples draining CSF.[13,14] Additionally, MRI is best performed immediately before therapeutic intervention.[9]

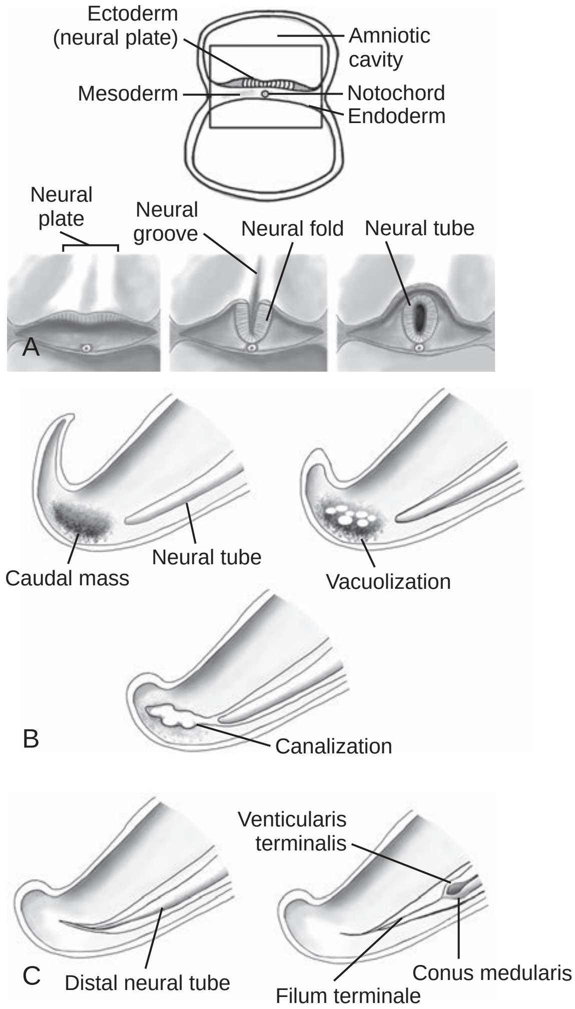

**Figure 40.1. Embryologic development of the spinal cord.** (A) Neurulation schematic illustrates progression from neural plate to groove to neural tube. (B) Canalization schematic depicts coalescence of cysts within the caudal cell mass that fuse to the distal neural tube. (C) A retrogressive differentiation schematic reveals the process of programmed cell death forming the conus medullaris and filum terminale.

## Abstract:

This chapter presents a brief overview of normal embryological development and anatomy of the spinal cord. This chapter also covers when specific modalities (radiography, ultrasound, CT, MRI) should be performed to evaluate the spine in the setting of certain clinical scenarios. The majority of the chapter is focused on discussing normal findings and anatomic variants. These normal variants of the lower spine include ventriculus terminalis, filar cyst, fatty filum, and prominent filum terminale which are discussed in detail with accompanying images.

## Keywords:

spinal cord
vertebral column
normal variants
ventriculus terminalis
filar cyst
fatty filum

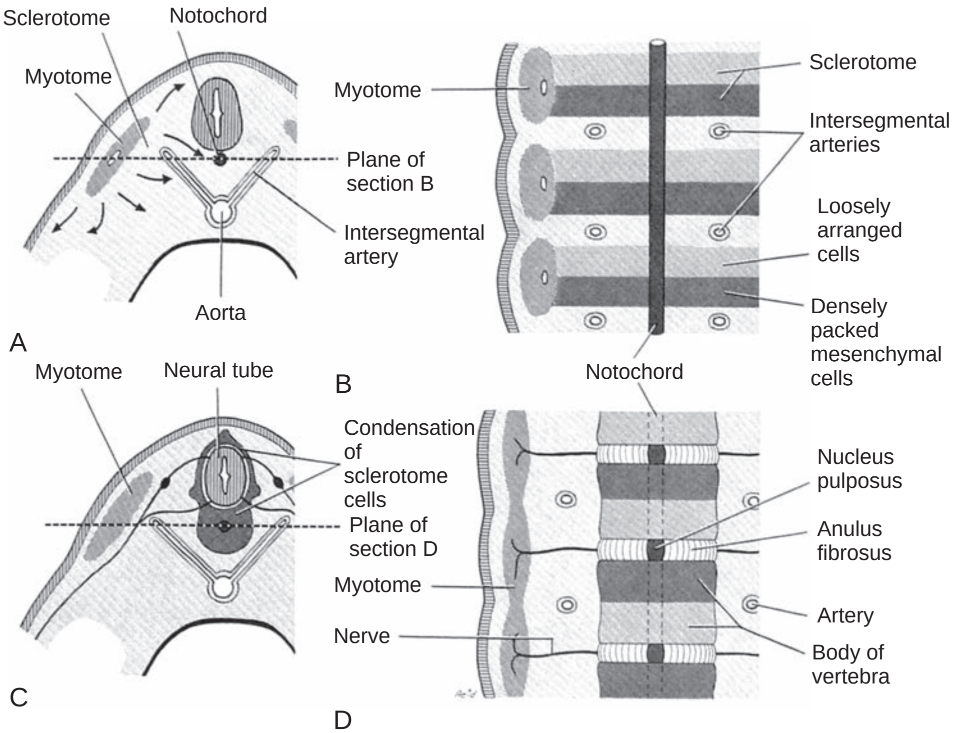

**Figure 40.2. Embryologic development of the vertebra.** (A) A partial transverse section through a 4-week embryo shows *arrows* indicating the spread of mesenchymal cells from the sclerotome region of the somite on the right. (B) A diagrammatic frontal section of this embryo shows that condensation of sclerotome cells around the notochord consists of a cranial area of loosely packed cells and a caudal area of densely packed cells. (C) A partial transverse section through a 5-week embryo shows the condensation of sclerotome cells around the notochord and the neural tube, which forms a mesenchymal vertebra. (D) A diagrammatic frontal section illustrates the vertebral body forms from the cranial and caudal halves of two successive sclerotomes. The intersegmental arteries cross the bodies of the vertebrae, and the spinal nerves lie between the vertebrae. The notochord persists as the nucleus pulposus within the intervertebral disks. *(From Moore KL.* The developing human: clinically oriented embryology. *4th ed. Philadelphia: Saunders; 1988:338.)*

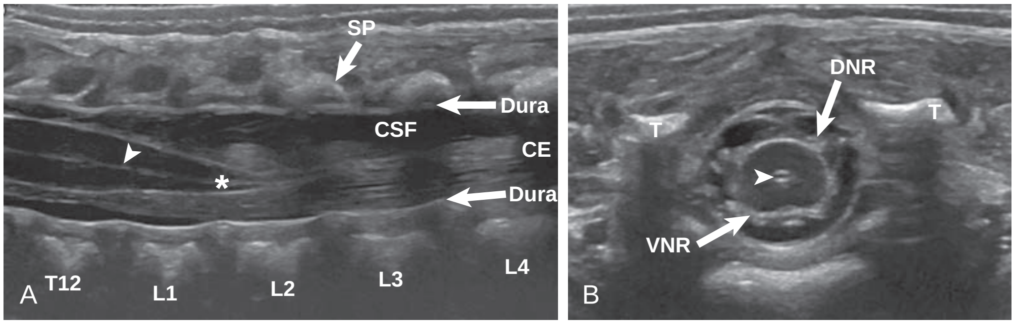

**Figure 40.3. Normal spine sonogram in a 1-day-old male infant with multiple congenital anomalies.** Longitudinal (A) and transverse (B) images demonstrate normal anatomy. Note the dura, central echo complex *(arrowheads),* and conus medullaris *(asterisk).* Other labeled structures include the vertebra (T12–L4); *CE,* cauda equina; *CSF,* cerebrospinal fluid; *DNR,* dorsal nerve roots; *SP,* spinous processes; *T,* transverse processes; *VNR,* ventral nerve roots.

The conus location is determined by counting down from the twelfth rib, as well as up from the lumbosacral junction.[11,13,15] In some cases, one may need to count down from the cervical level as well.[14] The end of the thecal sac ends at S2, and can be used as a landmark. If the conus level is still uncertain, follow-up ultrasound may be performed. Rarely, an immediate determination is important in patient management, in which case a BB can be placed at the tip of conus level (as determined by ultrasound) and a radiograph of the entire spine obtained for clarification.[16]

Spine sonography requires knowledge of normal anatomy and variants that may simulate pathology to prevent unnecessary referral and MRI. The spinal cord and conus medullaris are easily seen within the hypoechoic CSF (Fig. 40.3). Nerve roots may be observed pulsating (oscillating) with the cardiac cycle, which can be documented with cine or M-mode ultrasound. However, this motion

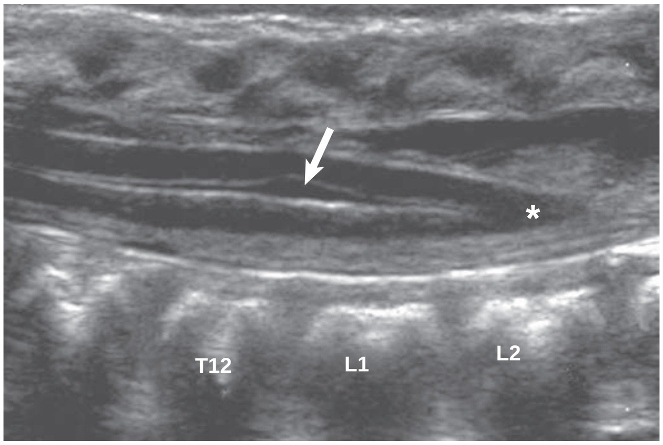

**Figure 40.4. Ventriculus terminalis in a 3-month-old girl with a deep dimple.** Longitudinal sonogram demonstrates focal distension of the distal central spinal canal *(arrow)* in the lumbar cord just above the conus medullaris *(asterisk).*

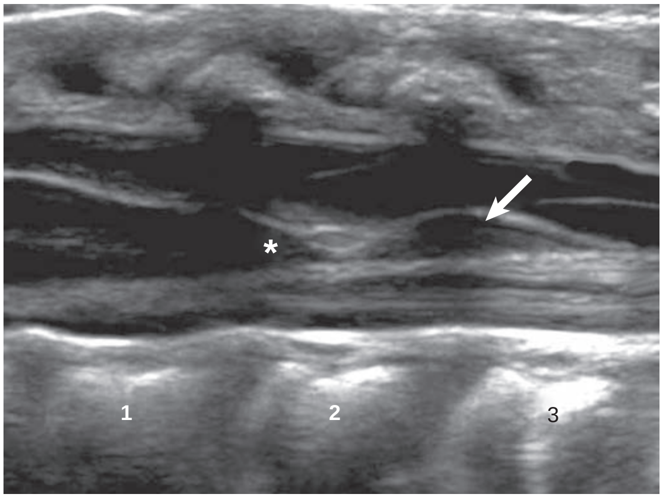

**Figure 40.5. Filar cyst in a 6-week-old male infant with an asymmetric gluteal crease.** Longitudinal sonogram shows a fusiform, midline hypoechoic cyst *(arrow)* just below the conus medullaris *(asterisk).*

is variably present in newborns.[15] The normal filum terminale, an echogenic linear structure that extends from the conus medullaris to the distal thecal sac, should be homogeneous in echotexture and morphology throughout its length, measuring less than 1 to 1.5 mm. The normal conus is located at or above the superior end plate of L3.[17] Recent reports indicate that infants with isolated borderline low conus position extending to the midbody of L3 are normal and will develop normally.[18] A conus tip below the midbody of L3 is abnormal.[17]

Common normal variants include the ventriculus terminalis, filar cysts, a prominent filum terminale, a pseudosinus tract, a cauda equina pseudomass, and a dysmorphic coccyx. The ventriculus terminalis, which is seen mostly in children younger than 5 years, and occasionally in adults, involves persistence of the normal fetal terminal ventricle. It is characterized by contiguity with the spinal canal, which forms a small fluid containing space (Fig. 40.4). It must be distinguished from a syrinx, which is larger and may grow over time.

Filar cysts are midline, fusiform, well-defined hypoechoic fluid spaces located in the cauda equina immediately below the conus medullaris (Fig. 40.5). They are seen on ultrasound in 11.8% of infants, typically are not seen on MRI, and lack pathologic description, indicating that they may be structural pseudocysts.[19] As isolated sonographic findings, they are of no known clinical significance.[19]

The normal filum terminale is more prominent than the rest of the cauda equina. It is distinguished as normal by its thickness (<1–1.5 mm) and midline location (e-Fig. 40.6). A prominent filum must be distinguished from a fibrofatty filum and a filar lipoma, which are suspected when focal hyperechogenicity and thickening (>2 mm) of the filum terminale are seen (Fig. 40.7).[20] A fibrofatty filum is most often incidental, but has been described as part of the "tight filum terminale syndrome," the symptoms of which include lower extremity weakness, spasticity, foot deformities, bladder dysfunction, scoliosis, and back pain.[21]

A pseudomass due to nerve root clumping may be seen when infants undergo sonography in the decubitus position. The finding is easily clarified by rescanning the infant prone, which resolves the mass. Pseudosinus tracts, normal fibrous cords extending from the base of dimples to the coccyx tip, are a frequent normal variant (Fig. 40.8). These echogenic cords do not have an associated mass or drain fluid as they do not connect to the thecal sac, as occurs with true dermal sinus tracts. True sinus tracts are caused by incomplete disjunction of cutaneous ectoderm from neuroectoderm.[22] A final normal variant, the misshapen or dysmorphic coccyx, is a common finding that may be discovered on physical examination when a "mass" is palpated.[23] Although the variety of dysmorphic coccygeal shapes may be impressive, the finding is of no significance (e-Fig. 40.9).

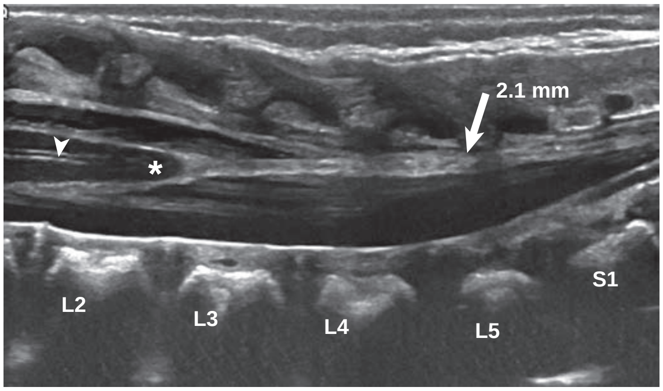

**Figure 40.7. Fatty filum in a 2-day-old male infant with VATER syndrome.** Longitudinal sonogram reveals a linear, hyperechoic, thickened (2.1 mm) filum *(arrow)* extending from the conus medullaris to the distal thecal sac. Note the normal central echo complex *(arrowhead).*

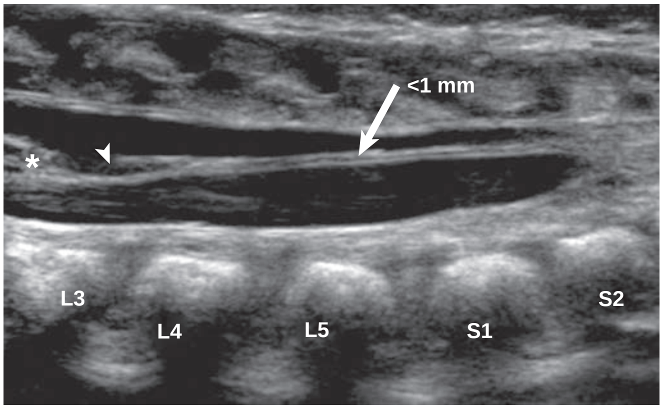
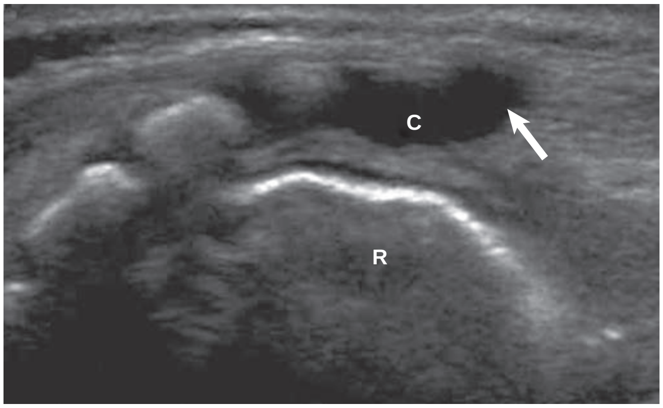
## KEY POINTS

- Spine ultrasonography and MRI are the imaging modalities of choice for the pediatric spine.
- Imaging requires knowledge of normal anatomy and variants to prevent improper clinical referral and unnecessary imaging.
- Frequent normal variants include a ventriculus terminalis, filar cyst, prominent filum terminale, pseudomass due to positional nerve root clumping, pseudosinus tract, and a dysmorphic coccyx.



**e-Figure 40.6. Prominent filum terminale in a 1-day-old male infant with multiple congenital anomalies.** Longitudinal sonogram reveals a midline linear filum terminale *(arrow)* of normal size (<1 mm) measured at L5–S1. The filum extends from the conus tip *(asterisk)* to the distal thecal sac. Note the incidental filar cyst *(arrowhead).*



**e-Figure 40.9. Dysmorphic coccyx in a 4-week-old male infant with a palpable lump beneath a dimple high in the gluteal crease.** Longitudinal sonogram shows the normal hypoechoic coccyx *(C)* with a dysmorphic dorsal curve *(arrow).* Note the gas-filled rectum *(R).*

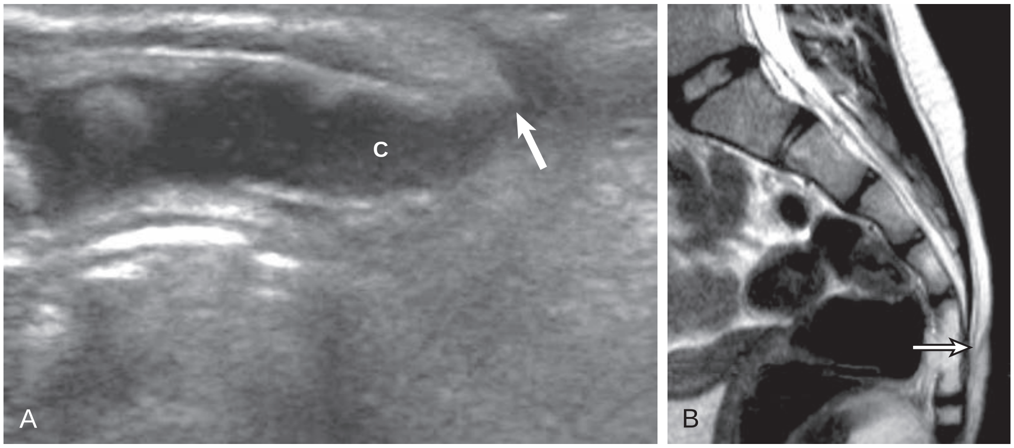


**Figure 40.8. Pseudosinus tract in a 3-month-old girl with a deep dimple in the gluteal crease.** (A) Longitudinal sonogram identifies the normal coccyx *(C)* with a cordlike hypoechoic pseudotract *(arrow)* extending to the skin dimple. (B) Follow-up MRI at age 6 months confirms the incidental pseudosinus tract *(arrow).*

# Spinal Cord Imaging Techniques

*Sumit Pruthi and Lisa H. Hutchison*

Pediatric spinal cord imaging relies heavily on ultrasound (US) in infants under 6 months of age and magnetic resonance imaging (MRI) thereafter.[1,2] Other imaging modalities, such as radiography, computed tomography (CT), and nuclear scintigraphy, have a limited role but may provide useful information in cases with specific questions.

## PLAIN RADIOGRAPHY

Plain radiographic spine series include frontal and lateral radiographs of the cervical, thoracic, or lumbar region. Oblique or odontoid views may be added depending on the clinical indication. Although they have limited ability to evaluate the spinal cord, radiographs are used to screen the pediatric spine and determine the most appropriate next study, particularly in acute trauma.[3] The PECARN (Pediatric Emergency Care Applied Research Network) study has identified eight variables that are highly associated with cervical spine injury (CSI). These data provide evidence-based risk stratification for pediatric CSI and help determine appropriate imaging after blunt trauma.[4]

## CONTRAST RADIOGRAPHY

Contrast radiography includes conventional angiography and myelography. As with plain radiography, contrast radiography has a limited role in pediatric spinal cord evaluation. Myelography, with or without CT, is used rarely to assess the spinal cord and thecal sac in situations where MRI is contraindicated.[5] Similarly, conventional angiography in spinal imaging is limited to diagnostic and therapeutic evaluation of dural fistulas and arteriovenous malformations, both of which are rare in children.[1]

## COMPUTED TOMOGRAPHY

CT plays a role in pediatric spinal imaging with the added risk of radiation. Multiplanar reconstructions provide superior sensitivity and specificity in delineating bony abnormalities compared with radiography and is complementary to MRI for spinal cord evaluation (Figs. 41.1 and 41.2).[3]

CT protocols must be optimized in children to limit radiation exposure. Examinations should be single phase, tailored to the specific indication, size of the patient, and region of interest. CT spine technique typically includes high-resolution 3-mm images obtained axially. Images are reformatted to submillimeter axial, sagittal, and coronal planes. Three-dimensional images may also be obtained if desired. Intravenous and, rarely, intrathecal contrast may be added for specific indications.

## ULTRASOUND

US is used for evaluation of the neonatal spinal canal and its contents.[2,6] Incompletely ossified spinal arches serve as excellent acoustic windows in infants; however, progressive ossification diminishes the window, limiting visualization of the spinal cord.[6] Because of this, US may not adequately demonstrate the spinal contents in infants over 6 months of age.[2]

Spinal US is performed with a high-frequency 7- to 12-MHz linear-array or 8- to 10-MHz curved-array transducer.[2] Imaging is performed with the infant prone in the longitudinal (sagittal) and transverse (axial) planes from the craniocervical junction to the coccyx (Fig. 41.3). Paramedian scanning is useful in older infants with smaller acoustic windows.[2] Vertebral body level is determined in multiple ways, often using an extended (panoramic) field of view to identify the lumbosacral junction and lowermost rib to confirm levels.[2,7] In cases when the level of the conus cannot be definitively assessed, correlation with radiographs is helpful. A radiopaque marker can be placed on the skin overlying the conus to correlate with the US level on spine radiographs. Real-time cine loops are obtained routinely to demonstrate the normal undulating cauda equina nerve roots during the cardiac cycle.[2] M-mode US can also be helpful in documenting motion of the cord and nerve roots.

Common indications for spine US include screening lumbosacral anomalies associated with low conus position (tethered cord), evaluation of atypical sacral dimples located greater than 2.5 cm above the anus, deep dimples in which the base cannot be visualized, and dimples with cutaneous stigmata.[7] Other indications include guidance for lumbar puncture and assessment of cause after failed lumbar puncture.[8]

## MAGNETIC RESONANCE IMAGING

### Overview

MRI is the primary modality for imaging the pediatric spinal cord because of its superior tissue contrast characteristics.[1] Not only does MRI provide detailed spinal cord evaluation, it also allows assessment of the surrounding soft tissues and osseous structures. Additional evaluation of cerebrospinal fluid flow characteristics are possible with velocity encoded phase contrast imaging, which is used most often to assess the craniocervical junction[9] (Fig. 41.4). Bone marrow changes associated with various disorders may be assessed with T1- and T2-weighted sequences.[10,11] MRI can be used to further define abnormalities identified on prenatal or antenatal US, conventional radiography, and CT.[1,10]

### Indications

The indications for pediatric spinal MRI are numerous, including evaluation of known or suspected masses, inflammatory processes, spinal trauma, metastatic spread of an intracranial primary neoplasm, spinal dysraphism, and dorsal dermal sinuses.[1,10,12]

### Pediatric Imaging Challenges

MRI is challenging when performed in infants and younger children who are unwilling or unable to cooperate for the examination. In these patients, it is crucial to use methods to control patient motion, such as swaddling, sleep deprivation, and sedation.[1] Likewise, imaging techniques that are less sensitive to motion such as noncartesian spiral or PROPELLER acquisitions can be helpful. Various sedation techniques may be used including oral and intravenous drug administration. No single recipe works for all patients and in all circumstances. Thus the sedation approach used depends on the resources available.

To produce high-quality pediatric spinal MRI, various technical challenges must be overcome. Because of the small spinal cord size, a smaller field of view, higher resolution, and decreased (or no) interslice gap must be used.[13,14] Because increasing resolution

## Abstract:

Pediatric spinal cord imaging is a complex and interesting area that relies predominantly on magnetic resonance imaging (MRI) for the evaluation, assessment of severity, and follow-up of diseases of the pediatric spinal cord. US is still utilized in neonates younger than 6 months to assess for spinal contents, its utility however diminishes significantly afterwards due to lack of an adequate acoustic window. Various other imaging modalities such as plain radiography, contrasted radiography, computed tomography (CT), and nuclear scintigraphy serve a limited role but can provide useful adjunctive information in cases with a specific question. Spinal MRI is one of the most sensitive imaging tests for detecting anatomic abnormalities of the cord and adjacent structures. That been said findings may be misleading if not closely correlated with the clinical history, clinical examination, and other tests. In this chapter, we will discuss the role of various imaging modalities and techniques available for assessment of pediatric spinal cord. The chapter will highlight the role of magnetic resonance imaging (MRI) with emphasis on optimizing the use of this modality and the challenges encountered in pediatric population.

Magnetic resonance imaging
Ultrasound

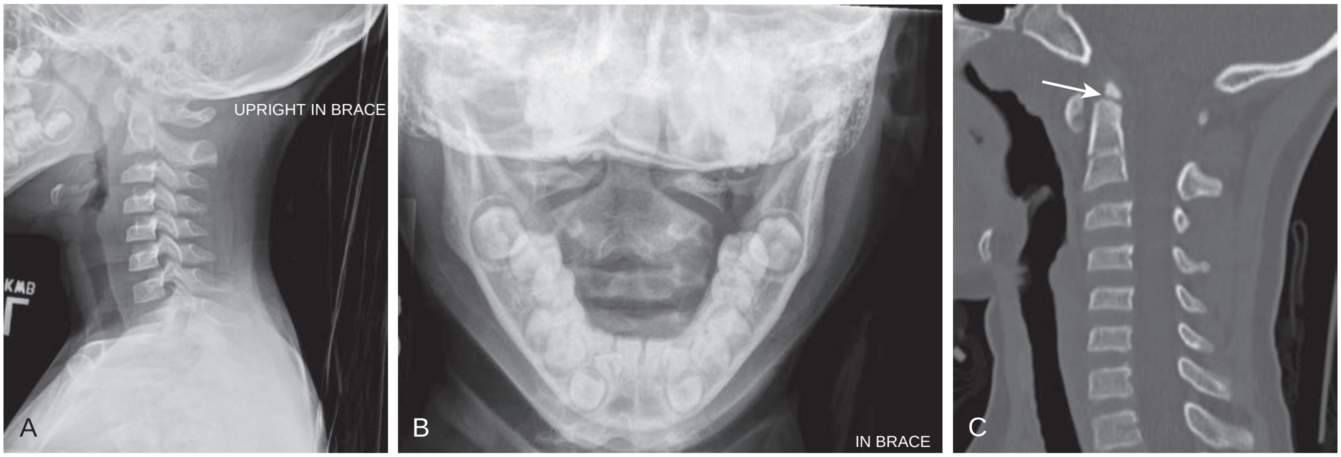

**Figure 41.1. An 8-year-old girl status post-MVC.** (A) Lateral and (B) odontoid cervical spine radiographs are normal. The alignment is normal and the dens is not completely visualized on odontoid view. (C) Sagittal reformatted CT image reveals a nondisplaced dens fracture. CT is very accurate for imaging bony spine trauma, but adds radiation risk.

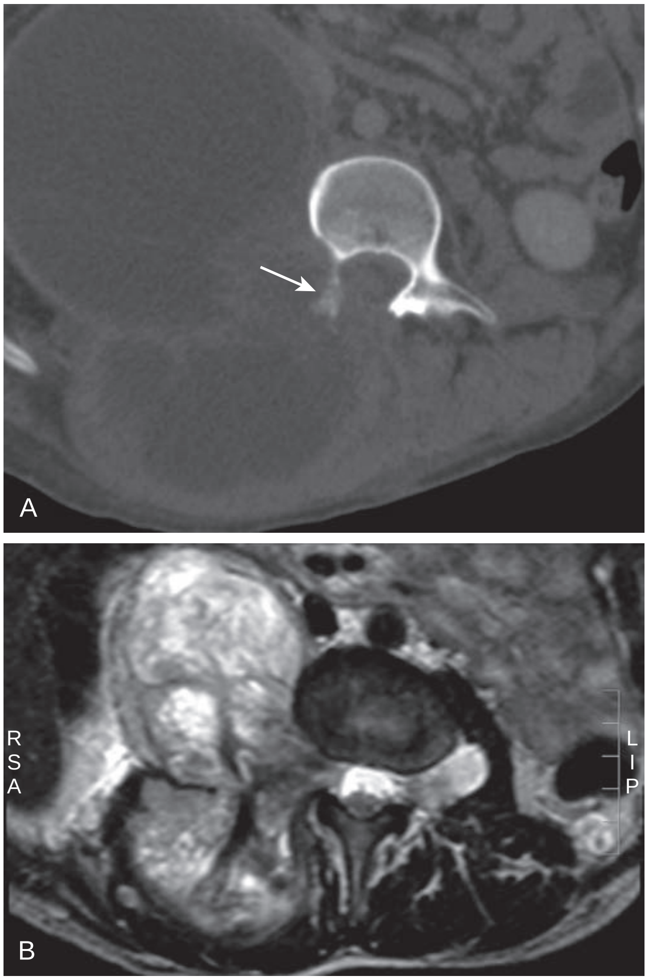

**Figure 41.2. Malignant peripheral nerve sheath tumor in a 16-year-old with neurofibromatosis.** (A) Axial CT image of the thoracolumbar spine demonstrate a large lobulated mass along the right side of the L2–L3 neural foramina. Associated bony destruction is shown on CT, whereas (B) axial T2-weighted MRI better demonstrates the internal characteristics of the mass and its intraspinal extension.

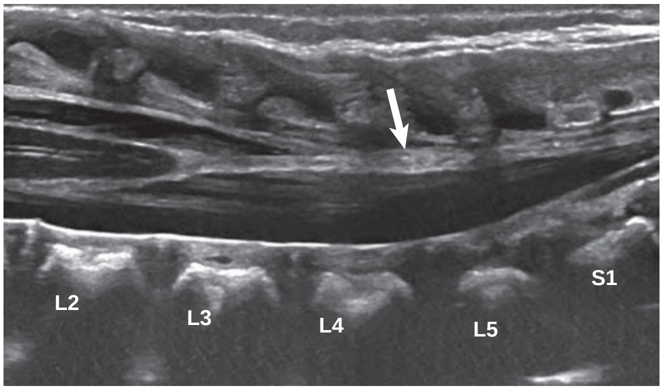

**Figure 41.3. Fatty filum in a neonate with VATER syndrome.** A longitudinal US reveals a normally positioned conus medullaris at L2–L3. Focal hyperechoic fat within the filum terminale *(arrow)* is noted. The child had normal development at 2 years of age.

and decreasing voxel volume leads to a decrease in signal-to-noise ratio (SNR), multiple image averages are frequently required, which increases the total imaging time. With longer imaging times, motion becomes more of an issue, even with proper sedation. Useful technical advances include prospective motion tracking and correction techniques, among others. Motion artifacts arising from fluid flow or respiration can be diminished with the application of flow compensation (gradient moment nulling), respiratory gating, and saturation bands.[14,15]

## High Field Strength Magnetic Resonance Imaging

With the increased utilization of 3-Tesla (T) MRI scanners, the inherent SNR limitations at 1.5 T may be overcome in some cases. With scan parameter modifications to account for differences produced by the increased field strength, 3-T MRI provides superior image quality and detail compared with 1.5 T.[16] This improvement is due to higher SNR and improved contrast between some tissues due to changes in their transverse and longitudinal relaxation times. The surplus of SNR can be used in children to decrease imaging times while maintaining image quality, potentially reducing sedation duration and increasing MRI throughput.[15-17]

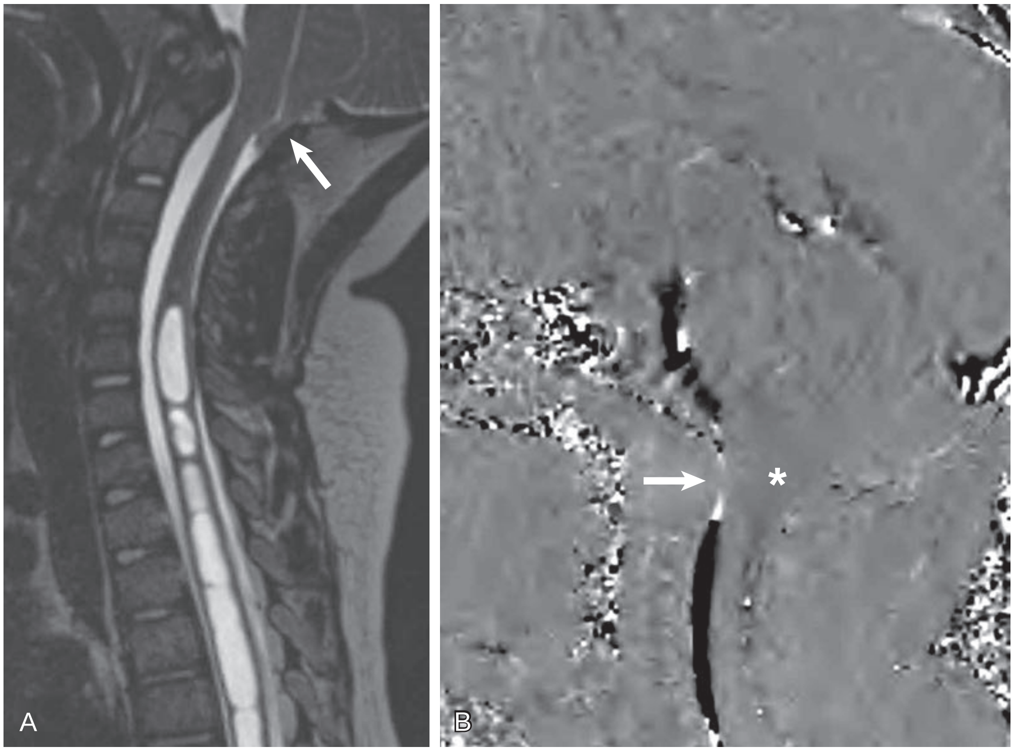

**Figure 41.4. Chiari 1 malformation in a 6-year-old boy with levothoracic scoliosis.** (A) A sagittal isometric heavily T2-weighted MRI reconstructed along the scoliotic curve shows the cerebellar tonsils extending into the posterior aspect of the upper cervical spinal canal *(arrow),* and a large multiseptated cervicothoracic syrinx. (B) Phase-contrast cerebrospinal fluid (CSF) cine (velocity encoded to 5 cm/sec) image reveals decreased CSF flow across the foramen magnum *(arrow)* and slight cerebellar tonsil motion *(asterisk).*

Although useful in the spine, high field strength MRI is not without limitations, including increased magnetic susceptibility artifact, chemical shift artifact, and specific absorption rate (SAR).[15,16] Higher field strengths markedly increase magnetic susceptibility artifact from metallic objects, tissue-bone interfaces, and tissue-air interfaces. Signal loss due to susceptibility artifact can be minimized with shorter echo times, though this can decrease tissue contrast. Metal artifacts can distort the slice profile in two-dimensional acquisitions and cause displacements in the frequency encoding direction of many sequences. These effects may be minimized by increasing the band width (slice select and/or frequency encoding), though this causes lower SNR.[18]

Chemical shift artifacts also increase with increasing field strength, carrying with it the same tradeoff of artifact reduction at the cost of lower SNR due to increased bandwidth. Finally, the increased SAR is a potential limiting factor at 3 T, although standard rates are rarely exceeded with routine imaging and can be decreased with use of multitransmit radiofrequency (RF) excitations.[16]

## Coil Selection

Use of whole body transmit coils for RF excitation is the best choice in the spine due to homogeneous excitation profile. For signal reception, surface coil arrays are the standard practice with the number of channels providing increasing image quality. Only coils covering the region of interest should be used.[19]

## Parameters

The choice of MRI pulse sequences is guided by the clinical history and study indications. Standard pediatric spinal MRI sequences include two-dimensional axial and sagittal T1- and T2-weighted images.[1,12] Coronal T2 sequences are helpful in patients with scoliosis or paraspinal lesions. Isometric sequences allow volumetric imaging with curved reformations in severe scoliosis.[20,21] Short tau inversion recovery (STIR) methods increase conspicuity of osseous and ligamentous lesions. T1 sequences with fat saturation are used with intravenous contrast administration.

Diffusion-weighted imaging (DWI) in the pediatric spine is challenging, but increasingly used. A major issue is image distortion due to single-shot echo planar imaging (EPI) methods. Read-out segmented EPI sequence is a newer technique that helps decrease distortion in diffusion data, thus improving the evaluation of many pediatric spine pathologies, including tumors, infarcts, infection, inflammatory and/or autoimmune diseases, and trauma.[22]

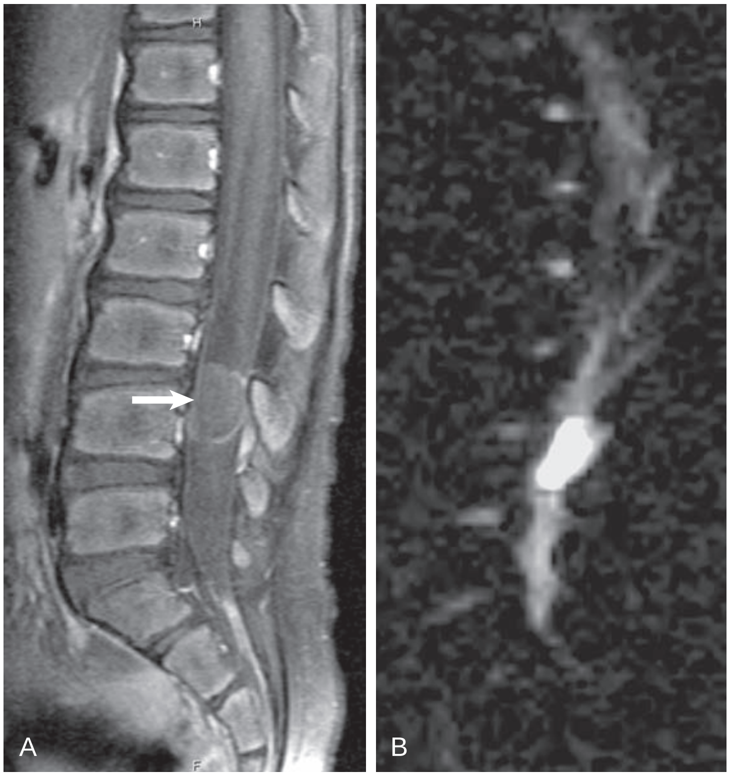
For example, DWI (e-Fig. 41.5) can distinguish dermoids from arachnoid cysts.[5,14] The role of diffusion tensor imaging, though currently limited, is expected to increase in future.

## Contrast Material

Contrast enhancement occurs in some lesions, allowing them to be better visualized.[23] Contrast is routinely administered when assessing neoplastic and inflammatory pathologies.[1,12] Recently, residual gadolinium has been found within the brain tissue of patients receiving multiple gadolinium-based contrast doses over their lifetimes. Although there are no known adverse clinical consequences associated with gadolinium deposition, caution should be used when using contrast media. This is particularly true in children who may receive contrast studies throughout their lives.[24]

## NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy has limited use in the evaluation of the pediatric spine and surrounding structures. Other than very rare use in assessment of shunt patency and cerebrospinal fluid leaks,



**e-Figure 41.5. Epidermoid in a 6-year-old boy with back pain.** (A) Sagittal fat-suppressed, contrast-enhanced, T1-weighted MRI identifies a well-circumscribed mass with minimal peripheral enhancement in the spinal canal posterior to L4 *(arrow)*. (B) Sagittal DWI shows hyperintense signal within the mass.

scintigraphy occasionally is used to evaluate osseous structures, such as gallium scanning for vertebral osteomyelitis and bone scintigraphy for metastatic disease. However, with the increasing utilization of positron emission tomography (PET) with[23] 18F-fluorodeoxyglucose, PET may develop a larger role in some disorders, particularly in tumors in which treatment response can be assessed.[25]

## KEY POINTS

- US can provide detailed evaluation of the pediatric spinal cord up to 6 months of age, after which time vertebral ossification limits visualization of anatomic detail.
- MRI is the primary imaging modality for pediatric spinal cord evaluation because of its superior soft tissue contrast.
- Recent advances in MRI techniques allow for the use of higher field strength and modern imaging sequences to fully evaluate pediatric spinal pathology.

# 42 Prenatal Imaging

Erin Simon Schwartz

Vast improvements have been made in the diagnosis and therapy of fetal anomalies as a result of advances in imaging and surgical technology. Nowhere is this more applicable than in the fetal spine. Ultrasonography is the primary imaging modality for fetal evaluation and helps distinguish normal from abnormal spine development and provides valuable information about spinal anomalies. Magnetic resonance imaging (MRI) is complementary to ultrasonography, as it has the advantage of better detection and depiction of associated central nervous system (CNS) and non-CNS anomalies that may have a significant impact on postnatal neurologic function and quality of life.

The major lesion of the CNS currently amenable to fetal diagnosis and intervention, and a driving force behind the use of highly detailed prenatal imaging, is open spinal dysraphism, commonly referred to as *myelomeningocele (MMC)*. The osseous detail and real-time evaluation of lower extremity configuration, position, and motion detectable with ultrasonography, combined with soft tissue and parenchymal assessments with MRI, provide the maternal-fetal-medicine specialist and pediatric neurosurgeon with highly detailed anatomic information. Because fetal surgery is not without risk to the mother and the fetus, obtaining accurate information is essential for determining surgical appropriateness and presurgical planning. When significant congenital anomalies are present outside of the CNS, information about associated spinal abnormalities is valuable for counseling and parental decision making regarding the management of the pregnancy, labor, and delivery or interruption of the pregnancy.

## IMAGING TECHNIQUES

The accuracy of identifying spinal anomalies during nontargeted screening ultrasonography varies, depending on the skill and experience of the operator. The accuracy of a referral center performing detailed targeting studies for a suspected neural tube defect (elevated maternal serum $\alpha$-fetoprotein) is close to 100%. A detailed protocol should be performed. Axial and longitudinal views of the spine should be obtained. Spine ossification progresses from 10 to 22 weeks' gestation. By 16 weeks' gestation, neural arch ossification is complete to L5. By 19 weeks, S1 is typically ossified, and by 22 weeks, S2 as well. Everted pedicles are best visualized in the transverse plane. An overlying sac may be imaged in transverse and longitudinal planes, with higher-frequency transducers showing cord tethering and placode contents (Fig. 42.1).

Because fetuses with open neural tube defects typically have Chiari II malformations, the fetal brain should be scanned initially. A small cisterna magna with rounded, small cerebellum is termed the *banana sign* and is 99% sensitive in the diagnosis of a Chiari II malformation (e-Fig. 42.2). The frontal bones may be concave and is termed the *lemon sign*. This sign is less specific, however, being present in 1% to 2% of normal fetuses, and may resolve by the third trimester. Ventriculomegaly may be present.

Fetal MRI is typically performed on 1.5 Tesla (T) magnets, although some centers are now performing fetal MRI at 3.0 T. A surface coil (torso, cardiac, or body phased-array) is used to maximize image quality. A standard localizer sequence generally facilitates quick identification of fetal position. This is used to guide the initial imaging plane, which should be appropriately aligned with the fetal anatomy in question. Subsequent imaging sequences are prescribed in orthogonal planes with respect to the fetal spine, each adjusted from the preceding image set, to account for changes in fetal position.

Ultrafast sequences are used to minimize image degradation by maternal and fetal movements. T2-weighted images provide most of the diagnostic information for the examination: single-shot fast spin echo (SSFSE) or half-Fourier acquisition single-shot turbo spin echo (HASTE) sequences at 2- to 4-mm slice thickness. Fast T1-weighted gradient echo imaging is frequently attempted but shows satisfactory contrast resolution and signal-to-noise ratio only after approximately 26 weeks' gestation. Extremely rapid gradient echo, echo planar imaging, or susceptibility weighted imaging, with their high sensitivity to paramagnetic susceptibility effect, may be used to identify osseous and vascular structures, hemorrhage, and mineralization. Steady-state free precession imaging, particularly at 3T, can improve visualization of spinal segments. Diffusion-weighted imaging can assess for acute ischemia.

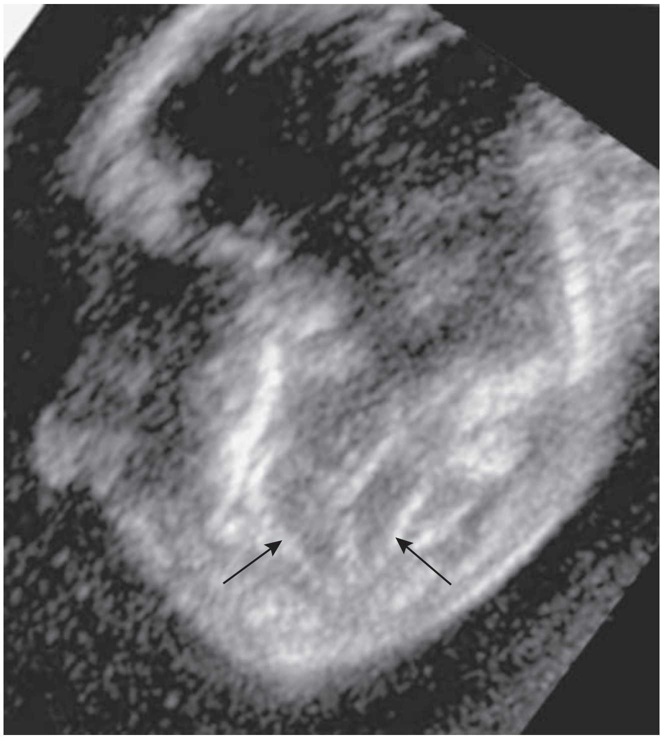
## OPEN SPINAL DYSRAPHISM

### Etiology

Abnormalities in formation of the primitive neural tube (neurulation) may result from defects in disjunction, the process by which the neural tube separates from the overlying ectoderm (see also Chapter 43). MMC occurs in the third week of gestation, when a localized failure of disjunction occurs. This failure may occur anywhere along the length of the spinal cord, but it is most common in the lumbar region. The resulting lesion is an open spinal canal with a flat neural placode instead of a cylindrical spinal cord. Prenatally, ultrasonography and MRI reveals the failure of neurulation in as a posterior osteocutaneous defect. In the presence of elevation of the neural placode, secondary to expansion of the subarachnoid space, the lesion is referred to as MMC (Fig. 42.3). This is distinguished from myeloschisis, also known as *myelocele*, where an open neural tube defect exists, but the subarachnoid space is not expanded, and the neural placode remains within the confines of the dysraphic spinal canal (Fig. 42.4).

The neurologic deficits sustained by the fetus are postulated to occur in stages, a "two-hit" hypothesis. The first "hit" is the original defect in neurulation that creates the dysraphism and any associated myelodysplasia. The second "hit" is the secondary chemical or physical trauma (or both) to the neural tissue as a result of its exposure to the intrauterine environment.

A unified theory regarding the pathogenesis of the associated Chiari II malformation suggests that the open spinal canal and associated free drainage of cerebrospinal fluid (CSF) promote collapse of the primitive ventricular system and cause lack of expansion of the rhombencephalic vesicle, from which the posterior fossa develops. This lack of distension leads to an abnormally small posterior fossa and subsequent hindbrain herniation. However, the Chiari II malformation is a pancerebral anomaly, affecting broad areas of the brain. Abnormalities include herniation of the medulla, cerebellar tonsils, and vermis through the foramen magnum; a small posterior fossa; "beaking" of the tectum of the midbrain; an enlarged massa intermedia of the thalami; partial or complete callosal dysgenesis; and structural changes in the skull (Fig. 42.5). Migrational abnormalities, particularly subependymal gray matter heterotopia, are commonly seen. The cause of hydrocephalus in patients with MMC is debated. Current theories



**e-Figure 42.2. Banana sign.** Axial sonogram through the posterior fossa in a 21-week fetus with a Chiari II malformation shows the crowding of the cerebellum around the brainstem that has been termed the *banana sign (arrows)*.

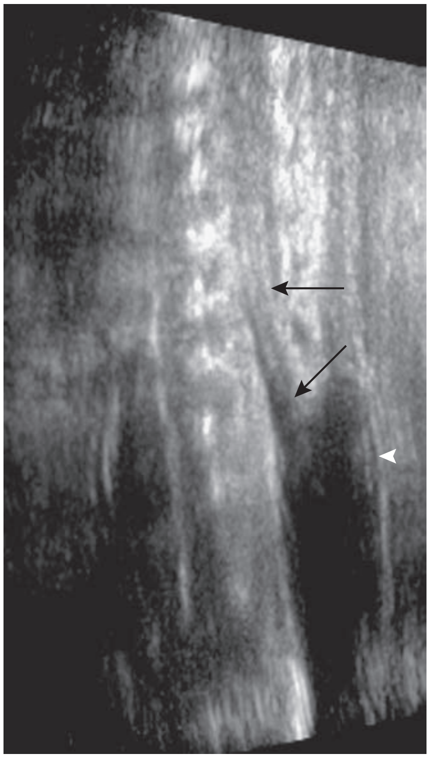


**Figure 42.1. Myelomeningocele.** Longitudinal sonogram through the lumbosacral spine in a 20-week fetus shows the defect in the posterior elements *(white arrow),* with the abnormally low spinal cord extending to the level of the defect *(black arrows)*.

include mechanical obstruction secondary to anatomic changes associated with the Chiari II malformation and dysfunctional CSF absorption. Clinically, hydrocephalus may not be present at birth but may become apparent after early postnatal closure of the defect.

## Treatment

Prenatal repair of MMC is now standard of care in the United States. While the initial intent was to preserve distal neurologic function by covering the exposed spinal cord, and some improvement in distal sensorimotor function is expected, the primary benefit of prenatal repair is the reduction in hindbrain herniation (Fig. 42.6) and substantially decreased need for ventricular shunting.

Ultrasound examination of fetuses with MMC at 18 weeks' gestational age frequently shows lower limb movements that correlate with the movements of unaffected fetuses, indicating that loss of motor function in these patients likely occurs later in gestation. Another argument for in utero repair of MMC came from the lesser degrees of neurologic deficits in many of the forms of closed spinal dysraphism in which the neural elements remain covered by skin (e.g., lipomyelomeningocele). The Management of Myelomeningocele Study (MOMS) trial found that fetuses who underwent in utero MMC repair demonstrated superior standardized test scores for motor skills and that twice as many children were walking independently at 30 months of age compared with those randomized to postnatal surgery. MMC is generally not a fatal disease in utero or postnatally, and most prenatally diagnosed infants survive to lead productive lives. Fetal surgery is associated with premature delivery and its attendant complications, including fetal/neonatal loss. Maternal complications may range from uterine rupture and hemorrhage to deep venous thrombosis.

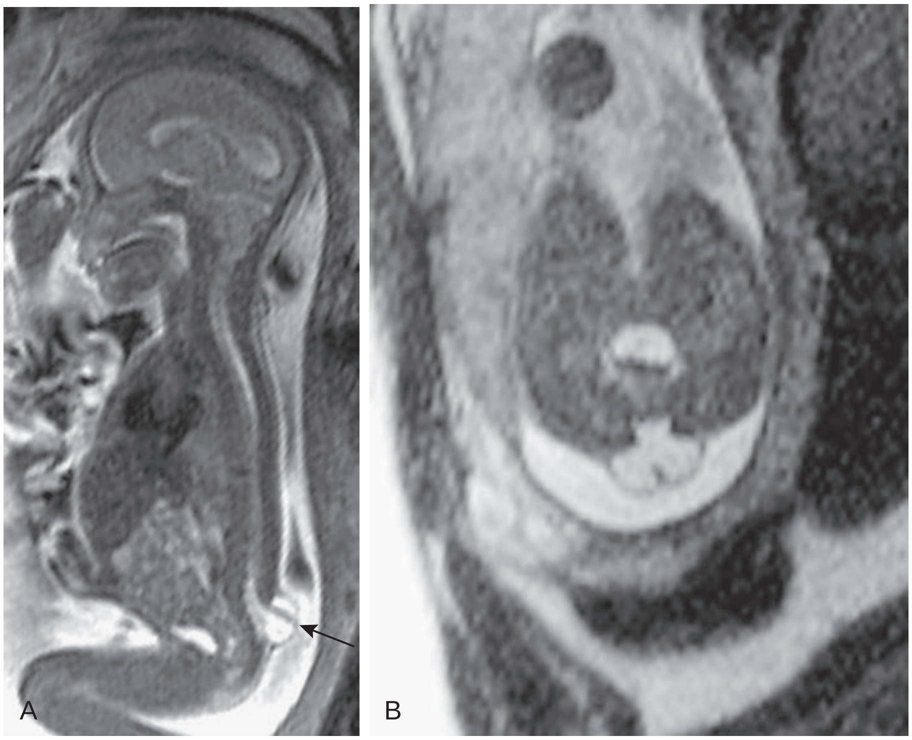

**Figure 42.3. Myelomeningocele.** (A) Sagittal HASTE magnetic resonance (MR) image in a 21-week fetus with a small myelomeningocele sac protruding at the lumbosacral junction level. The neural tissue can be readily identified traversing the sac *(arrow)*. Note the Chiari II malformation findings. (B) Axial HASTE image at the lumbosacral level shows the expanded subarachnoid space protruding through the wide posterior element deficiency. Note the neural placode outside the confines of the canal, traversing the sac.

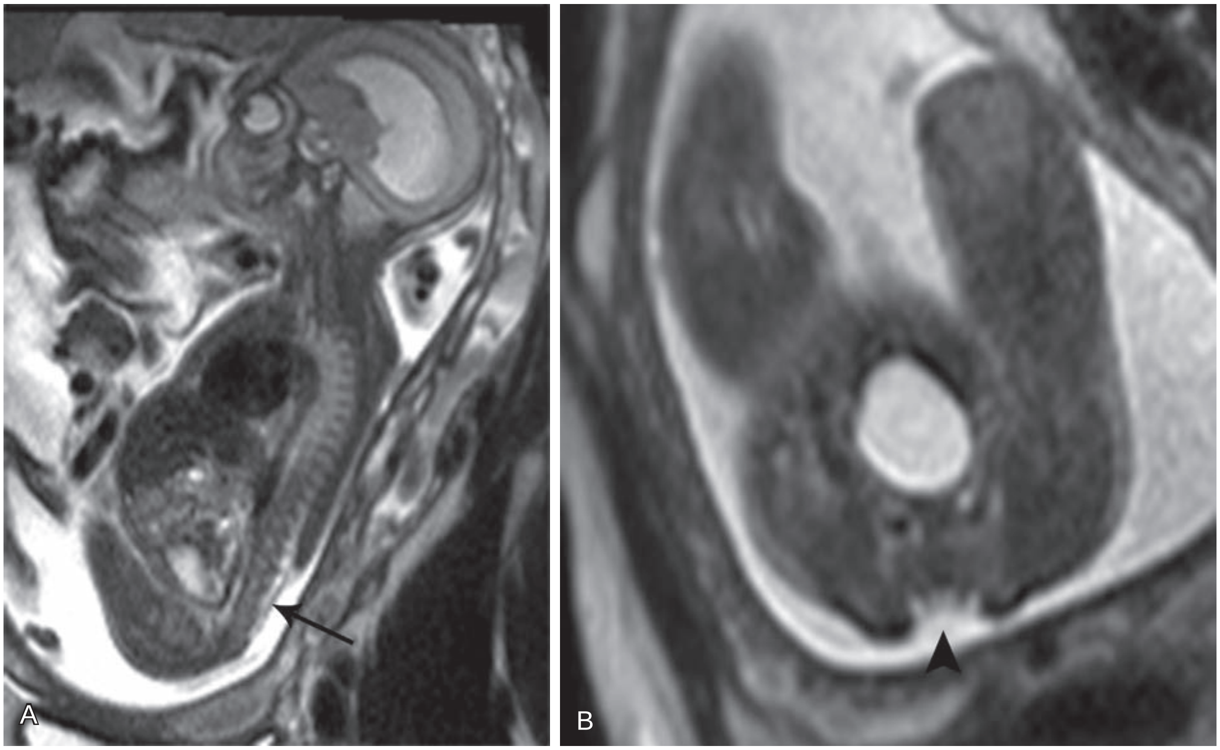

**Figure 42.4. Myeloschisis.** (A) Sagittal HASTE MR image of the spine in a 22-week fetus with a posterior spinal defect. The placode remains within the spinal canal *(arrow)*. (B) Axial HASTE image at the lumbosacral level shows the wide posterior element deficiency and neural placode within the confines of the broad canal *(arrowhead)*.

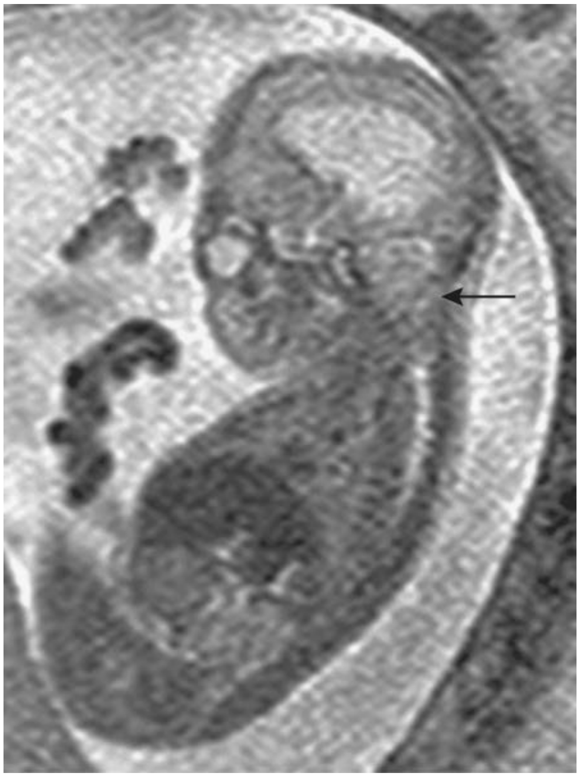

**Figure 42.5. Chiari II malformation.** Sagittal HASTE MR image at the craniocervical junction in a 19-week fetus shows the hindbrain herniation and funneling of the posterior fossa of the Chiari II malformation *(arrow)*. Note the ventriculomegaly and loss of the supratentorial subarachnoid spaces.

## CLOSED SPINAL DYSRAPHISM

Many other spinal anomalies may be recognized in utero. Although none are candidates for prenatal surgery at this time, it is important to recognize these anomalies and distinguish them from MMC to allow for proper patient counseling.

Spinal dysraphism, particularly the terminal myelocystocele, is frequently seen in association with systemic anomalies, most commonly anomalies of the genitourinary and lower gastrointestinal systems (cloacal anomalies). This is likely caused by the relative proximity of the embryonic caudal cell mass to the cloaca. The caudal cell mass is the origin of the conus medullaris, filum terminale, and lower lumbar and sacral nerve roots. Constellations of anomalies that commonly have associated congenital spinal malformations include the OEIS (*o*mphalocele, *e*xstrophy, *i*mperforate anus, *s*pinal anomalies), VACTERL (*v*ertebral, *a*nal atresia, *c*ardiac, *t*racheal, *e*sophageal, *r*enal, *l*imb), and Currarino triad (sacral hypogenesis, anorectal malformations, presacral teratoma or meningocele). The vertebral anomalies seen with OEIS and VACTERL are most commonly hemivertebrae or butterfly vertebrae can be difficult to diagnose in utero; however, they may be detected prenatally, particularly if they distort spinal alignment. More severe anomalies have been reported as well. The association of the notochord with the induction of visceral organ formation is a likely explanation of the associations between congenital vertebral and spinal cord anomalies, and thoracic or abdominal anomalies, including the VACTERL association and congenital diaphragmatic hernia.

### Lipoma With Dorsal Defect

Premature disjunction of the cutaneous ectoderm from the neuroectoderm allows mesenchyme to contact the inner portion of the developing neural tube. As the tube begins to close, the

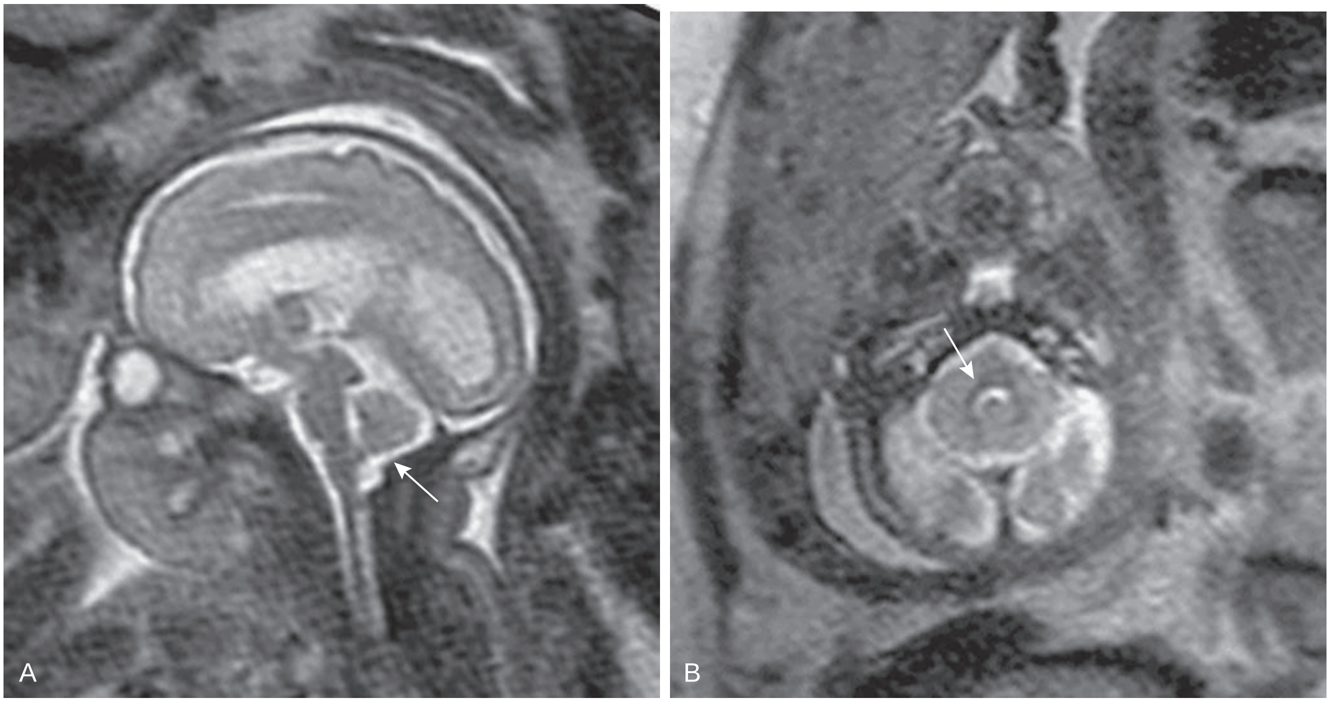

**Figure 42.6. Reversal of hindbrain herniation after fetal myelomeningocele repair.** (A) Sagittal HASTE MR image of the same fetus as in Fig. 42.5 reveals the dramatic improvement in the appearance of the brain 6 weeks after surgery. The hindbrain herniation has resolved, with return of the posterior fossa subarachnoid spaces *(arrow)*. The supratentorial subarachnoid spaces are now normal, but the ventricles remain enlarged. (B) Axial HASTE MR image through the posterior fossa shows the now normal appearance of the fourth ventricle *(arrow)*.

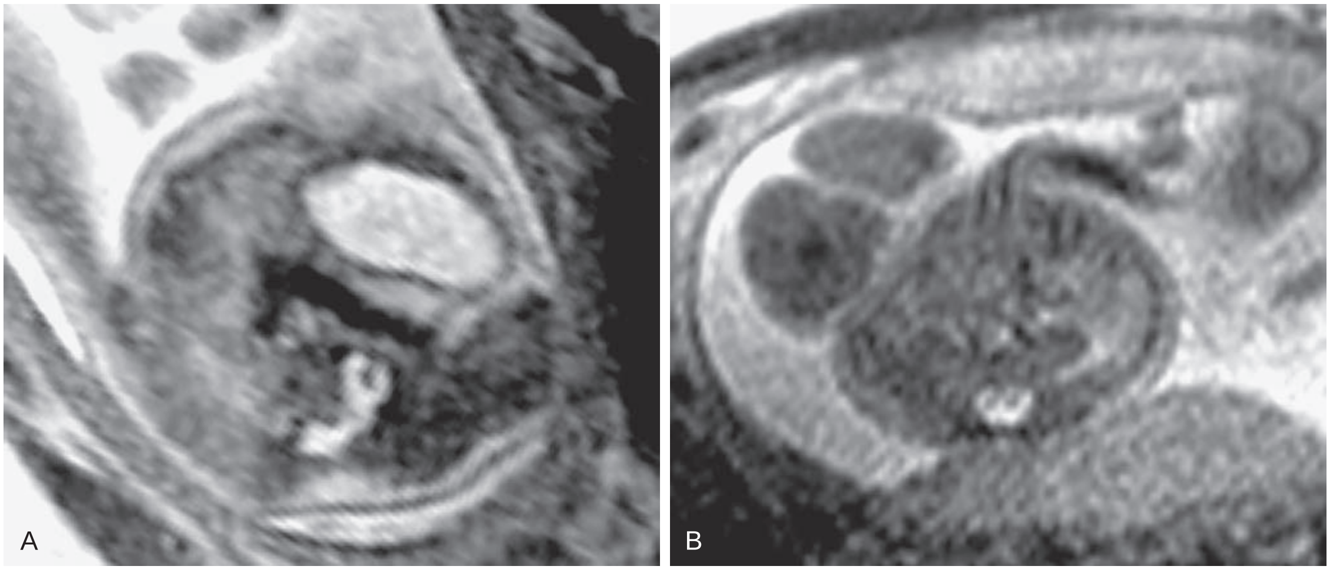
mesenchyme is induced to become fat, the presence of which may interfere with neurulation. This may result in a lipoma with dorsal defect—the lipomyelomeningocele or lipomyeloschisis. These lesions are skin covered and consequently not associated with the Chiari II malformation or abnormal elevation of maternal serum or amniotic fluid α-fetoprotein and acetylcholinesterase (markers of an open neural tube). A small lipomyelomeningocele may be harder to detect with screening ultrasonography but should be apparent with MRI, particularly later in the second trimester and in the third trimester (Fig. 42.7). As in the case of MMC, the distinction between lipomyelomeningocele and lipomyeloschisis lies in the location of the placode–lipoma interface with respect to the plane of the back. The expansion of the subarachnoid space characterizes the lipomyelomeningocele but, in contrast to MMC, it is much less common than its flat counterpart. The placode in the lipomyelomeningocele is much more likely to be deformed, being rotated toward the lipoma and away from the protrusion of the meninges. This poses an additional problem for the pediatric neurosurgeon performing postnatal repair because the spinal nerve roots are similarly deformed, with shortened roots on the side of the lipoma, which tether the cord. The elongated roots on the side of the meninges must be carefully negotiated as the surgeon attempts to access the placode–lipoma interface.

## Split Cord Malformation

Split cord malformation (SCM) is a developmental abnormality of the notochord. It is not always possible on imaging to distinguish between diastematomyelia (spinal cord and canal splitting) and diplomyelia (spinal cord and canal duplication). As such, SCM is the preferred terminology.

The spinal cord is split into two hemicords, often asymmetrically. This may involve the entire anteroposterior aspect of the cord or a portion of the spinal cord, the latter being quite rare. Each hemicord contains a central canal, and at least one dorsal horn and one ventral horn, from which nerve roots arise. An osseous septum between dual dural tubes (type I) or fibrous septum within a single dural tube (type II) may separate the hemicords. Occasionally, no intervening septum exists in type II lesions. SCM most commonly occurs in the lumbar region, and the type I is frequently associated with vertebral body anomalies. Cervicothoracic junction lesions may be more common than is currently reported because they are often asymptomatic owing to the absence of spinal cord tethering.

Type I SCM is readily recognized with fetal imaging (e-Fig. 42.8). An often-subtle alteration in spinal alignment from the associated anomalous vertebral bodies should be a clue that a spinal anomaly is present. When present, the osseous septum may appear on ultrasonography as an echogenic structure traversing the spinal canal. Echo planar or susceptibility weighted MRI techniques may be valuable in assessing for the osseous septum, which commonly tethers the spinal cord, and is significant in determining the extent of postnatal surgical intervention. The simple fibrous septum or cord duplication without intervening septum (type II) may be difficult to visualize prenatally, particularly when imaging is performed in the second trimester. SCM is reported to be present in 40% of MMC, although this most commonly involves only duplication or splitting of the placode, which may be impossible to detect prenatally. It is imperative to search for SCM when MMC is encountered because the spinal cord may remain tethered by the septum after MMC repair.



**e-Figure 42.8. Split cord malformation.** (A) Axial HASTE MR image through a type I split cord malformation. The osseous septum traversing the two canals is visible. (B) Axial HASTE MR image through a type II split cord malformation. No septum is visible between the two hemicords.

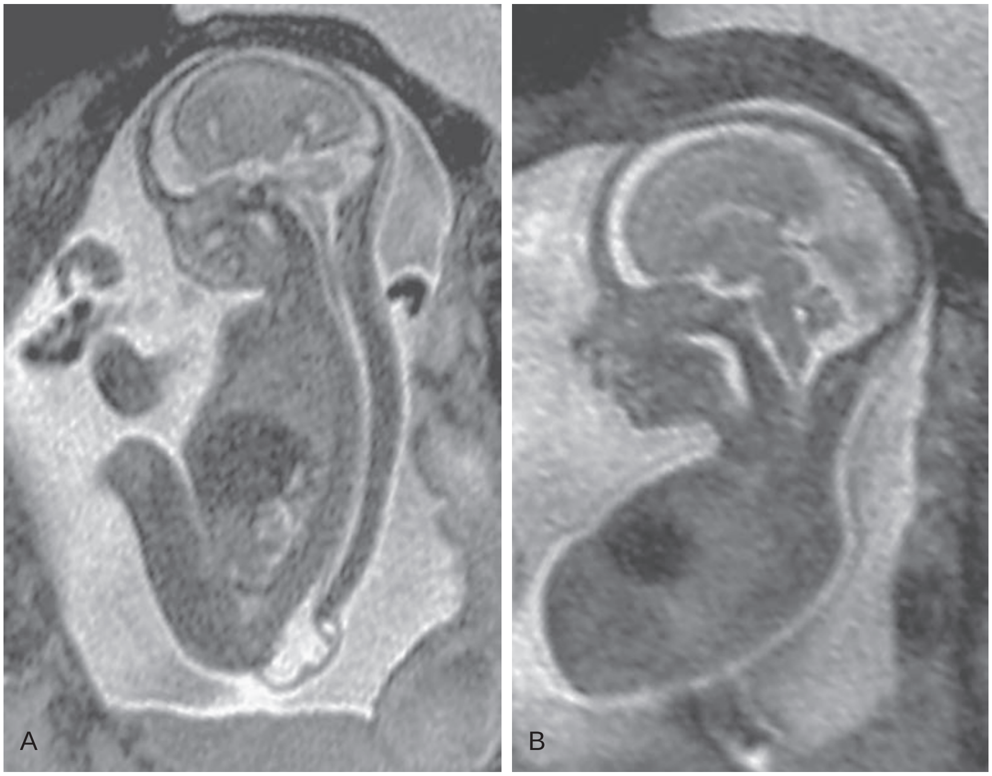


**Figure 42.7. Lipomyelomeningocele.** (A) Sagittal HASTE MR image of a 21-week fetus shows a large lumbosacral defect with neural tissue traversing the sac. The sac appears slightly thicker walled than that of a myelomeningocele, although correlation with open neural tube defect markers is required. (B) Sagittal HASTE MR image through the midline of the brain shows normal morphology, including a normal corpus callosum. No Chiari II malformation is present.

## Terminal Myelocystocele

This rare malformation may represent a severe manifestation of the persistent terminal ventricle, resulting from an inability of CSF to escape from the neural tube during its formation. The marked dilation of the distal central canal is also referred to as the *terminal ventricle* of the spinal cord, which herniates through a posterior lumbosacral spinal defect. The leptomeninges herniate around the bulbous distal spinal cord (Fig. 42.9). With prenatal imaging, terminal myelocystocele may sometimes be distinguished from the MMC with close attention to the morphology and wall thickness of the protruding sac, the absence of Chiari II malformation, and the lack of elevation of maternal serum and amniotic fluid markers of an open neural tube defect. A degree of downward displacement of the cerebellar tonsils through the foramen magnum and reduction of the infratentorial and supratentorial subarachnoid spaces may develop late in gestation with a large terminal myelocystocele, but this should not be mistaken for the Chiari II malformation.

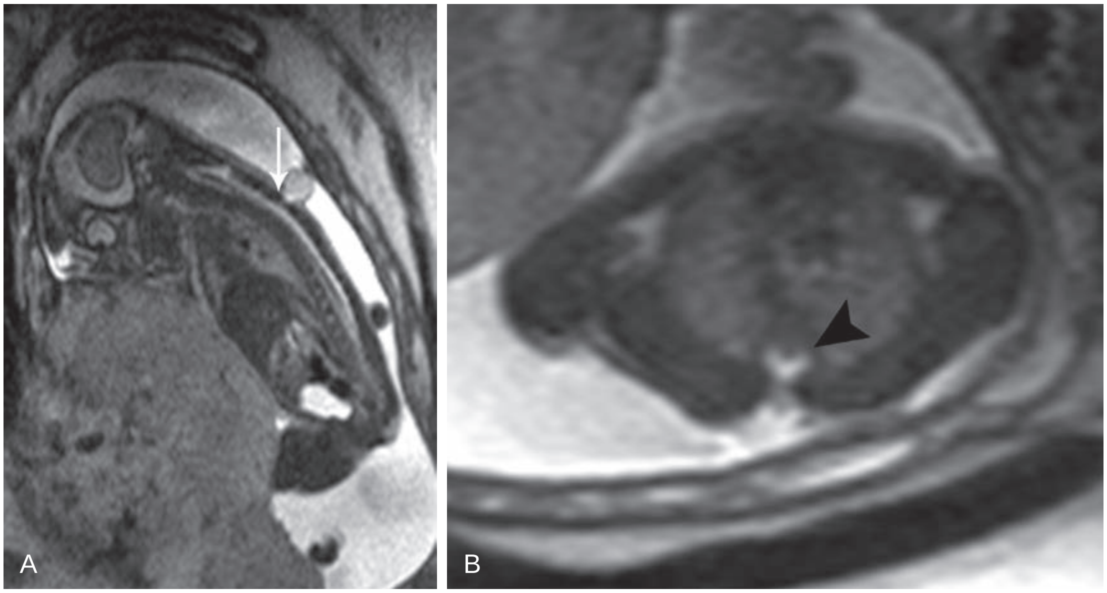
## Meningocele

The simple posterior meningocele is characterized by a meningeal-lined CSF sac, which protrudes through a posterior osseous spinal defect (e-Fig. 42.10). The spinal cord does not enter the sac, although it may be associated with hypertrophy of the filum terminale or spinal cord tethering. Its etiology is not well understood, but some postulate that CSF pulsations cause the meninges to herniate through a focal posterior osseous defect. Most commonly encountered in the thoracic spine, these anomalies rarely may be present in utero and must be differentiated from thoracic MMC. Similar to the terminal myelocystocele and lipomyelomeningocele, these skin-covered (closed) lesions do not have an associated Chiari II malformation, and the maternal serum or amniotic fluid does not contain markers of an open neural tube defect.

## CAUDAL REGRESSION SYNDROME

Caudal regression syndrome represents a wide spectrum of anomalies, ranging from coccygeal or lumbosacral hypogenesis to sirenomelia. Infants of mothers with diabetes are the most susceptible, and the incidence is 1:7500 live births. This entity may be diagnosed prenatally, by a single lower extremity in the most extreme form to an absence or reduction in number of lower vertebral segments in lesser degrees of involvement. The less severe forms may not be detectable prenatally.

The lower extent of the spine determines the type of caudal regression and the severity of the clinical and imaging findings. The more severe form is diagnosed (type I) when the spine ends at or above the S1 level. The lowest formed level may even be in the midthoracic region. The spinal cord terminates abnormally high, with an abrupt, blunted tip, rather than the smooth taper that should be seen with a normal conus medullaris. Associated deformation of the cauda equina is common, with anterior and posterior separation of nerve roots. A spine terminating at or below the S2 level (type II) contains many fewer malformations, although the distal-most portion of the conus medullaris is absent, resulting in a blunted appearance. Typically, the spinal cord is tethered by a tight filum terminale or filum lipoma.



**e-Figure 42.10. Dorsal meningocele.** (A) Sagittal HASTE MR image in a 22-week fetus shows the sac protruding through the posterior osseous defect *(arrow).* (B) Note the spinal cord traversing, and not entering, the sac on the axial image *(arrowhead)*.

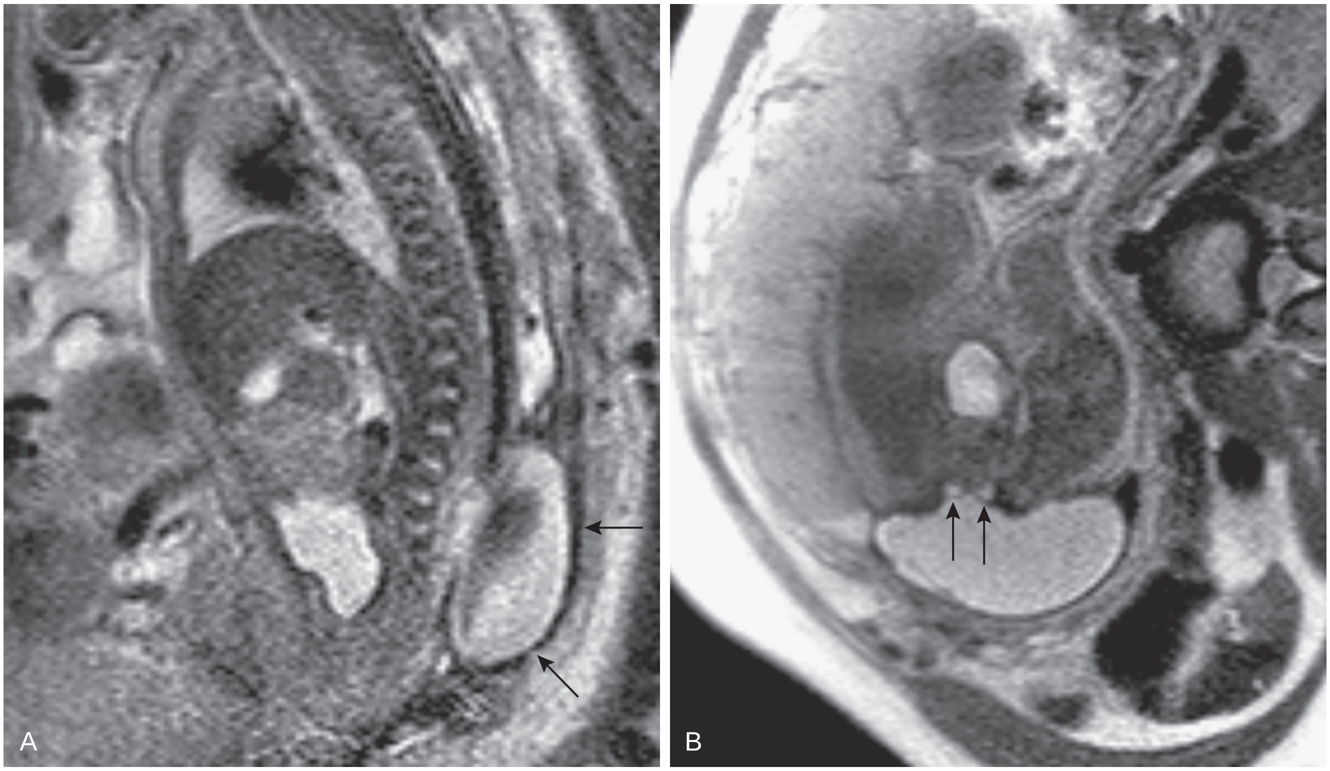


**Figure 42.9. Terminal myelocystocele.** (A) Sagittal HASTE MR image in a 32-week fetus shows the thick-walled posterior sac *(arrows)* protruding through a focal lower lumbar osseous defect. (B) Axial HASTE MR image through the osseous defect and large sac shows the distal spinal cord *(arrows)* splitting around the dilated central canal.

In unusual cases of mild caudal regression syndrome, only the tip of the conus medullaris may be absent, and the spinal cord may not be tethered. It is not expected that these findings would be detectable prenatally. This complex continuum is also associated with syndromes, including OEIS, VACTERL, and the Currarino triad.

## SEGMENTAL SPINAL DYSGENESIS

Segmental spinal dysgenesis is a rare entity in which a focal segment of the lumbar or thoracic spine is agenetic or markedly hypogenetic. The spinal cord at this level is segmentally disrupted, the distal spinal cord is often abnormally large, and a sharply angled focal kyphosis develops after birth. Some authors believe that segmental spinal dysgenesis falls within the caudal regression spectrum and that the morphology depends on the level of notochordal disruption. If the notochordal development is affected distally, caudal regression syndrome ensues, but if the lesion occurs more proximally, segmental spinal dysgenesis is seen. No known treatment is currently available to improve function in this condition, although postnatal surgical decompression has been reported to prevent worsening neurologic function.

## SECONDARY SPINAL MALALIGNMENT

Severe neurologic abnormalities, such as forms of congenital muscular dystrophy, or extensive non-CNS anomalies, including limb-body wall complex (Fig. 42.11), may result in acquired spinal malalignment. Fetal spinal malalignment can also be the secondary result of intrauterine factors, such as synechiae. While a careful evaluation of the spinal column should be performed to assess for associated vertebral anomalies, in utero scoliosis may have a purely neuromuscular or mechanical origin.

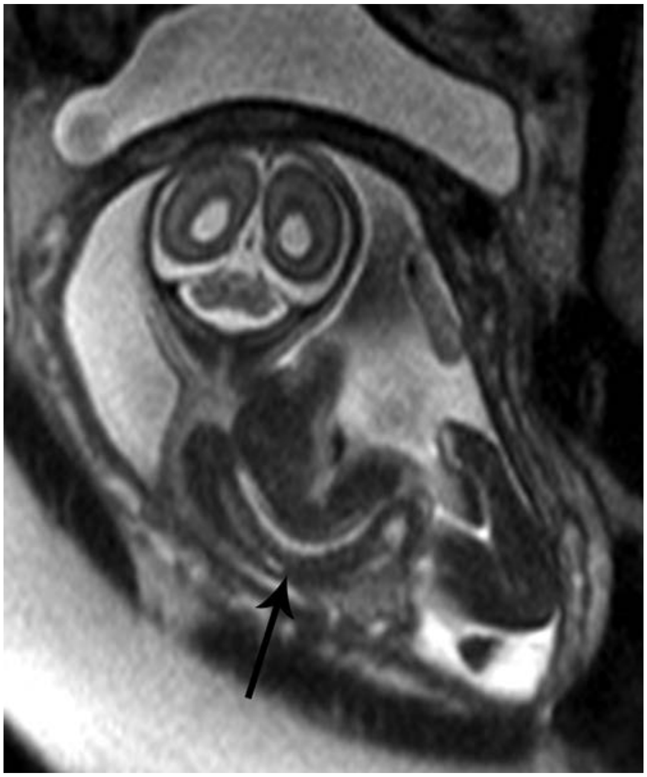

**Figure 42.11. Fetal scoliosis.** MRI in a fetus with limb-body-wall complex, the fetal spine is markedly scoliotic, turning nearly 90 degrees *(arrow)* in this 20-week fetus.

## KEY POINTS

- Careful attention to morphology in the prenatal evaluation of spinal dysraphism may aid in distinguishing between entities with similar features (i.e., MMC, lipomyelomeningocele, and meningocele).
- Prenatal surgical repair is the standard of care for the treatment of open spinal dysraphism in the United States.

# Congenital Abnormalities of the Spine

Kevin R. Moore

## EMBRYOLOGY AND DEVELOPMENTAL ANATOMY

Spine formation begins early in gestation, commencing at the end of the second gestational week with formation of the Hensen node and continuing into the beginning of the third week with the appearance of the neural plate during gastrulation. The notochordal process forms at day 16 or 17, with transient communication of the amnion through the notochordal canal to the yolk sac and through the neurenteric canal of Kovalevsky. The spine develops in a mostly orderly progression, with the vertebral axis and spinal cord developing synchronously. The rostral spinal cord (to about the level of S2) forms by the process of primary neurulation, whereas the caudal spinal cord (below the S2 level) forms by secondary neurulation, previously referred to as canalization and retrogressive differentiation. Most congenital spinal anomalies can be explained by one or more events going awry during these processes.

The neural tube folds and closes at the end of the third gestational week, during primary neurulation; this leaves temporary cranial and caudal openings called neuropores. Normal neural tube closure by day 25 to 27 signals the end of primary neurulation. Meanwhile, the neural tube separates from the overlying ectoderm during the related process of disjunction. If disjunction occurs prematurely, perineural mesenchyme is permitted access to the neural groove and ependymal lining. This mesenchyme may differentiate into fat and prevent complete neural tube closure, which leads to the lipomatous malformation spectrum. If disjunction fails to occur (nondisjunction), an ectodermal–neuroectodermal tract forms that prevents mesenchymal migration. Nondisjunction results in posterior dysraphism, producing the open neural tube defect spectrum of myelomeningocele (MMC), dorsal dermal sinus, and myelocystocele.

The neuroepithelial cells (neuroblasts) around the inner neural tube form the mantle layer, which produces the spinal cord gray matter. The outermost layer forms the marginal layer, which subsequently myelinates to produce the spinal cord white matter. The central neuroepithelial cells differentiate into ependymal cells along the central canal. Neural crest cells along each side of the neural tube form the dorsal root ganglia, autonomic ganglia, Schwann cells, leptomeninges, and adrenal medulla.

Concurrent with the neural tube folding during primary neurulation, spinal cord development below the caudal neuropore commences within the pluripotent tissue at the caudal eminence in the process of secondary neurulation. The initially solid cell mass canalizes and becomes contiguous with the rostral neural tube that was formed by primary neurulation. By day 48, a transient ventriculus terminalis appears in the future conus. If this persists after birth, it is noted incidentally as a normal variant ventriculus terminalis (“fifth ventricle”), usually of no clinical significance. Failure of proper secondary neurulation leads to caudal spine anomalies in the caudal regression, tethered cord, or sacrococcygeal teratoma (SCT) spectra in addition to terminal myelocystocele and anterior sacral meningocele.

By the third gestational month, the spinal cord extends the entire length of the developing spinal column. In fact, the more rapid elongation of the vertebral column and dura relative to the cord produces the apparent ascent of the cord during the remainder of gestation. Most important, the conus should be at adult level soon after birth, and persistent cord termination below L2–L3 after the first month of life in a full-gestation infant is probably abnormally low-lying.

Occurring simultaneously with spinal cord development is vertebral formation. During neurulation, the notochord induces the surrounding paraxial mesoderm derived from the primitive streak to form paired somite blocks (myotomes and sclerotomes). The myotomes form the paraspinal muscles and skin cover, and the sclerotomes divide into medial and lateral formations to produce the vertebral bodies, intervertebral disks, meninges, spinal ligaments (medial), and posterior spinal elements (lateral). Failure of correct notochordal induction leads to incomplete splitting of the neural plate from the notochord, producing the split notochord syndromes (neurenteric cyst and diastematomyelia).

From day 24 until the fifth week, sclerotomal resegmentation commences, during which a horizontal sclerotomal cleft appears in the vertebra, and the caudal half of one vertebra combines with the rostral half of the vertebra below to form a “new” vertebral body. The notochord within the vertebral body degenerates, and the intervertebral notochord remnant becomes the intervertebral disk nucleus pulposus. Between days 40 and 60, the vertebrae undergo chondrification followed by subsequent ossification at distinct centers within the vertebral body and arches. This process continues past birth and into young adulthood. Ossification begins in the lower thoracic and upper lumbar regions and diverges cranially and caudally. In the cervical region, the vertebral primary ossification centers appear after the neural arch centers, beginning in the lower cervical spine (C6, C7) and proceeding rostrally. Aberrances occurring during the chondrification and ossification process produce myriad segmentation and fusion anomalies (SFAs; hemivertebrae, butterfly vertebrae, block vertebrae).[1]

## SPINAL DYSRAPHISM

*Spinal dysraphism* is a broad term that encompasses a variety of disorders that have as a common feature abnormal dorsal spine formation; it is defined as incomplete or absent fusion of midline mesenchymal, osseous, and neural structures. This term refers to large spinal defects, and not to the common spina bifida occulta, in which there is only a small cleft within a spinous process or a minor incomplete fusion of the L5 or S1 laminae. Use of the older term *spina bifida occulta* is strongly discouraged in favor of the preferred term *incomplete posterior element fusion*, because this finding is generally incidental and without clinical significance.

The osseous abnormalities associated with true spinal dysraphism may involve multiple vertebrae. Spina bifida (Latin, “cleft into two parts”) is characterized by incomplete neural arch fusion with absence of all or parts of the affected posterior elements (laminae and spinous processes). Associated segmentation anomalies of the vertebral bodies may be present, such as hemivertebrae, butterfly vertebrae, and block vertebrae.

Children with spinal dysraphism may come to medical attention with a back mass, abnormal cutaneous manifestations, gait disturbance, and bowel and bladder incontinence. Classically, spinal dysraphism is classified into two categories, based on the clinical presence or absence of a back mass. Two categories of dysraphism with back mass are described. The first category is spinal dysraphism with back mass that is not covered by skin (e.g., spina bifida aperta or cystica, MMC, myelocele); the second is spinal dysraphism

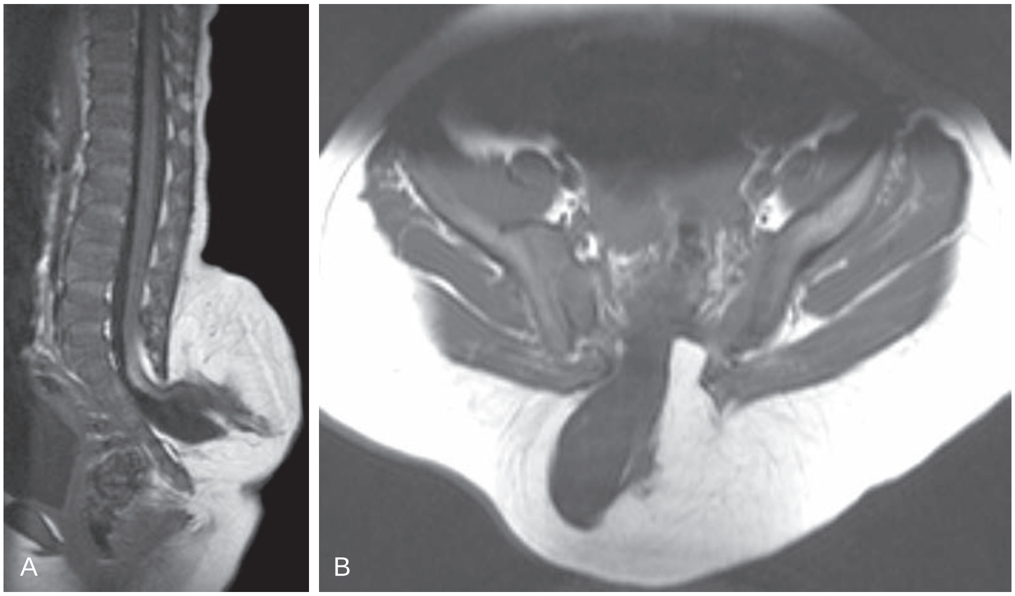

**Figure 43.1. Lipomyelomeningocele.** Sagittal (A) and axial (B) T1-weighted MRI demonstrated a typical lipomyelomeningocele, with a low-lying cord tethered into a large lipomatous malformation contiguous with the subcutaneous fat through a posterior dysraphic defect.

with skin-covered back mass (e.g., lipomyelomeningocele, myelocystocele, dorsal meningocele).

## ABNORMALITIES OF PRIMARY NEURULATION

Primary neurulation abnormalities result from premature disjunction, nondisjunction, or a combination of both.

### Premature Disjunction

Premature disjunction of the neural tube from overlying ectoderm permits perineural mesenchyme to access the neural groove and ependymal lining. This mesenchyme differentiates into fat and prevents complete neural tube closure, resulting in skin-covered lipomatous malformations with or without posterior spinal dysraphism. The most commonly observed anomalies are lipomyelocele and lipomyelomeningocele (LMC, LMMC) (Fig. 43.1) and intradural spinal lipoma (Fig. 43.2).

An LMC is a skin-covered, closed dysraphism anomaly in which the neural placode is complexed with a lipoma that is contiguous with the subcutaneous fat through a dysraphic defect, attaching to and tethering the cord. An LMMC is an LMC with enlargement of the subarachnoid space that displaces the neural placode outside of the spinal canal. In both cases, syringomyelia is a common associated finding. LMC and LMMC account for 20% to 56% of occult spinal dysraphism and 20% of skin-covered lumbosacral masses. LMMC is not affected by maternal folate metabolism, unlike the less common MMC.

Multiplanar magnetic resonance imaging (MRI) best delineates the critical anatomy and facilitates the search for additional associated sacral dysgenesis, segmentation anomalies, or visceral organ anomalies. Early surgery can arrest or prevent neurologic deficits, and progressive deterioration after untethering prompts a search for retethering or for other previously undiagnosed congenital spinal anomalies.

The spinal lipoma is subdivided into intradural (juxtamedullary, subpial) and terminal lipomas. Intradural lipomas are most common in the cervicothoracic or thoracic spine and commonly occur near the conus. They are more often dorsal than ventral, variable in size, and grow proportionally with the infant. Neurologic symptoms are representative of the lipoma level and usually progress slowly. More distal lipomas within the filum or at the filum insertion (terminal lipoma) may also present with tethered cord symptoms. A focal sacral dysraphism is frequently seen in terminal lipoma.

MRI is the imaging modality of choice for lipoma diagnosis and treatment planning. A lipoma follows fat signal on all sequences, assisting differentiation from dermoid or proteinaceous cysts. Spinal lipoma and dermal sinus are occasionally detected concurrently, so a dedicated search for multiple nondisjunction or premature disjunction anomalies is always merited.

The fatty filum (filum fibrolipoma) is an exception to the previously described clinical presentations. It is common, occurs in up to 4% to 6% of people, and is seldom symptomatic. When it does produce symptoms, they are those of a tethered cord. It is always prudent to search for other occult anomalies before ascribing responsibility for neurologic symptoms to the fatty filum.

All lipomatous lesions may be asymptomatic, but frequently they produce the clinical symptoms of tethered spinal cord. For simplicity, some authorities lump all premature disjunction disorders that feature abnormal fat together under the unifying term *lipomatous malformation*. Given the overlap of neurologic symptoms and imaging appearance between LMMC and lipoma, this simplified classification is plausible. In all cases, it is critical to assess how much fat is present and where it is located, the status and level of the spinal cord involved, the levels and extent of spinal dysraphism, and the presence or absence of other visceral or neuraxial anomalies for treatment planning because symptomatic patients usually require lipoma resection and cord untethering. MRI is the best modality for both preoperative planning and for follow-up after symptom recurrence.

### Nondisjunction

In contrast to lipomatous malformations, anomalies that result from nondisjunction occur when the neural tube fails to dissociate from adjacent cutaneous tissue. The simplest and least extensive variation is the dorsal dermal sinus, which occurs when a single connection persists and forms a fibrous cord from a skin dimple to the dural sac, conus, or central spinal cord canal.[2] It is important to distinguish dermal sinus from its clinically asymptomatic mimic,

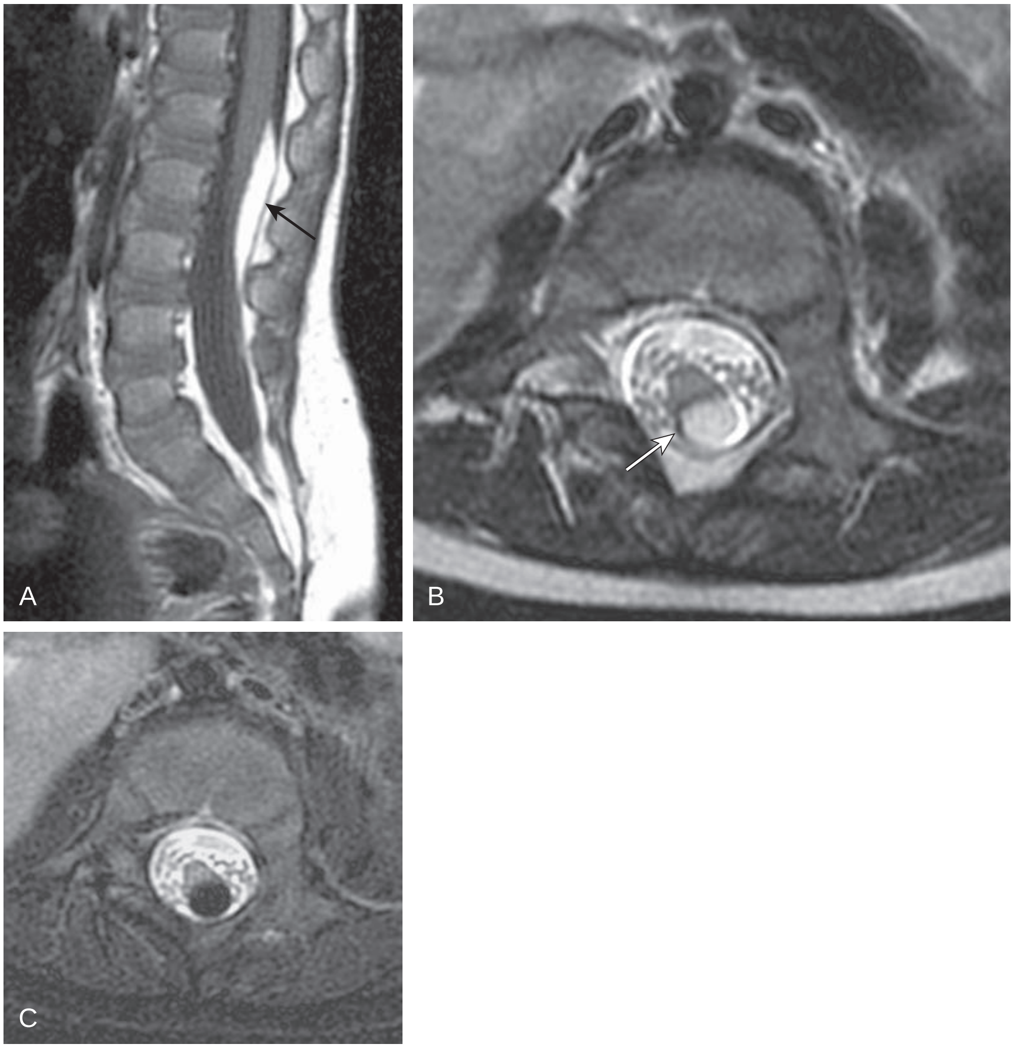

**Figure 43.2. Juxtamedullary (subpial) spinal lipoma.** (A) Sagittal T1-weighted MRI shows a small subpial intradural lipoma *(arrow)* adherent to the dorsal conus surface. (B) Axial T2-weighted MRI confirms direct contiguity of the neural placode with the lipoma. Note chemical shift artifact *(arrow)* in the frequency encoding direction, indicating fat. (C) Axial fat-saturated T2-weighted MRI confirms fat content by homogeneous signal loss within the lipoma.

simple coccygeal dimple (Fig. 43.3). The low sacral or coccygeal sinus originates from a low skin dimple and attaches to the coccyx via a short fibrous tract. These dimples are nearly always found within the intergluteal cleft, never communicate with the spinal canal, and require no treatment or imaging if there are no associated abnormalities.

Conversely, the true congenital dorsal dermal sinus tract (DST; Fig. 43.4) usually has an atypical dimple at the ostium that is larger (>5 mm), often asymmetric, and remote (>2.5 cm) from the anus. It may also be found in combination with other cutaneous anomalies, such as a hair patch or vascular lesion. The most common DST location is in the lumbosacral spine, followed by the occiput. In all dermal sinus cases, there is some degree of focal dysraphism, which may be as subtle as a bifid spinous process. The sinus tract cord is epithelial-cell lined and may or may not be canalized. When patent, it exposes the patient to an elevated risk of meningitis. It is critical to look for this anomaly in all patients with atypical skin dimples, cutaneous back lesions, or lipomas. Additionally, 30% to 50% of DSTs may have an associated dermoid or epidermoid cyst. These patients should be imaged with MRI. The best MRI sequence is usually sagittal T1-weighted MRI, windowed widely so that the hypointense tract is visualized as a gray cord immersed in bright fat that passes inferiorly and ventrally to the lumbodorsal fascia; it then turns upward to ascend within the spinal canal, often tenting the dorsal dura at the point of entry. Dermal sinuses are surgically excised to prevent meningitis and to untether the spinal cord.

More extensive nondisjunction produces MMC (Fig. 43.5). Infants come to medical attention with an open, red, weeping skin defect on the back that features protruding neural elements. Most MMC lesions are either lumbosacral or thoracolumbar, but cervical and thoracic MMCs occur. Lesion level and severity of associated hydrocephalus determine the patient's prognosis. MMCs are linked to methylenetetrahydrofolate-reductase (MTHFR) mutations with abnormal folate metabolism, and are associated with maternal folate deficiency. *PAX3* paired box gene derangements and trisomy 13 or 18 (14% of fetuses with neural tube defect) are also described. These gene derangements and folate metabolism abnormalities are postulated to interfere with carbohydrate molecule expression on the neuroectodermal surface, which causes neural tube closure to fail. Prevalence in the United States is 2 in 10,000 live births, and it is more common in females by a ratio of 3 : 1. The prevalence

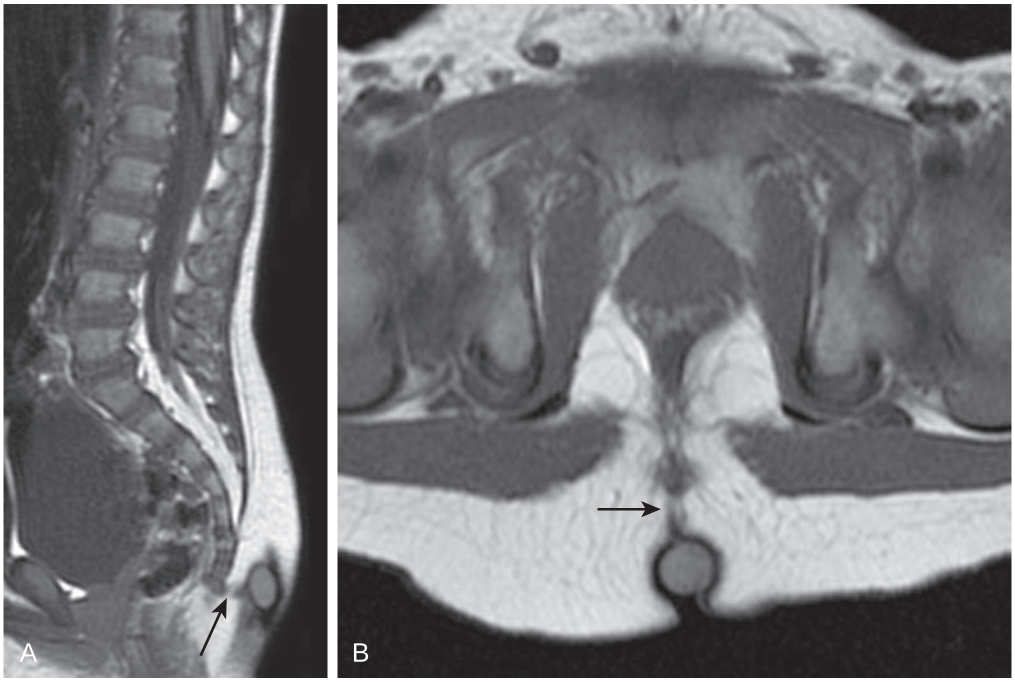

**Figure 43.3. Simple sacrococcygeal dimple.** Sagittal (A) and axial (B) T1-weighted MRI demonstrates a low sacral dimple within the intergluteal cleft, marked by a hyperintense vitamin E capsule. The short fibrous tract *(arrow)* that extends from the dimple to the coccyx tip confirms the diagnosis.

of MMC decreased 23% from 1995 to 2004, attributed to more widespread folate fortification of food.

Associated orthopedic and neuraxial anomalies are common, and Chiari II malformation is universally present. Complications of the Chiari II malformation are the major cause of death in these patients. MMC patients should have a stable neurologic deficit after MMC closure, and a progressive or new neural deficit should prompt an imaging search for other occult spinal abnormalities, such as diastematomyelia, or complications of MMC repair, such as cord tethering, dural ring constriction, spinal cord ischemia, or syrinx. MRI is the best modality for postoperative imaging in the clinical context of progressive deficits. Imaging before MMC closure is rarely indicated.

## ANOMALIES OF THE CAUDAL CELL MASS

Caudal cell mass anomalies are a diverse group of anomalies that result from aberrant secondary neurulation, postulated to be an insult to the caudal cell mass before the fourth gestational week. Most cases are sporadic, although a dominantly inherited defect in the *HLXB9* gene has been described. The mothers of 15% to 20% of these infants are diabetic, the offspring of 1% of diabetic mothers are afflicted, and an association has been found with VACTERL syndrome (***v***ertebral, ***a***nal atresia, ***c***ardiac, ***t***racheal, ***e***sophageal, ***r***enal, ***l***imb), omphalocele, bladder exstrophy, imperforate anus, and the Currarino triad. The range of severity is substantial, from clinically unapparent mild dysgenesis to absence of the lower body.

Hypogenesis or agenesis of the caudal cell mass produces caudal regression syndrome (CRS; Fig. 43.6). Two types are described. The more severe type 1 CRS features a foreshortened terminal vertebral column, high-lying wedge-shaped conus termination, and more severe associated visceral and orthopedic anomalies. The less severe type 2 CRS has a low-lying tethered spinal cord with milder associated malformations. In general, the higher the cord termination, the more severe the sacral anomalies. The most severe CRS presentations are lumbosacral agenesis, in which the spine terminates at the lower thoracic level, and severe sacral dysgenesis, with fused lower extremities in a "mermaid" configuration (sirenomelia).[4] In contrast, the mildest CRS cases may manifest merely as a missing terminal sacral segment identified on imaging that is clinically asymptomatic. CRS is associated with myriad other visceral abnormalities, including renal or pulmonary hypoplasia and anorectal malformations. Other commonly associated spinal malformations include open dysraphism, vertebral SFAs, and split-cord malformations.

Segmental spinal dysgenesis (SSD) is a very rare dysraphic anomaly characterized by segmental thoracolumbar or lumbar vertebral and spinal cord dysgenesis or agenesis. Congenital thoracic or lumbar kyphosis is characteristic, with a palpable dorsal bone spur located at the gibbous apex. The upper spinal cord is normal, but the cord segment below the dysgenetic segment is bulky, thickened, and low-lying. The spinal canal proximal and distal to the dysgenetic level is of normal caliber. Some authors believe that SSD and CRS represent different phenotypes along a single malformation spectrum, and that spinal morphology depends on the level of developmental disruption. If development is affected distally, CRS results, but if the lesion occurs more proximally, SSD is observed.

Perhaps the most common entity within the caudal cell mass dysplasia spectrum is tethered cord syndrome (TCS), which manifests clinically as gait spasticity, low back and leg pain that is worse in the morning, lower extremity sensory abnormalities, and/or bladder dysfunction. TCS patients are most likely to present during periods of rapid somatic growth. TCS refers strictly to patients with a low-lying cord and thickened filum, not those with other spine and cord abnormalities, although in fact those patients may be similar in clinical presentation and may be considered "clinically tethered." It is important to consider TCS a distinct clinical diagnosis, with imaging relegated to the role of preoperative planning rather than establishing the primary diagnosis. On imaging, TCS manifests either as a taut spinal cord without definitive conus or a low-lying conus (Fig. 43.7). The filum is frequently thickened and shortened, and an associated terminal

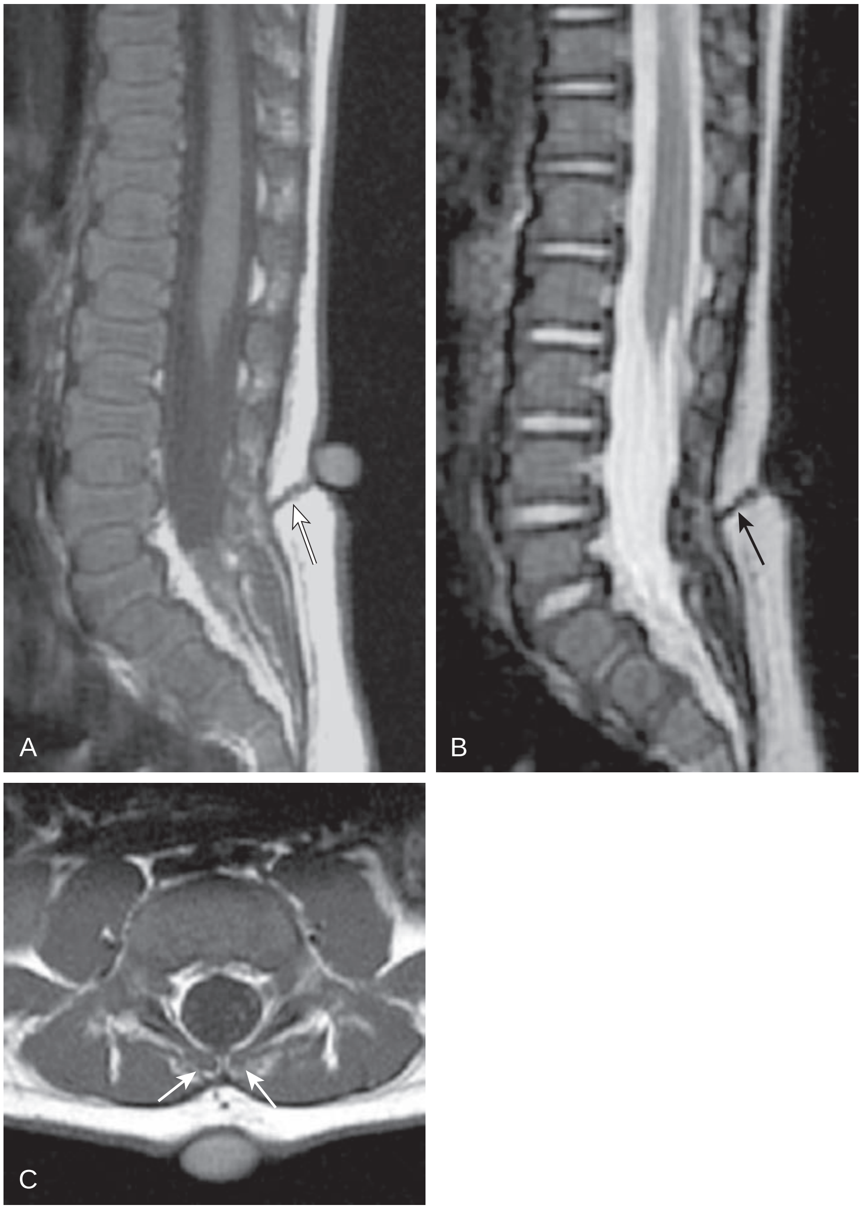

**Figure 43.4. Dorsal dermal sinus.** Sagittal T1-weighted (A) and T2-weighted (B) MRI demonstrates a low-lying spinal cord tethered by a dorsal dermal sinus tract *(arrows).* The skin opening is marked by a vitamin E capsule. Axial T1-weighted MRI (C) confirms the tract accessing the dural sac through a bifid spinous process *(arrows).*

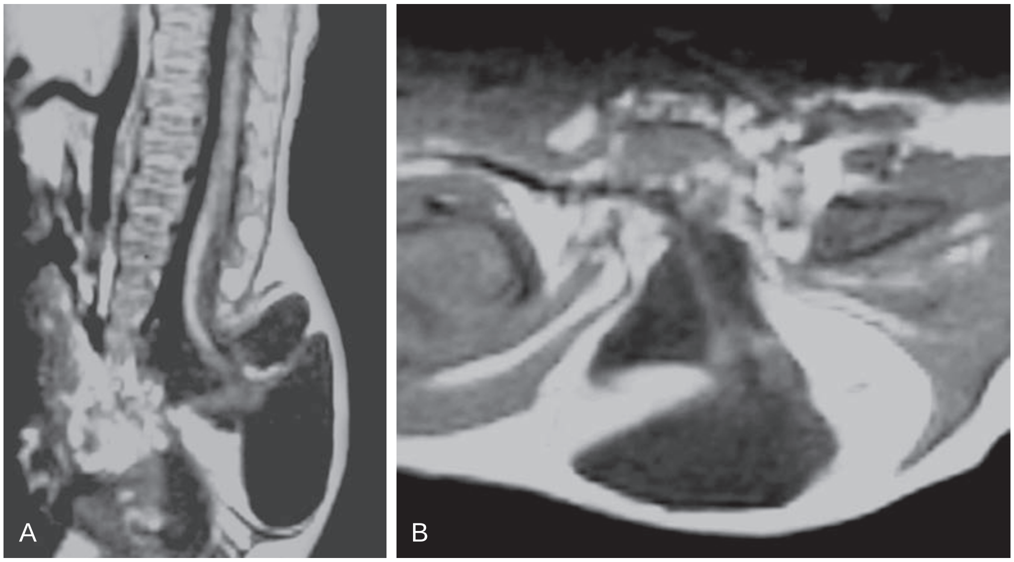
lipoma may be present. Symptomatic patients may benefit from surgery, but it is crucial to exclude other associated anomalies.

Two other important rare presentations of caudal cell mass dysplasia are the anterior sacral meningocele (ASM) and the terminal myelocystocele. ASM features a large anterior meningocele outpouching that traverses an enlarged sacral foramen and produces a presacral cystic mass. This may be clinically mistaken for a SCT and may prompt neuroimaging. Most ASMs are sporadic, but a minority show an inherited predisposition within the Currarino triad or in syndromes that feature dural dysplasia, such as neurofibromatosis type 1 (NF1) and Marfan syndrome. As with other caudal cell mass dysplasias, additional congenital abnormalities may be found, such as anorectal malformations, caudal dysgenesis, and dermoid or epidermoid cysts. Fortunately, imaging is highly characteristic in the more common simple form, with a presacral cystic mass that connects to the thecal sac through an enlarged sacral neural foramen (Fig. 43.8). Complex ASMs with fat or neural elements are also recognized by their extension through the neural foramen. Terminal myelocystocele is a very rare malformation that manifests as a hydromyelic spinal cord that traverses a meningocele to terminate in a skin-covered myelocystocele (e-Fig. 43.9). Associated anorectal and visceral anomalies are common. Infants with terminal myelocystocele may be neurologically intact at birth but subsequently lose neurologic function.

Finally, if the primitive streak incompletely regresses and leaves a caudal totipotential cell rest remnant, an SCT (Fig. 43.10) may result. SCTs demonstrate tissue from all three cell layers and contain varying proportions of mature and immature elements. These are surgically graded, according to the American Academy of Pediatrics (AAP) classification, based on the proportion of internal (pelvic) and external components from type 1 (all external) to type 4 (all internal). Prognosis is determined by the grade and by the presence or absence of mature or malignant components. External tumors, mature elements, and younger patient age predict



**e-Figure 43.9. Terminal myelocystocele.** Sagittal T1-weighted MRI (A) depicts a low-lying hydromyelic cord with terminal cyst projecting through a sacral meningocele. Axial T1-weighted MRI (B) confirms the origin of the terminal cyst as the hydromyelic terminal central canal.

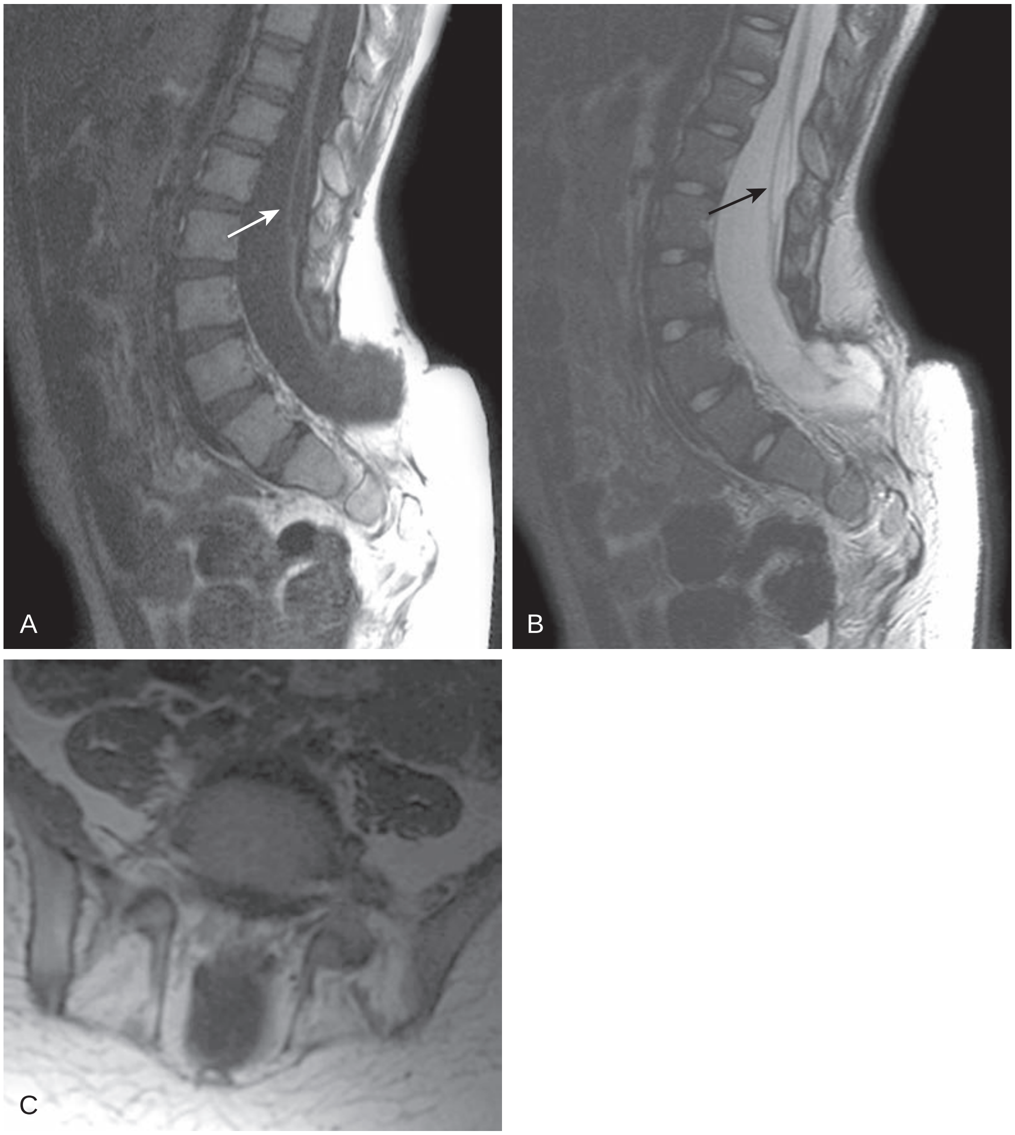


**Figure 43.5. Myelomeningocele.** Sagittal T1-weighted (A) and T2-weighted (B) MRI shows the postoperative appearance of the spine after myelomeningocele closure. The large dysraphic defect is now covered with skin, and the attenuated distal spinal cord is scarred into the closure. A small syrinx is present *(arrow).* Axial T1-weighted MRI (C) reveals the protrusion of the distal sac through parallel dysraphic posterior elements.

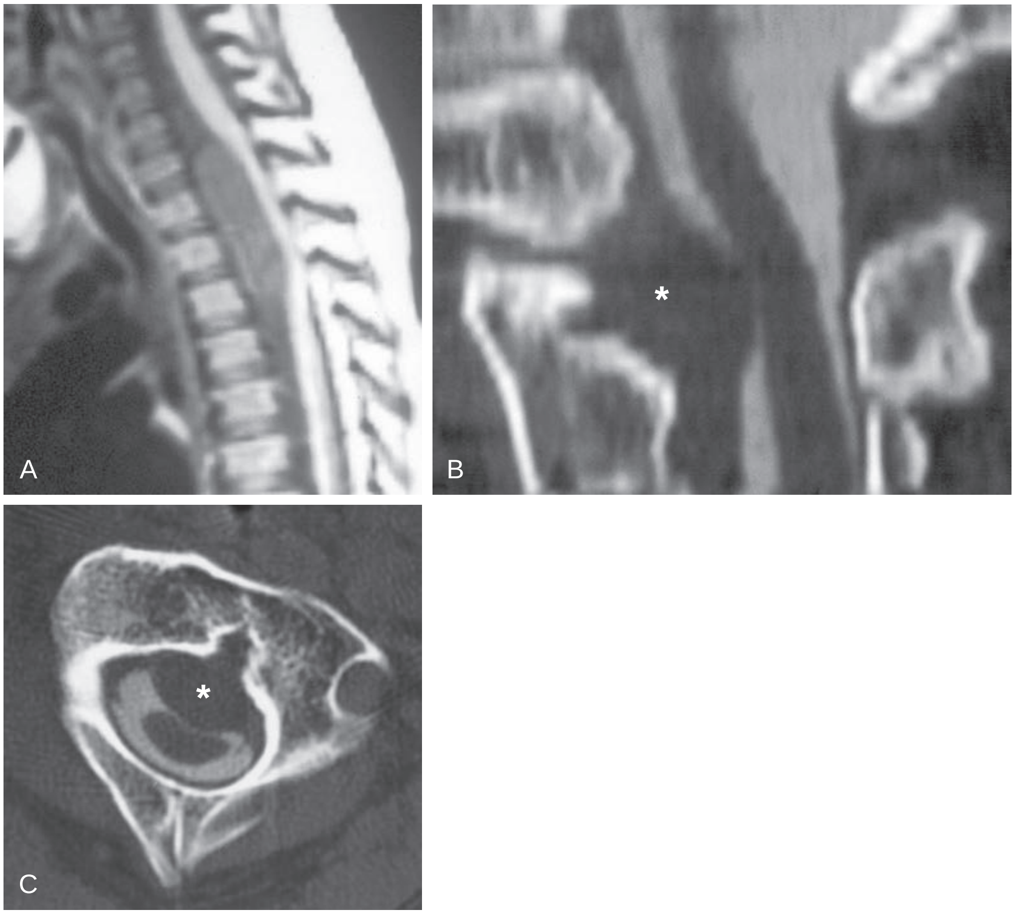
a better outcome. The surgeon must resect the coccyx to prevent recurrence. Fetal and early infancy morbidity and mortality are related mostly to cardiac failure from intratumoral shunting and associated visceral anomalies, whereas later mortality is related to lesion malignancy.

MRI is the best modality for preoperative planning and staging for all caudal cell mass anomalies.[8] Computed tomography (CT) has a more limited role, such as in screening for visceral organ anomalies or evaluating bones. Ultrasonography may be helpful for initial newborn screening, because it can be performed portably in the newborn nursery, but it usually does not provide all the necessary information for surgical planning.

## ANOMALIES OF NOTOCHORD DEVELOPMENT

Neurenteric cyst (e-Fig. 43.11) consists of an intraspinal cyst lined by enteric mucosa, and is most common in the thoracic spine, followed by the cervical spine. Such cysts putatively arise from an abnormal connection between primitive endoderm and ectoderm that persists beyond the third embryonic week. Whereas normally the notochord separates ventral endoderm (foregut) and dorsal ectoderm (skin, spinal cord) during embryogenesis, in a neurenteric cyst a separation failure "splits" the notochord and hinders the development of mesoderm, which traps a small piece of primitive gut within the developing spinal canal. This gut remnant may become isolated, forming a cyst, or it may maintain connections with gut or skin (or both); this produces the spectrum of fistulas and sinuses that constitute the spectrum of dorsal-enteric spinal anomalies. The most severe malformations remain in communication through the primitive vertebral osseous canal of Kovalevsky, but even mild cases usually show some vertebral segmentation anomalies on close inspection. MRI best demonstrates the cyst and its relationship to the spinal cord, as well as connections to the mediastinal or abdominal viscera. CT, particularly with multiplanar and three-dimensional reformats, optimally demonstrates osseous vertebral anomalies for preoperative planning.

Diastematomyelia (DSM) arises from an aberrant process similar to that of the neurenteric cyst and results in a splitting



**e-Figure 43.11. Neurenteric cyst.** Sagittal T1-weighted MRI (A) shows a ventral neurenteric cyst in the spinal canal that compresses the spinal cord. Additionally, a small cyst of similar signal characteristics was found along the anterior spine that on axial imaging (not shown) was contiguous with the neurenteric cyst through a midline sagittal vertebral cleft. Sagittal (B) and axial (C) CT myelogram images in a different patient with Klippel–Feil syndrome show a ventral extradural neurenteric cyst *(asterisk)* compressing the ventral thecal sac and spinal cord, contiguous with a sagittal vertebral body cleft.

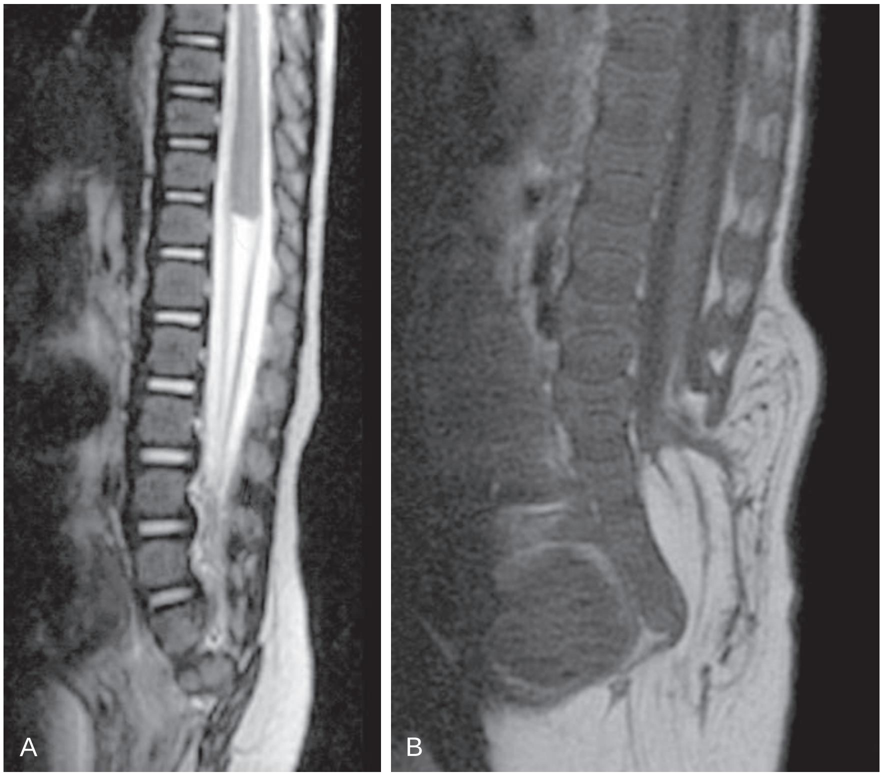


**Figure 43.6. Caudal regression syndrome.** Sagittal T2-weighted MRI (A) shows the typical appearance of type 1 CRS, with severe sacral dysplasia and the characteristic wedge-shaped high conus termination. Sagittal T1-weighted MRI (B) contrasts the appearance of type 2 CRS (with a less severe sacral dysgenesis) with an elongated spinal cord that inserts distally into a terminal lipoma.

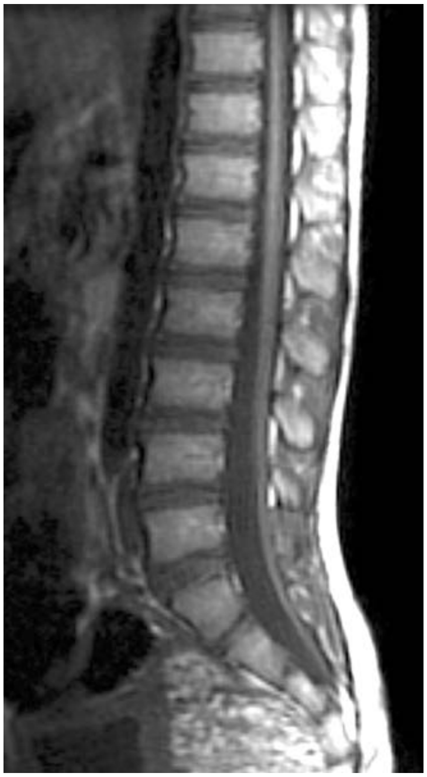

**Figure 43.7. Tethered cord syndrome.** Sagittal T1-weighted MRI reveals an elongated spinal cord, indistinguishable from the filum, inserting into the terminal thecal sac.

of the spinal cord into two hemicords, each with one ventral and one dorsal root. The hemicords may be symmetric, or they may be asymmetric, known as partial DSM; one or both may feature hydromyelia or be tethered. The much rarer (perhaps mythical) diplomyelia, or duplicated spinal cord, is the only other differential entity to consider; it occurs probably in the context of a duplicated spinal axis, and many authorities think it most likely represents a very severe DSM rather than true spinal cord duplication.

Because the notochord influences vertebral development, vertebral segmentation anomalies are very commonly associated with DSM. Therefore important factors for preoperative planning include the presence (type 1 DSM; Fig. 43.12) or absence (type 2 DSM; Fig. 43.13) of an osseous or fibrous spur and whether the cords reside in separate or single dural tubes. Occasionally in type 2 DSM, a nerve root or roots may become adherent to the dura and may tether the spinal cord, producing the meningocele manqué malformation. DSM may be isolated or found in conjunction with other spinal anomalies, particularly MMC, thus it is critical to search for DSM before any spinal anomaly repair or scoliosis correction. A patient with MMC whose symptoms progress after surgical closure is a relatively common presentation of undiagnosed DSM. Cutaneous abnormalities such as skin dimples or discoloration, vascular lesions, or hair patches are sometimes present and can guide attention to the most likely level of DSM.

## OTHER CONGENITAL AND DEVELOPMENTAL ANOMALIES

Other uncommon but important congenital spinal anomalies whose etiology is not definitively known include the simple dorsal meningocele and the lateral meningocele.

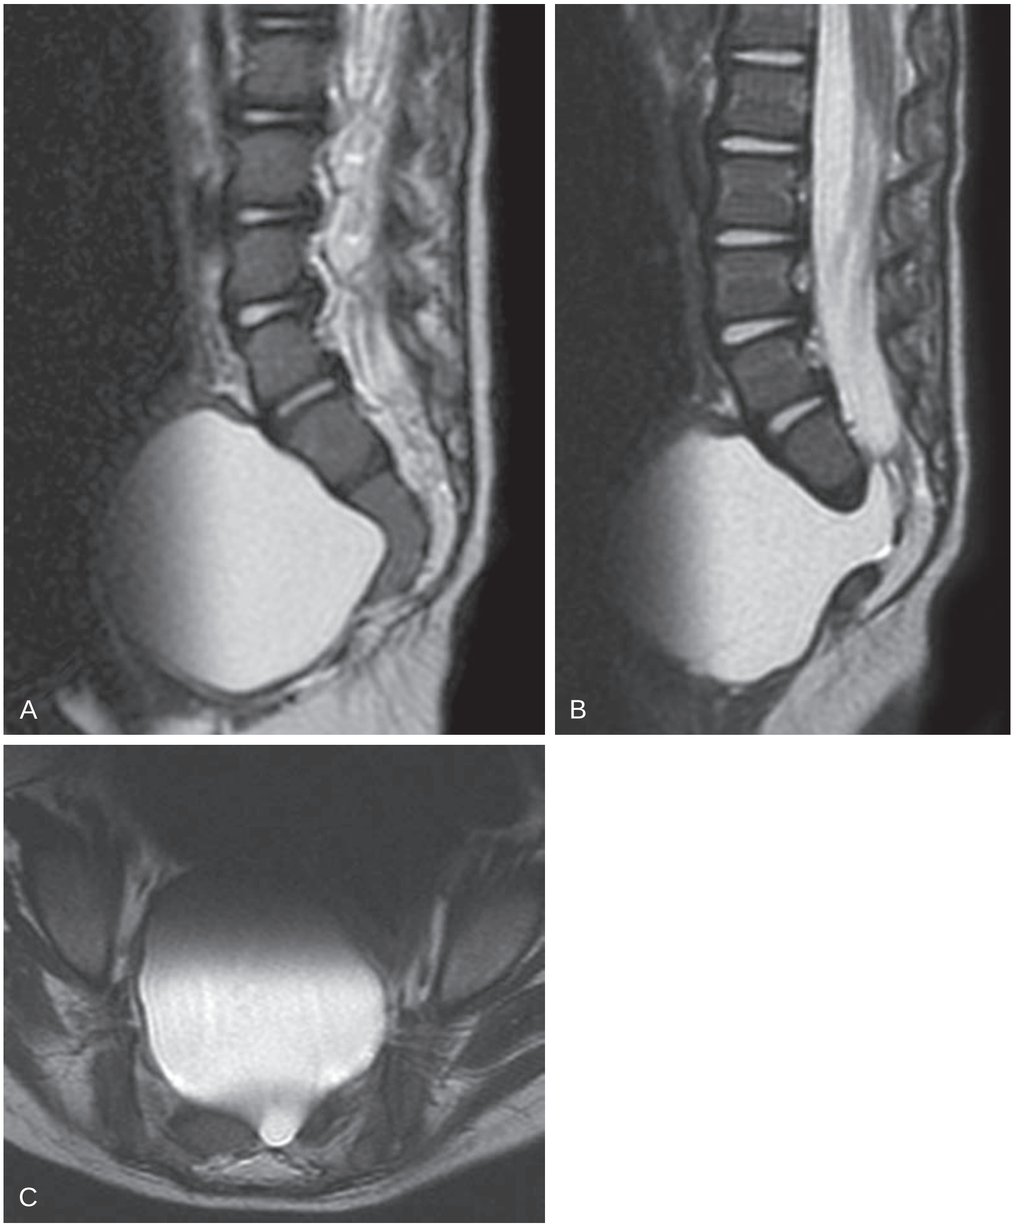

**Figure 43.8. Anterior sacral meningocele.** Sagittal midline T2-weighted MRI (A) shows the characteristic scimitar shape of the sacrum. Parasagittal (B) and axial (C) T2-weighted MRI confirms a typical, simple, anterior sacral meningocele that appears as a presacral cyst contiguous with the thecal sac through an enlarged left sacral neural foramen.

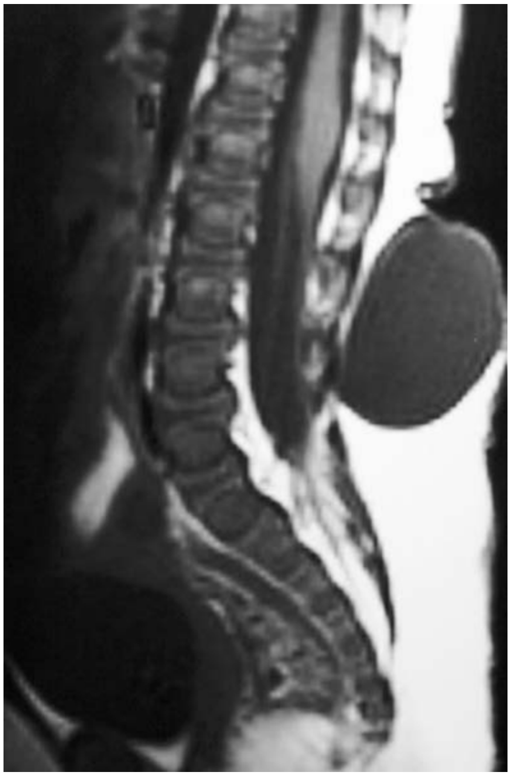
Dorsal meningoceles by definition occur dorsally, most often over the lumbosacral spine, and feature a skin-covered meningocele devoid of neural elements that protrudes through a posterior dysraphic defect (e-Fig. 43.14). In practice, however, it is not uncommon to find a dysplastic nerve root or other neural tissue within a meningocele.

Lateral meningoceles manifest as paraspinal masses filled with cerebrospinal fluid that are contiguous with the thecal sac and extend through the neural foramen, with adjacent pedicular and foraminal osseous remodeling (e-Fig. 43.15). They are generally “simple,” but some may contain fat or neural tissue and are then better termed “complex.” Important associations include Marfan syndrome and NF1.

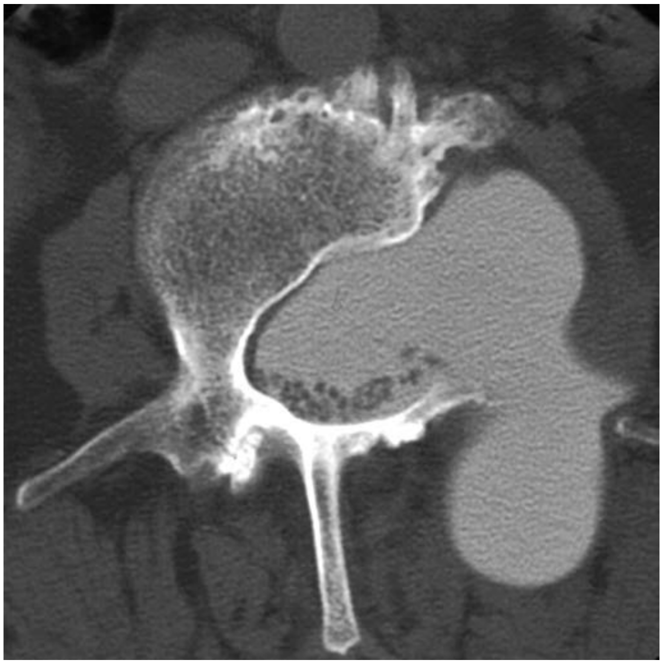
In both anomalies, MRI is the best modality to demonstrate the soft tissue components. CT is helpful for clarifying the osseous anatomy, and is usually done before surgery. If MRI is contraindicated or inconclusive, CT myelography can demonstrate the meningocele and confirm its continuity with the dural sac.

## VERTEBRAL FORMATION AND SEGMENTATION ANOMALIES

Anomalies of vertebral formation and segmentation arise from aberrancies in vertebral column formation. These are generally divided into anomalies that result from either partial or total failure of vertebral formation and failure to correctly segment after vertebral formation (vertebral segmentation failure). The abnormal vertebra may be supernumerary, or it may replace a normal vertebral body. Abnormal *PAX1* expression is a postulated etiology in the development of segmentation anomalies, and other



**e-Figure 43.14 Dorsal meningocele.** Sagittal T1-weighted MRI shows a large, skin-covered cystic back mass connected to the thecal sac by a thin cerebrospinal fluid–filled stalk. The tethered conus terminates at L2–L3. *(Image courtesy of Marvin Nelson Jr, MD.)*



**e-Figure 43.15 Lateral meningocele.** Axial CT myelogram image shows a large left lateral meningocele with pedicular erosion in a patient with neurofibromatosis type 1. The image confirms vertebral remodeling and contiguity of the meningocele with the thecal sac. In addition to lateral extension, the meningocele also extends posteriorly into the paraspinal muscles.

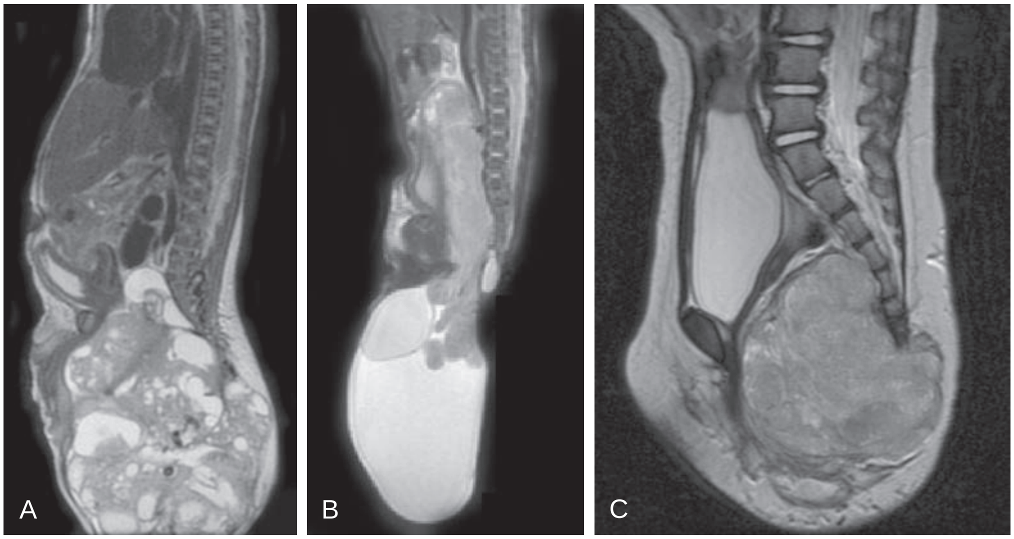


**Figure 43.10. Sacrococcygeal teratoma.** Sagittal T2-weighted MRI in three different infants shows large, mixed cystic and solid pelvic masses confirmed pathologically as sacrococcygeal teratomas. The proportions of internal and external tumor produce diagnoses of grade 1 (A), grade 2 (B), and grade 3 (C) using the American Academy of Pediatrics classification.

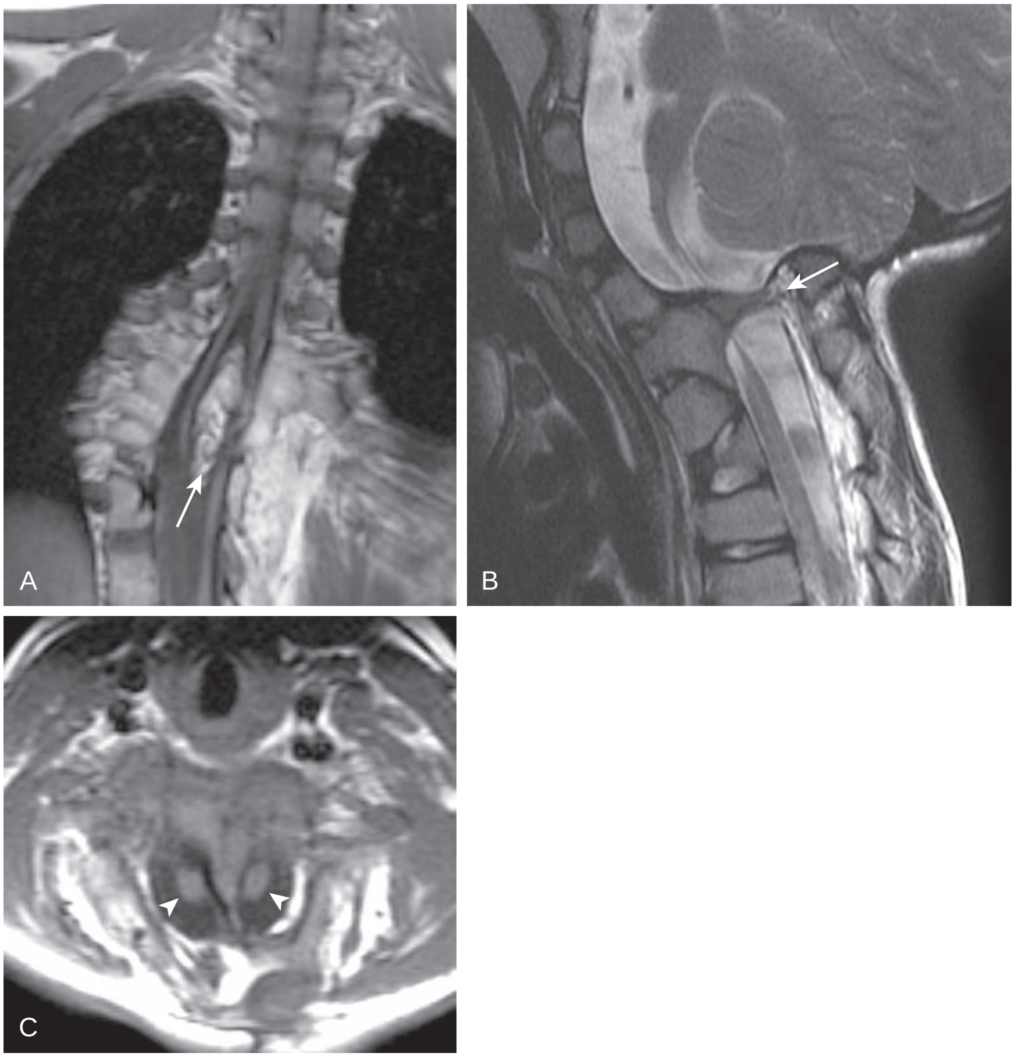

**Figure 43.12. Diastematomyelia type 1.** Coronal (A) T1-weighted MRI in a patient with type 1 DSM shows a large ossified spur *(arrow)* that splits the thoracic spinal cord. Numerous vertebral segmentation anomalies with posterior rib fusions are present. Sagittal T2-weighted (B) and axial T1-weighted (C) MRI of a different patient shows a type 1 cervical DSM with ossified spur (*arrow* in B) and two hemicords (*arrowheads* in C).

visceral and neuraxis anomalies are also commonly identified. More severe SFAs tend to have a higher incidence of concurrent visceral organ or other neuraxis anomalies. The degree and location of vertebral formation failure predicts morphology; unilateral chondral center deficiency and failure of ossification produces a hemivertebra, whereas central failure of ossification centers to unite produces a butterfly vertebra (Fig. 43.16). Conversely, vertebral segmentation failure presents with composite or "block" vertebra and posterior element fusions (Fig. 43.17 and e-Fig. 43.18). Not surprisingly, block vertebrae frequently coexist with hemivertebrae and butterfly vertebrae (Fig. 43.19), leading many to lump these various vertebral anomalies together into the working term SFAs. Many clinical syndromes prominently feature SFAs, including Klippel–Feil and Jarcho–Levin (spondylothoracic dysplasia) syndromes. SFAs are imaging markers that should prompt further consideration of a possible syndromic process.

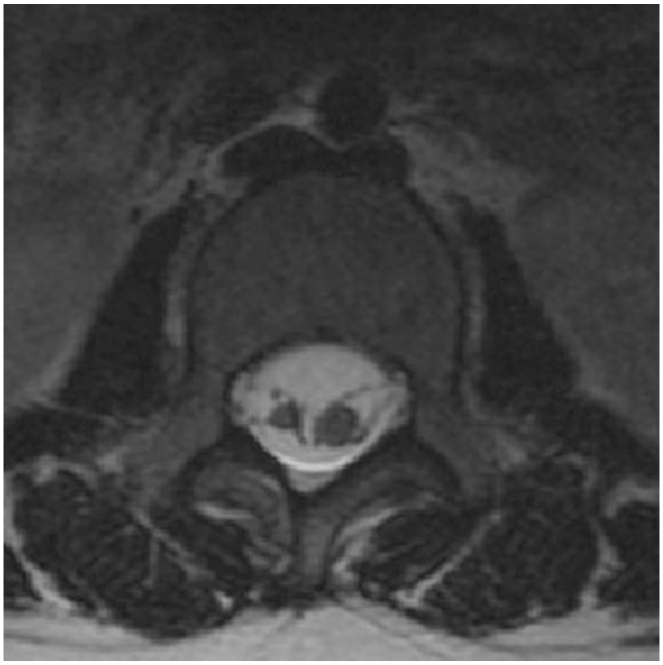

**Figure 43.13. Diastematomyelia type 2.** Axial T2-weighted MRI in a patient with type 2 DSM shows the spinal cord split into two hemicords within a single dural tube. No fibrous or osseous septum was identified.

## KEY POINTS

- The conus is normally at adult level (L2 or above) soon after birth; conus termination below L2–L3 is probably abnormally low-lying.
- LMC and LMMC account for 20% to 56% of occult spinal dysraphism and 20% of skin-covered lumbosacral masses.
- The simple coccygeal sinus that originates from a low sacral dimple found within the intergluteal cleft never communicates with the spinal canal, is usually incidental, and does not require imaging.
- The offspring of 1% of diabetic mothers have a caudal cell mass anomaly.
- TCS is a specific clinical entity that usually presents during periods of rapid somatic growth.
- MRI is the best modality for preoperative planning and staging of caudal cell anomalies, as well as assessing postoperative recurrence.
- Anomalies that reflect failure of vertebral formation and vertebral segmentation failure frequently coexist.

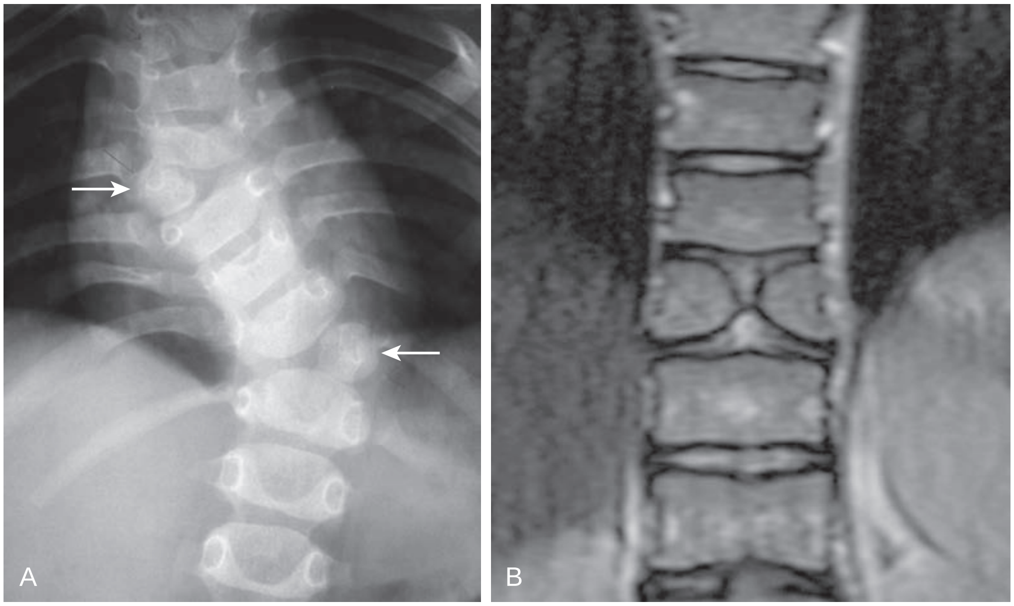

**Figure 43.16. Failure of vertebral formation.** (A) Frontal radiograph demonstrates balanced thoracic hemivertebrae *(arrows)* detected during evaluation of congenital scoliosis. (B) Coronal T2-weighted MRI shows a classic butterfly vertebra. Both of these may coexist with each other and with malformations of vertebral segmentation failure.

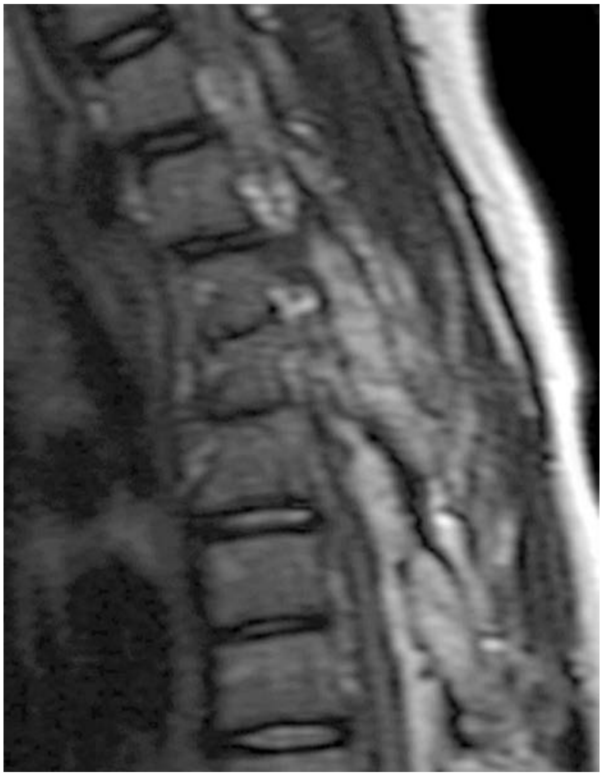

**e-Figure 43.18 Posterior element segmentation failure with fusion.** Sagittal T2-weighted MRI shows a multilevel pedicular and facet bar associated with vertebral segmentation failure at the same levels.

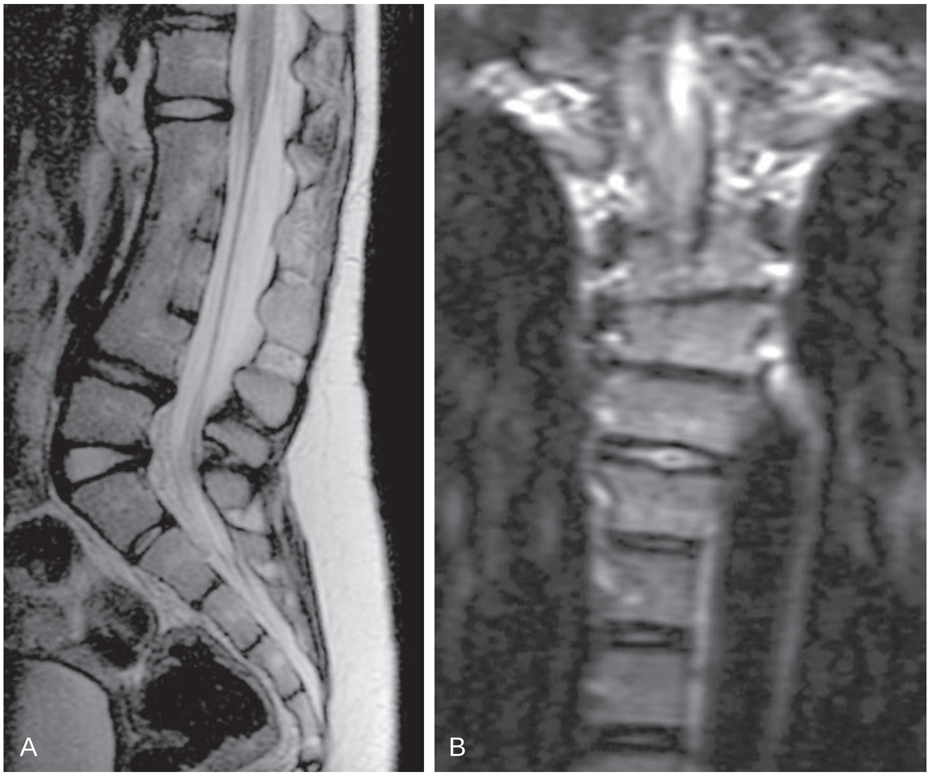

**Figure 43.17. Vertebral segmentation failure.** (A) Sagittal T2-weighted MRI demonstrates multilevel vertebral segmentation failure producing a large block vertebra and kyphotic lumbar curve. Incomplete segmentation of the posterior elements is also evident. (B) Coronal T2-weighted imaging in a different patient shows a three-level thoracic block vertebra and mild scoliotic curve related to a slightly better attempt at segmentation on the left.

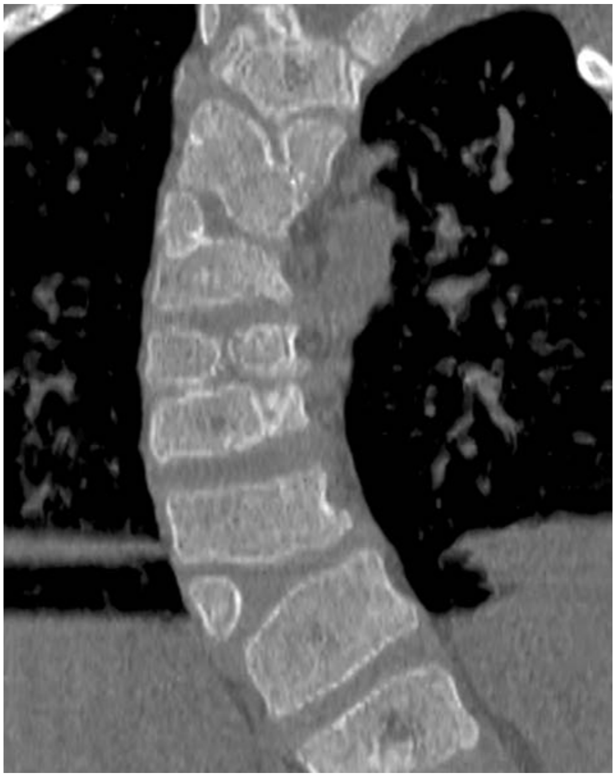

**Figure 43.19. Coexistent vertebral segmentation and vertebral formation failure anomalies.** Coronal CT image in a patient with VACTERL syndrome shows multiple combinations of both segmentation and formation failure with resultant congenital dextroscoliosis.

# Infections of the Spine and Spinal Cord

*Alexis B. Rothenberg Maddocks and Avrum N. Pollock*

Spinal infections in children occur uncommonly. Etiologies include direct and indirect (hematogenous) inoculation by bacterial, viral, parasitic, and fungal agents. Direct bacterial infectious inoculation may be as a result of trauma, instrumentation, or via a preexisting congenital sinus tract or area of spinal dysraphism (i.e., meningocele). Lyme disease (Fig. 44.1), caused by a *Borrelia burgdorferi*-infected tick bite, is also a cause of spinal cord infection, especially in the Northeastern United States. Mosquito-borne West Nile virus (e-Fig. 44.2), with cases initially appearing along the east coast of the US, has emerged as an infectious cause of spinal cord infection. Enterovirus D68 (Fig. 44.3) is a respiratory illness that has been recently described to be a cause of spinal cord infection, which can result in acute flaccid paralysis. Tuberculosis (TB) (Fig. 44.4) of the spinal cord usually occurs in the thoracic region in children and manifests as an intramedullary tuberculoma, most often seen in patients with AIDS or other immunocompromised states. TB is most prevalent in India but is also widespread in Africa and Southeast Asia. Cysticercosis (e-Fig. 44.5) is the most common parasitic infection encountered within the spinal cord. It occurs after ingestion of uncooked pork infected with *Taenia solium* and is most prevalent in South America and Southeast Asia. The parasitic infection Gnatosthomasis (e-Fig. 44.6), caused by the nematode *Gnathostoma spinigerum*, can lead to the clinical presentation of myeloradiculitis. Acquired by ingesting contaminated fish or meat, it is endemic in Southeast Asia and is virtually unknown in North America, other than in cases acquired abroad.

Inflammatory entities, related in some form to infections, are often how spinal cord infections manifest. Neurologic deficits often prompt imaging in the search for a diagnostic explanation for the patient’s symptoms. Magnetic resonance imaging (MRI) remains the gold standard examination for the evaluation of spinal cord infection. In general, central nervous system infections present with hyperintensity on fluid-sensitive T2-weighed sequences, and with variable enhancement on gadolinium-enhanced T1-weighted sequences. Like infections elsewhere, increase in cord caliber often occurs secondary to an increase in water content/edema. Rare related hemorrhages can at times be more clearly seen using gradient echo sequences.

## DISCITIS AND OSTEOMYELITIS

Disc space infection often coexists with vertebral osteomyelitis in children secondary to hematogenous spread, through capillary tufts in vertebral body endplates, and vascular channels of immature intervertebral disc spaces. Contrast-enhanced MRI is the study of choice and should be performed without delay

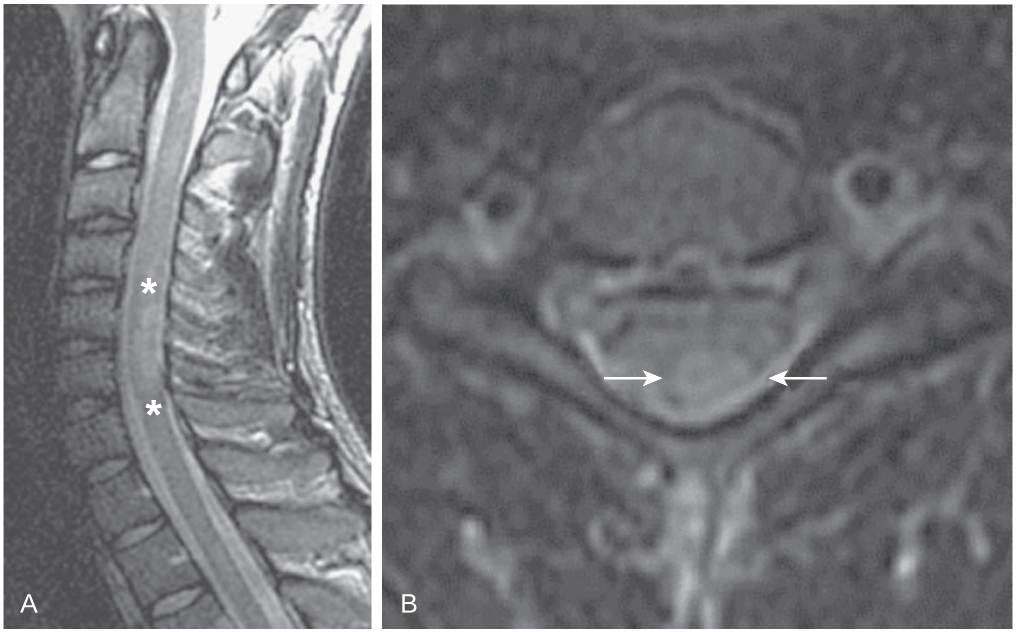

**Figure 44.1. Lyme disease in a patient with prior tick bite.** (A) Sagittal and (B) axial T2-weighted magnetic resonance (MR) images of the cervical spine demonstrates T2 prolongation (*asterisks* in A and *arrows* in B) within the dorsal spinal cord at the level of C5/C6 secondary to demyelination, similar to those seen in the brain in patients with Lyme disease. *(Case courtesy of Dr. Gul Moonis, MD, Beth Israel Deaconess Medical Center, Division of Neuroradiology.)*

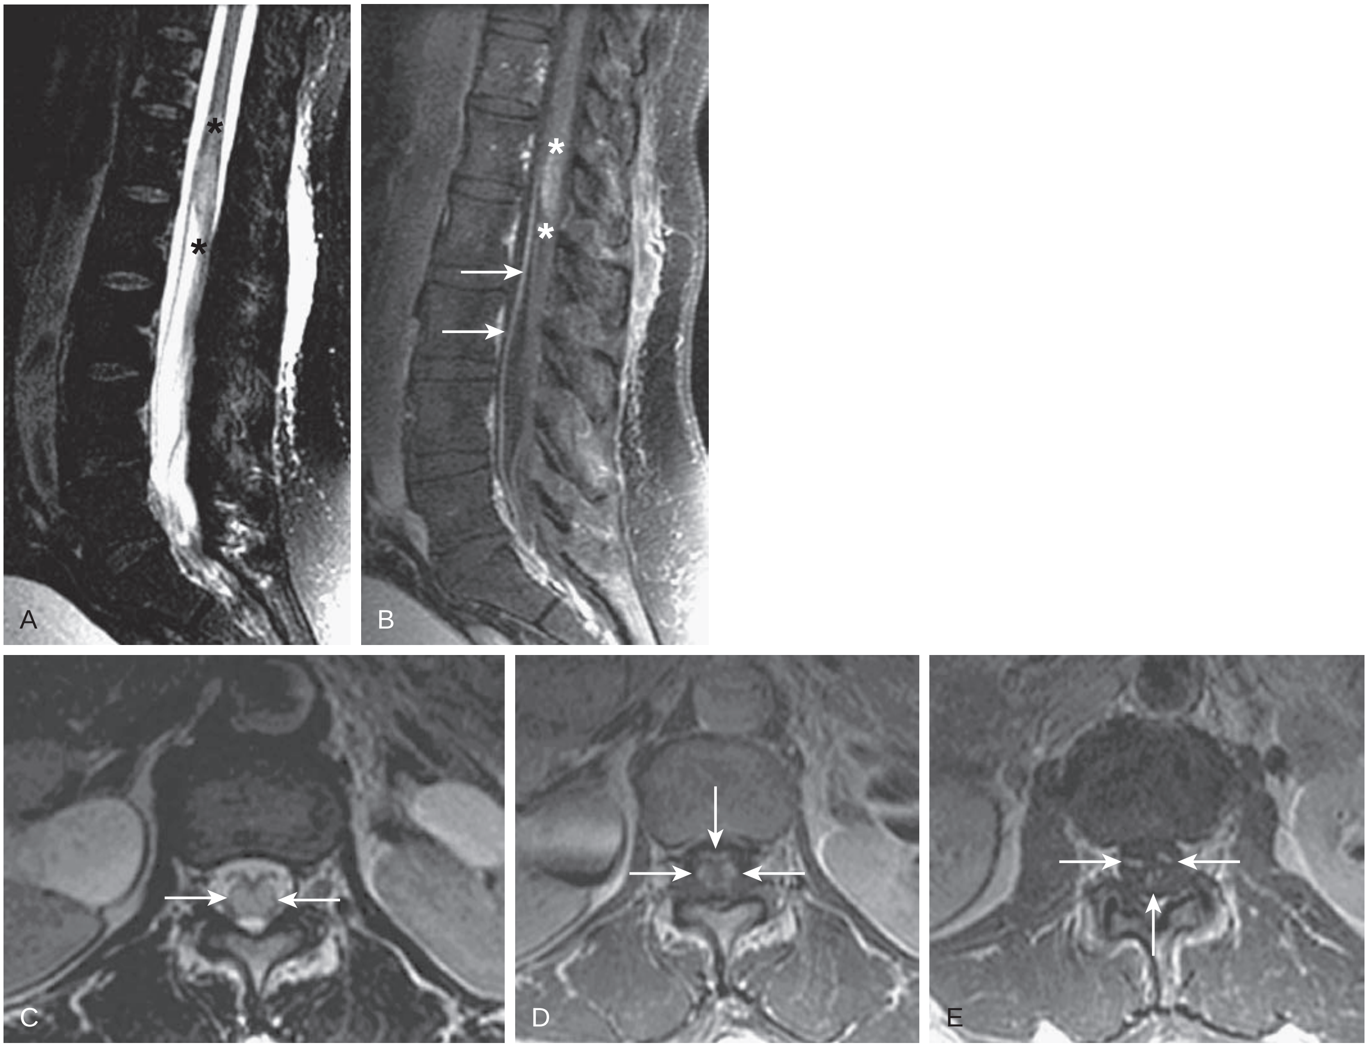
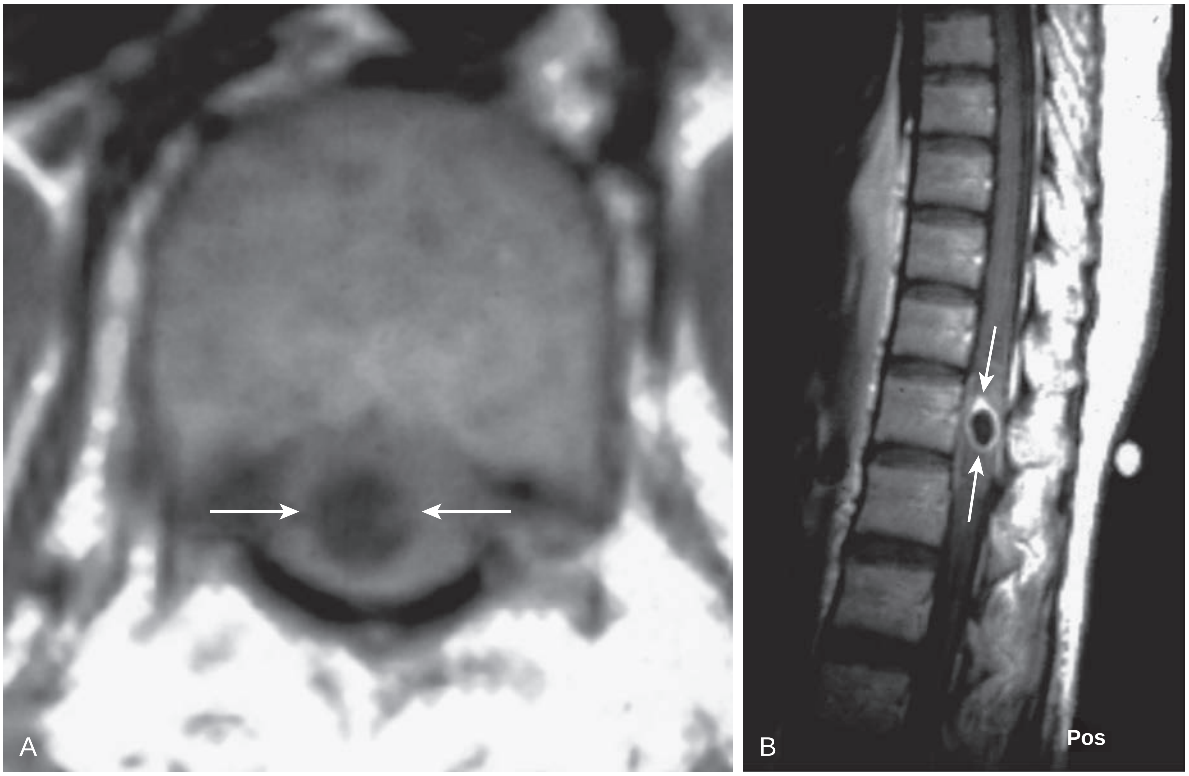
## Abstract:

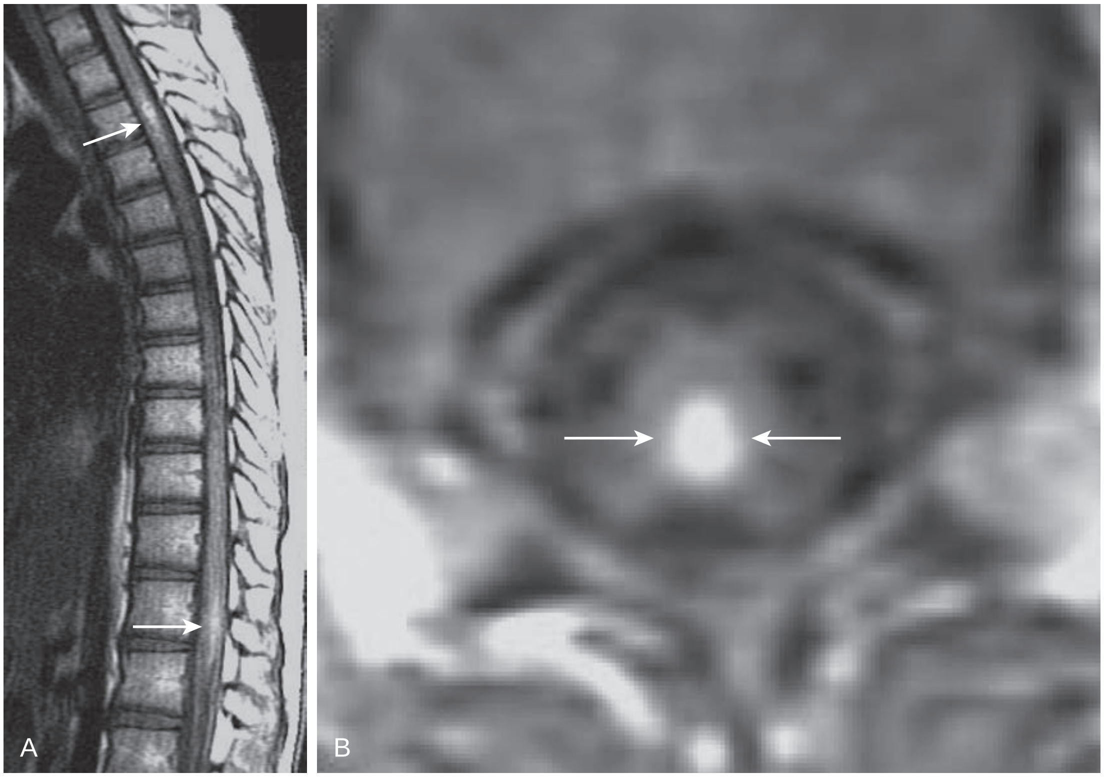
Although spinal cord infections are rare in children, when they do occur, the causative pathogens may be bacterial, viral, fungal or parasitic, and their incidence is dependent upon where in the world the child lives.



**e-Figure 44.2. (A–E) West Nile virus in a patient after mosquito bite.** (A) Sagittal and (C) axial T2-weighted MR images (Fig. 44.2A and 44.2C, respectively), as well as sagittal (Fig. 44.2B) and axial (Fig. 44.2D and 44.2E) postgadolinium T1-weighted images of the lumbar spine demonstrate T2 prolongation (*asterisks* in A and *arrows* in C) within the distal spinal cord/conus medullaris as well as contrast enhancement of the distal cord *(asterisks)*/ conus medullaris (*arrows* in B and D) and within the cauda equina (*arrows* in E) secondary to viral myeloradiculitis. *(Case courtesy of Dr. Gul Moonis, MD, Beth Israel Deaconess Medical Center, Division of Neuroradiology.)*



**e-Figure 44.5. Cysticercosis in 20-year-old male presenting with paraparesis developing over 2 weeks.** (A) Axial T1-weighted and (B) sagittal postcontrast T1-weighted MR images of the thoracic spine demonstrate central T1 prolongation within the spinal cord proper (*arrows* in A), with corresponding rim enhancement on the postcontrast images (*arrows* in B). *(Case courtesy of Dr. Manu Shroff of the Hospital for Sick Children in Toronto, Canada.)*



**e-Figure 44.6. Gnathosthomiasis.** A 17-year-old boy from Thailand with exposure to Gnathostoma parasite. (A) Sagittal and (B) axial postcontrast T1-weighted MR images of the thoracic spine demonstrate enhancing nodules *(arrows)* within the spinal cord secondary to parasitic infection. *(Case courtesy of Dr. Jiraporn Laothamatas of Mahidol University, Bangkok, Thailand.)*

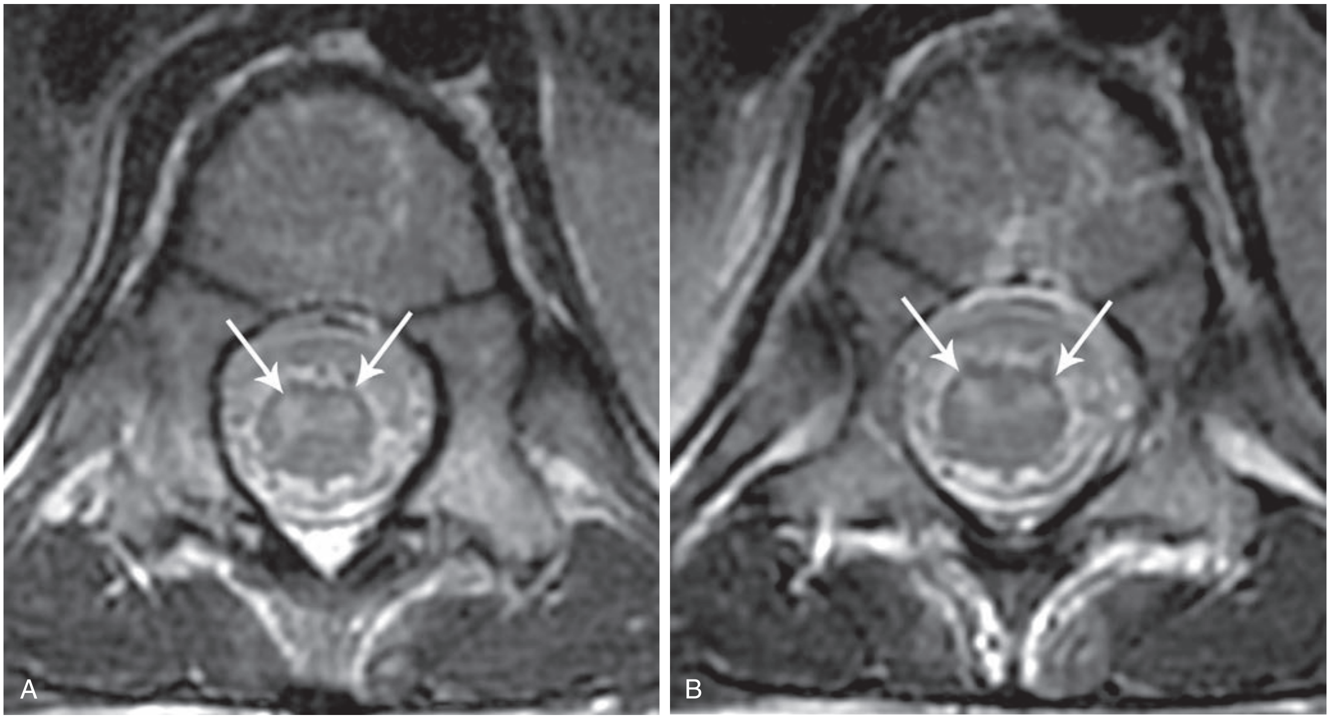


**Figure 44.3. Enterovirus D68.** Axial T2-weighted images (A and B) through the lower thoracic spine demonstrate T2 prolongation involving the central gray matter of the spinal cord with predominant involvement of the anterior horn cells *(arrows)*.

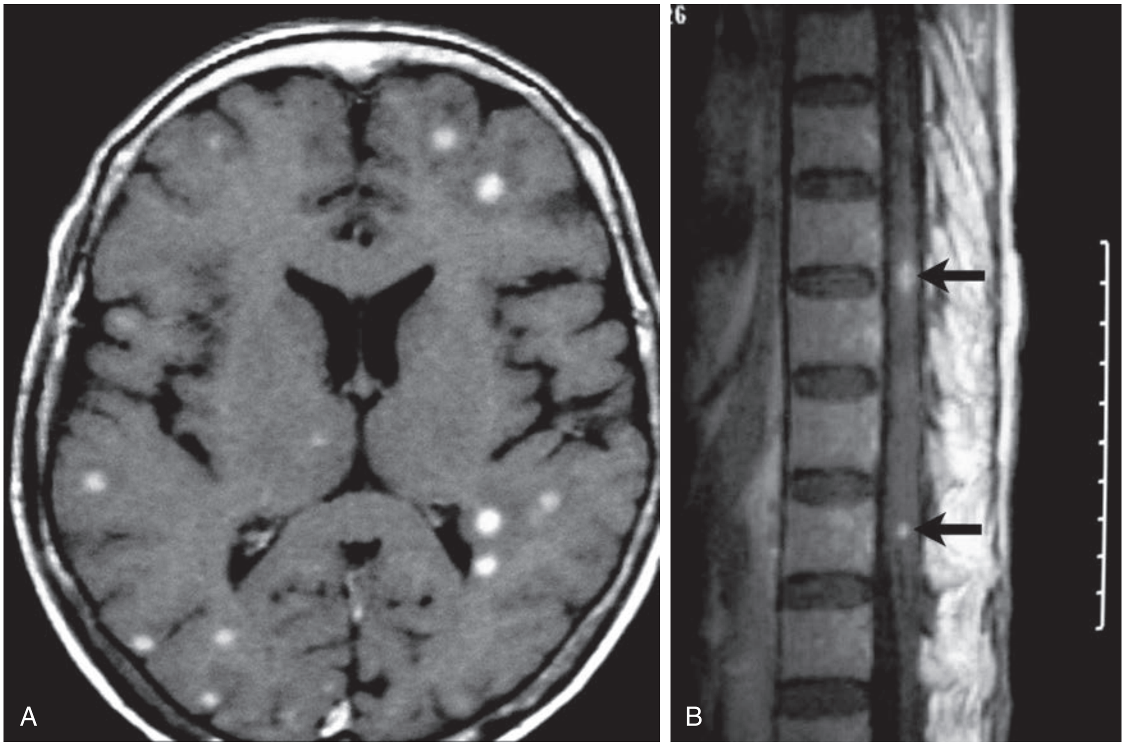

**Figure 44.4. Tuberculosis.** Adult patient with TB exposure. (A) Axial postcontrast T1-weighted MR images of the brain and (B) thoracic spine demonstrate multiple enhancing intraaxial nodules corresponding to tuberculomas (*arrows* in B). *(Case Courtesy of Drs. Pranjal Goswami, Nirod Medhi, and Pratul Kr. Sarma of Primus Institute in Guwahati, India.)*

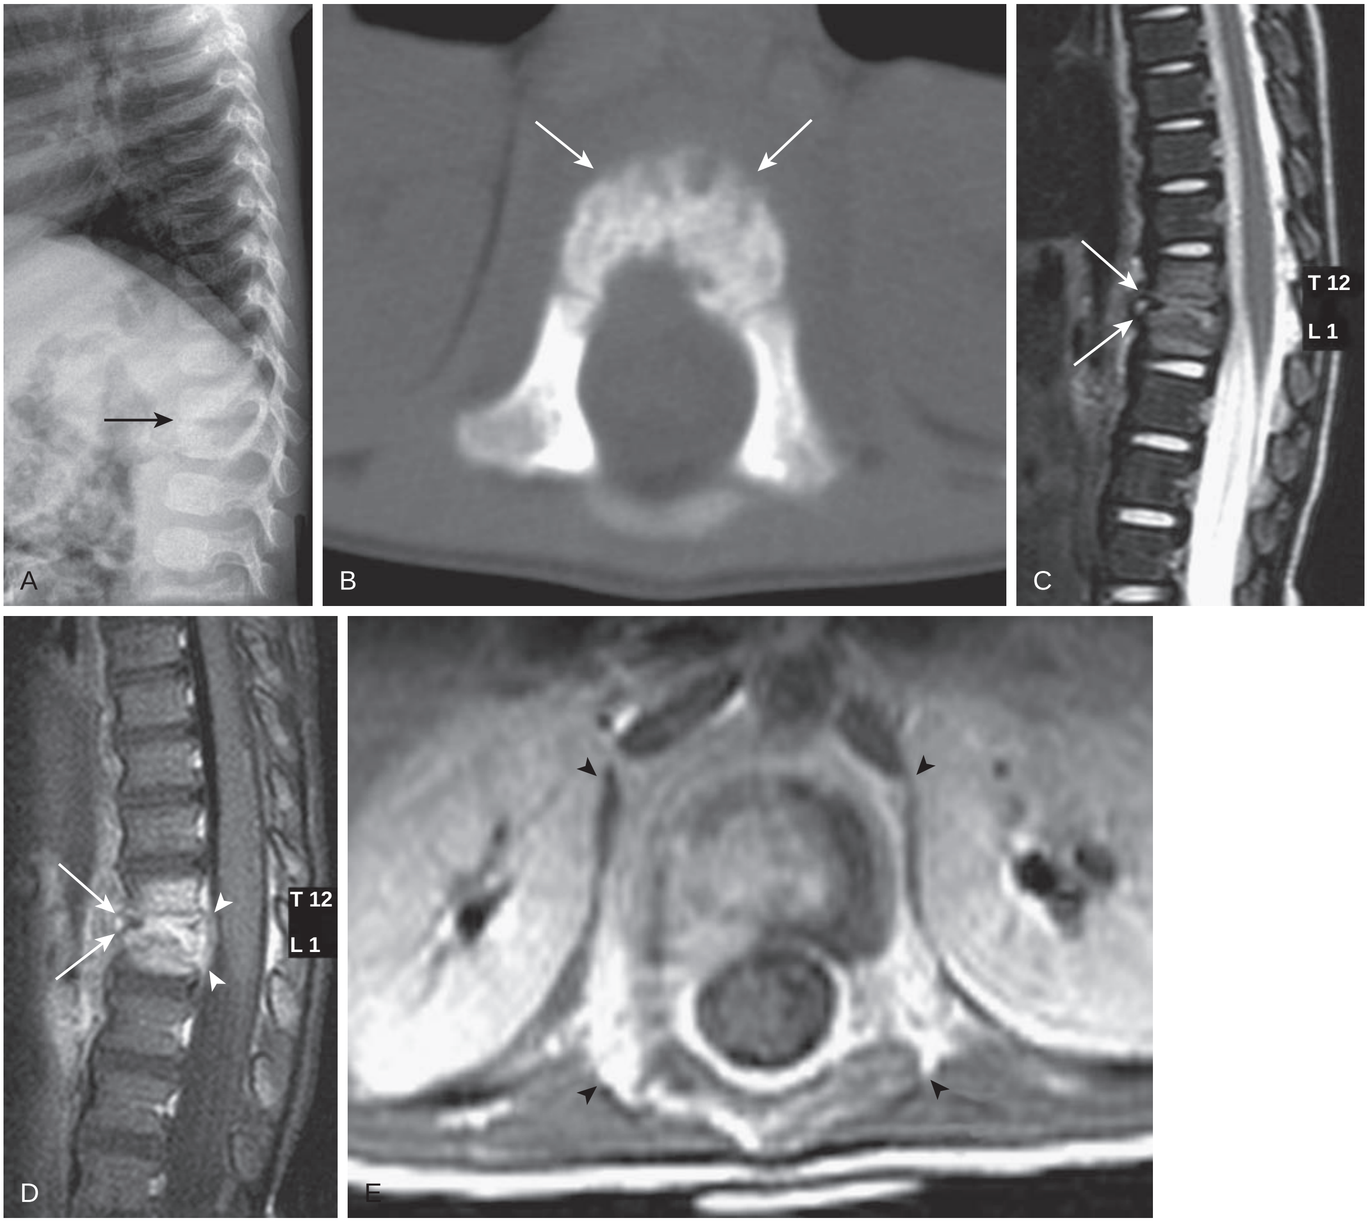

**Figure 44.7. Discitis/Osteomyelitis.** A 15-month-old female with abnormal gait and concern for intraspinal mass. (A) Lateral spine radiographs demonstrate narrowing of the T12-L1 intervertebral disc space *(arrow)*. (B) Axial noncontrast CT of the spine demonstrates irregularity to the vertebral endplates *(arrows)*. (C) Sagittal T2-weighted and (D) sagittal fat-saturated postcontrast T1-weighted image, and (E) axial postcontrast T1-weighted MR images of the thoracolumbar junction demonstrate loss of height of the T12-L1 intervertebral disc space with T2 prolongation of the adjacent endplates (*arrows* in C), with corresponding abnormal enhancement in the same regions (*arrows* in D), and surrounding masslike soft tissue enhancement (*arrowheads* in E).

in suspected cases (Fig. 44.7). While infection can occur at any level, the midlumbar spine is most often affected. *Staphylococcus aureus* represents the most common etiologic organism. Worldwide, atypical etiologic organisms such as TB are not uncommon. The first radiographic sign of infection is irregularity of the vertebral body endplates. The affected disc space is most often narrowed and demonstrates low signal intensity on T2-weighted sequences. Edema and postcontrast enhancement in adjacent vertebral body endplates indicate the presence of associated osteomyelitis and possible disc space abscess. Complicated cases demonstrate epidural/paravertebral abscess/phlegmon, which are well seen on MRI. Signs of late detection include vertebral body collapse and spinal deformity (Fig. 44.8). After treatment, vertebral body and disc space findings may persist for up to 24 and 34 months, respectively. Chronic recurrent multifocal osteomyelitis (CRMO) is the most severe form of chronic

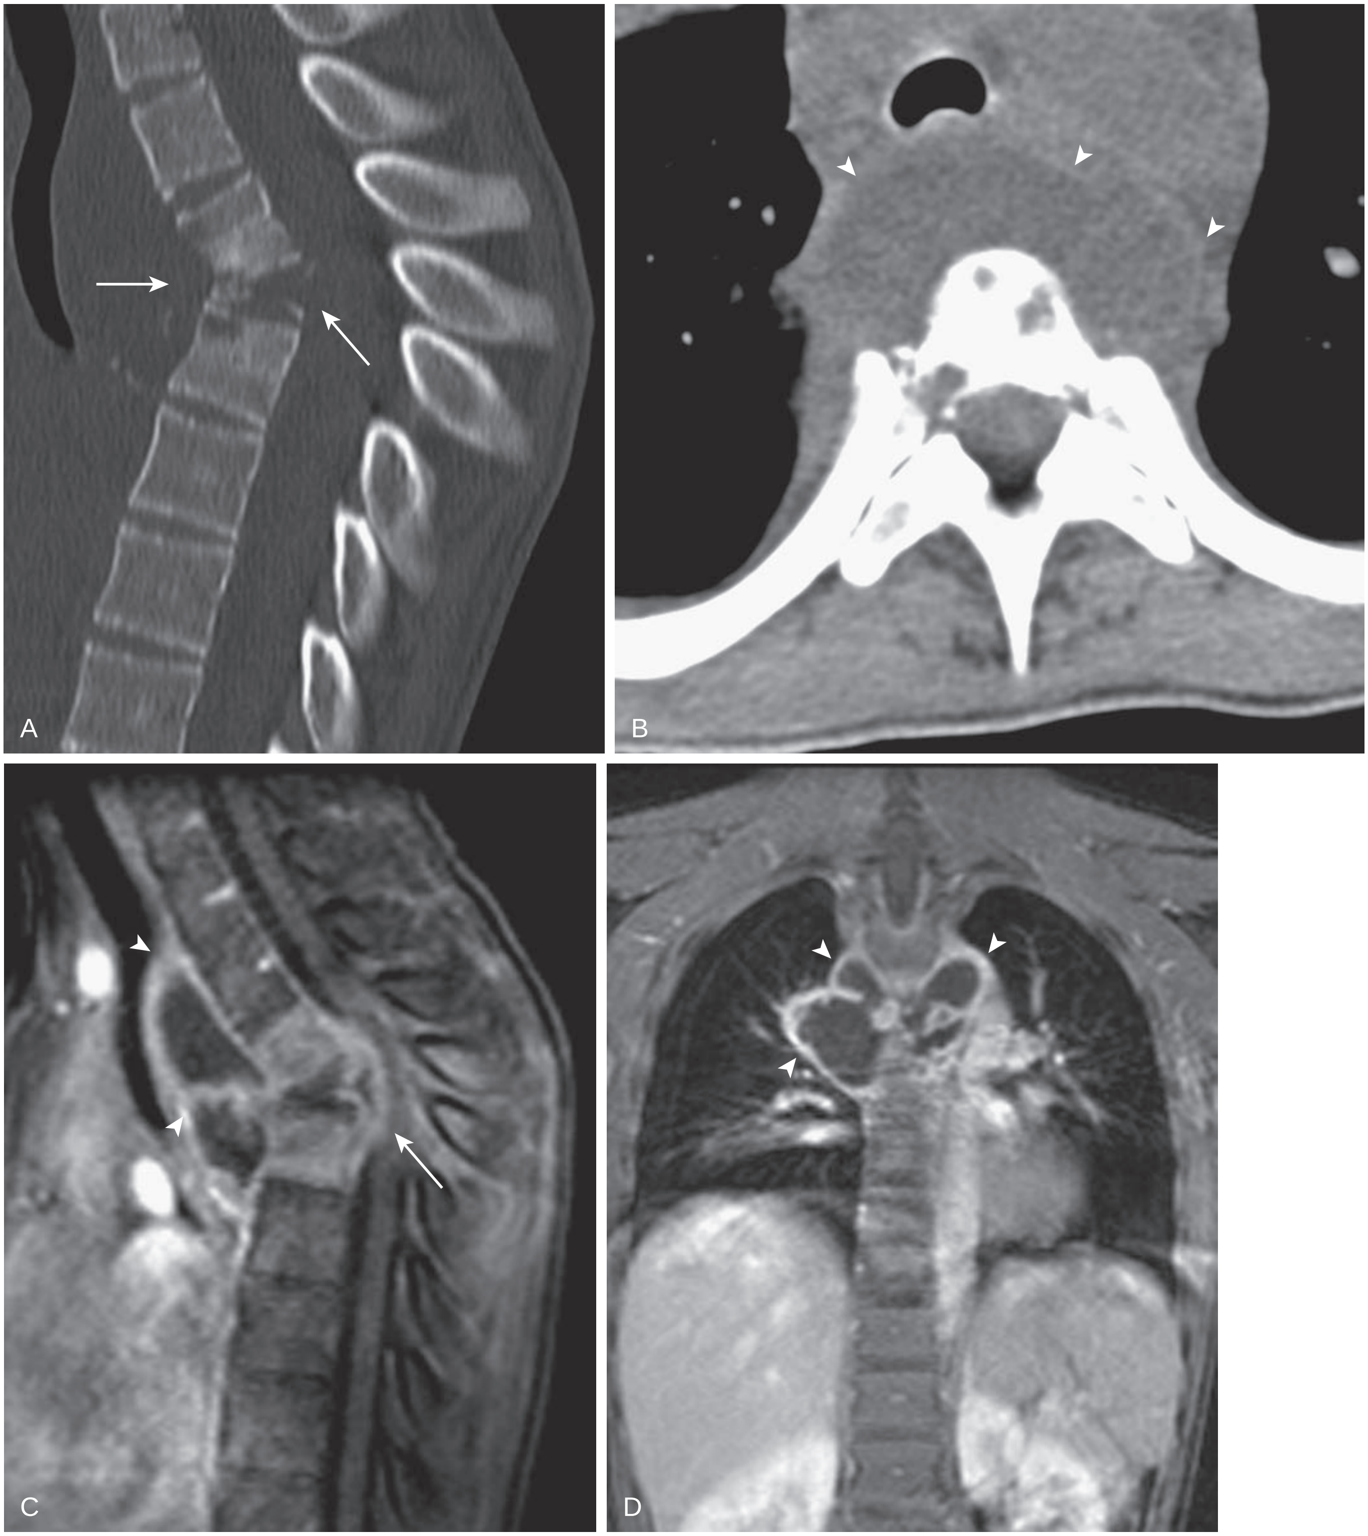

**Figure 44.8. Tuberculous osteomyelitis in 13-year-old female with progressive loss of strength and coordination in legs.** (A) Sagittal reformatted and (B) axial soft-tissue window images from a CT of the spine, and (C) sagittal and (D) coronal fat-saturated postcontrast T1-weighted MR images of the thoracic spine demonstrate marked kyphosis at site of bony collapse at the level of the midthoracic spine (*arrows* in A and C), as well as surrounding soft tissue abscess (*arrowheads* in B–D), predominately anteriorly, at the same level.

nonbacterial osteomyelitis. The etiology remains unknown, and it is a diagnosis of exclusion. Although CRMO most commonly affects the metaphyses of long bones and medial clavicles, vertebral column and pelvic involvement is relatively common (Fig. 44.9).

## GUILLAIN-BARRÉ SYNDROME

Since the eradication of poliomyelitis, Guillain-Barré syndrome (GBS), or acute inflammatory demyelinating polyradiculoneuropathy has become the most common cause of acute motor paralysis in children. It is believed to arise from an abnormal T-cell response precipitated by a preceding infection. Infectious etiologies include Epstein-Barr virus, cytomegalovirus, hepatitis, varicella, *Mycoplasma pneumonia*, and *Campylobacter jejuni*. MRI of the spinal axis in patients with GBS often shows thickening of the cauda equina and intrathecal nerve roots as well as anterior predominant nerve root gadolinium enhancement, even beyond the time period of the initial presentation (Fig. 44.10). Imaging findings have been described to be 83% sensitive for acute GBS and are present in 95% of typical cases. Chronic inflammatory demyelinating polyneuropathy (CIDP) (e-Fig. 44.11) is thought to be a chronic form of GBS that shares similar imaging characteristics but often shows marked nerve root thickening.

## TRANSVERSE MYELITIS

Transverse myelitis (TM) is an inflammatory condition that traverses a focal area of the spinal cord and extends over three or more vertebral segments. The midthoracic spine is most often affected, and patients present with symmetrical bilateral sensory and motor deficits related to the affected region. While viral etiologies are believed to be the leading infectious cause of TM, as many as 60% of cases are thought to be idiopathic in nature. In most cases, a specific viral etiology is never determined. Vasculidites seen with autoimmune diseases such as systemic lupus erythematosus have also been described as potential etiologies. TM manifests on MRI (Fig. 44.12) with increased T2 signal encompassing more than two-thirds of the spinal cord's diameter on fluid-sensitive sequences, generally extending along more than three vertebral segments, with variable enlargement of the spinal cord secondary to edema, and variable degrees of enhancement after administration of intravenous contrast.

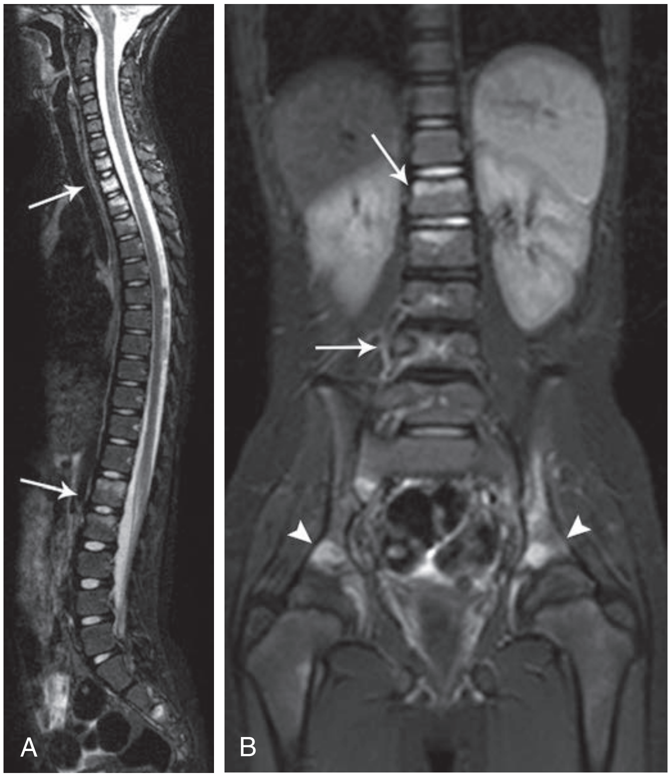

**Figure 44.9. Chronic recurrent multifocal osteomyelitis.** (A) Sagittal and (B) coronal STIR images demonstrate multilevel vertebral increased signal *(arrows)* as well as bilateral pelvic involvement *(arrowheads)*. *(Courtesy of Dr. Nancy Chauvin, Philadelphia, PA.)*

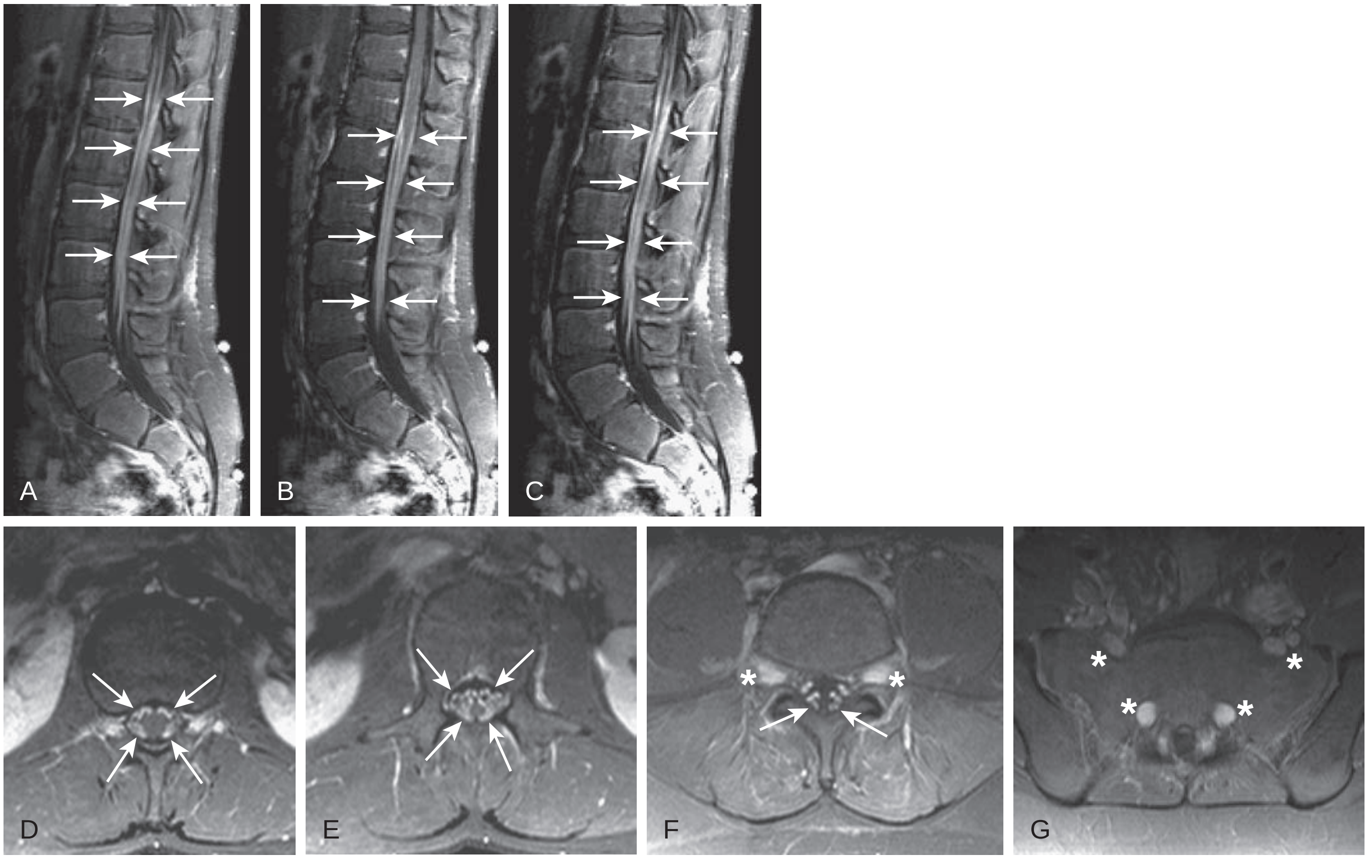
## ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is a monophasic focal or multifocal perivascular inflammatory and demyelinating disorder, which often presents after a vaccination or viral infection. Lesions are generally hyperintense on T2-weighted sequences and have corresponding hypointensity or isointensity on T1-weighted sequences. These lesions often present as a diagnostic dilemma in which the differential diagnosis also includes neoplasm of the spinal cord and can in isolation often be indistinguishable from the demyelinating lesions of multiple sclerosis (MS). The lack of abnormal apparent diffusion coefficients (ADC) within the corpus callosum (brain) may aid in diagnosing ADEM, as opposed to those seen with MS, which classically demonstrates abnormal ADC within the corpus callosum. A clinical history of a recent viral illness and/or vaccination is the key to properly diagnosing these lesions. MRI characteristics of ADEM (Fig. 44.13) are variable, with enhancement patterns including solid or ringlike enhancement, to no enhancement at all, in lesions that range from small to large, and which affect gray matter, white matter, or both. These lesions often show dramatic response to plasmapheresis, corticosteroids, and immunoglobulin therapies, with consequent improvement or resolution of the imaging findings.

## MULTIPLE SCLEROSIS

Although it is much more prevalent in the adult population, MS is also seen in children. Its presentation and diagnosis mimics that seen in adults. While the cause is not known, viral and immune diseases are believed to be etiologic factors. MRI is part of the McDonald diagnostic criteria for diagnosis of MS and demonstrates disease in most patients presenting with compatible clinical symptoms. The majority of patients affected by MS will have spinal lesions (Fig. 44.14), and there is cervical cord predominance. MS can involve the white matter as well as gray matter and most often manifests as eccentrically situated lesions involving the dorsolateral aspect of the spinal cord. Spinal MS is associated with concomitant brain lesions in 80% of cases, making brain imaging essential when MS is a differential consideration. Concomitant presence of optic neuritis, in addition to spinal cord involvement, constitutes Devic disease, also known as *neuromyelitis optica*. MS lesions usually span less than two vertebral bodies in length and demonstrate hypointense signal on T1-weighted images and corresponding hyperintense signal on T2-weighted images. Prompt contrast enhancement occurs in active lesions. Studies have shown the greater sensitivity of fast-STIR (short tau inversion recovery) sequences when compared with fast spin echo sequences.



**e-Figure 44.11. Chronic inflammatory demyelinating polyneuropathy (CIDP).** A 13-year-old male with peripheral neuropathy and gait disturbances. Sagittal fat-saturated T1-weighted MR images off midline to the right, at midline, and off midline to the left (Fig. 44.11A–C, respectively), and axial fat-saturated postcontrast T1-weighted MR images through the lower thoracolumbar junction, conus medullaris, and proximal as well as distal nerve roots (Fig. 44.11D–G, respectively), demonstrate marked enhancement of the spinal nerve roots *(arrows)*, with expansion of the nerve roots seen as they exit the neural foramina *(asterisks)*. This enlargement and enhancement is typical of CIDP.

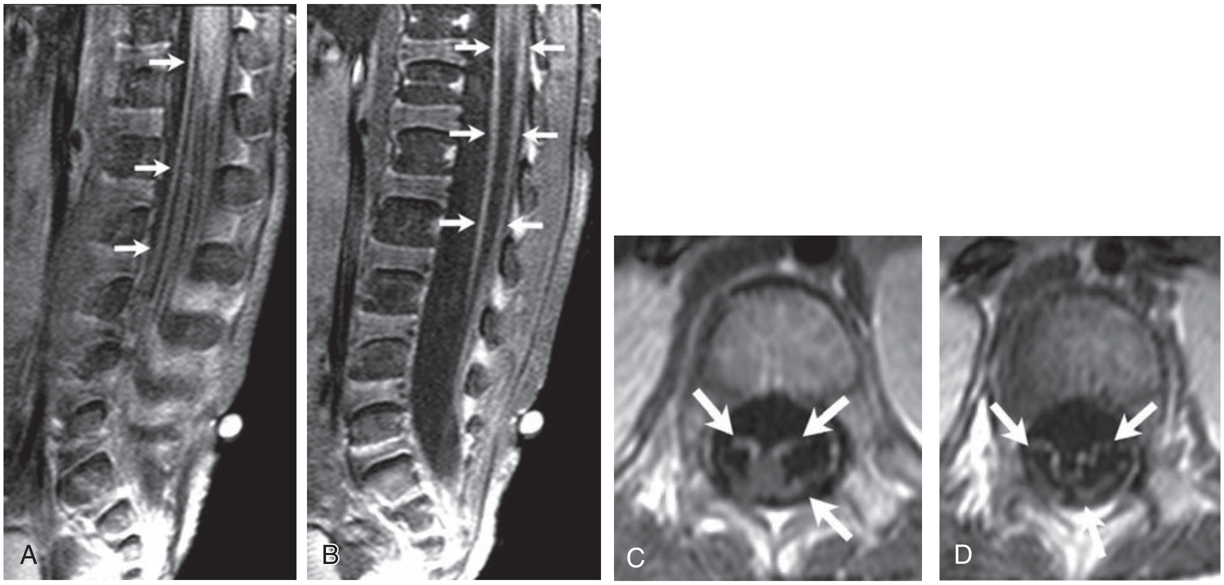


**Figure 44.10. Guillain-Barré Syndrome.** (A) Sagittal off midline and (B) midline fat-saturated postcontrast T1-weighted MR images through the lumbar spine, demonstrate extensive contrast enhancement of nerve roots *(arrows)*, typical of Guillain-Barré.

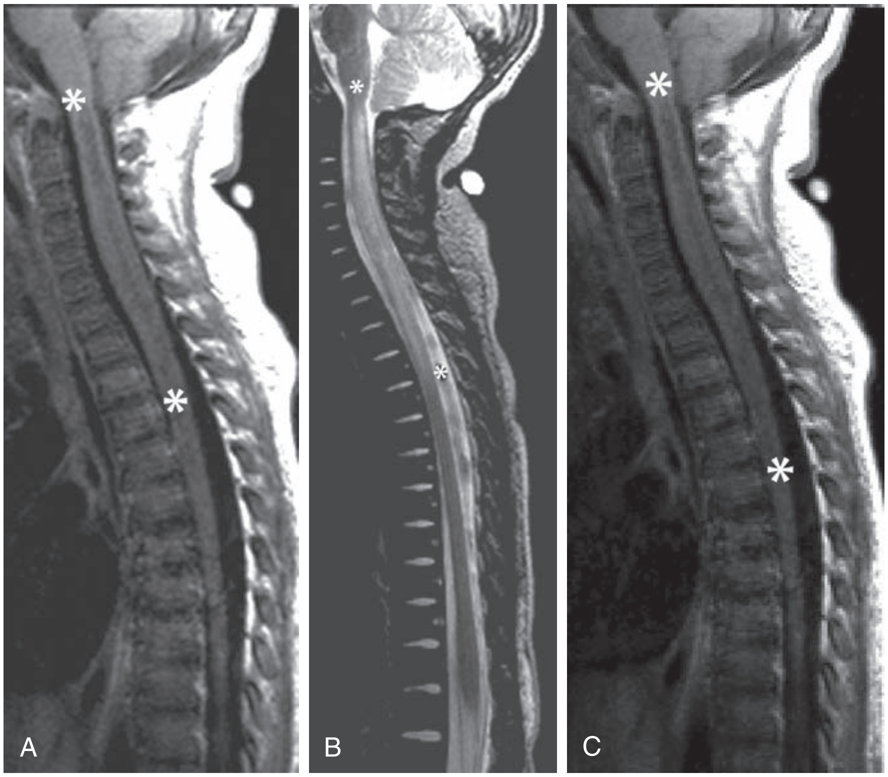

**Figure 44.12. Transverse myelitis.** Fever and rapidly ascending paralysis in a 17-month-old boy. (A) Sagittal T1-weighted, (B) sagittal T2-weighted, and (C) sagittal postcontrast T1-weighted MR the lower cervical and upper thoracic spinal cord. Note the diffuse T1 and T2 prolongation *(asterisks)* of the entire cervical and upper thoracic spinal cord, with associated expansion of the cervical cord. There is no associated contrast enhancement (*asterisks* in C).

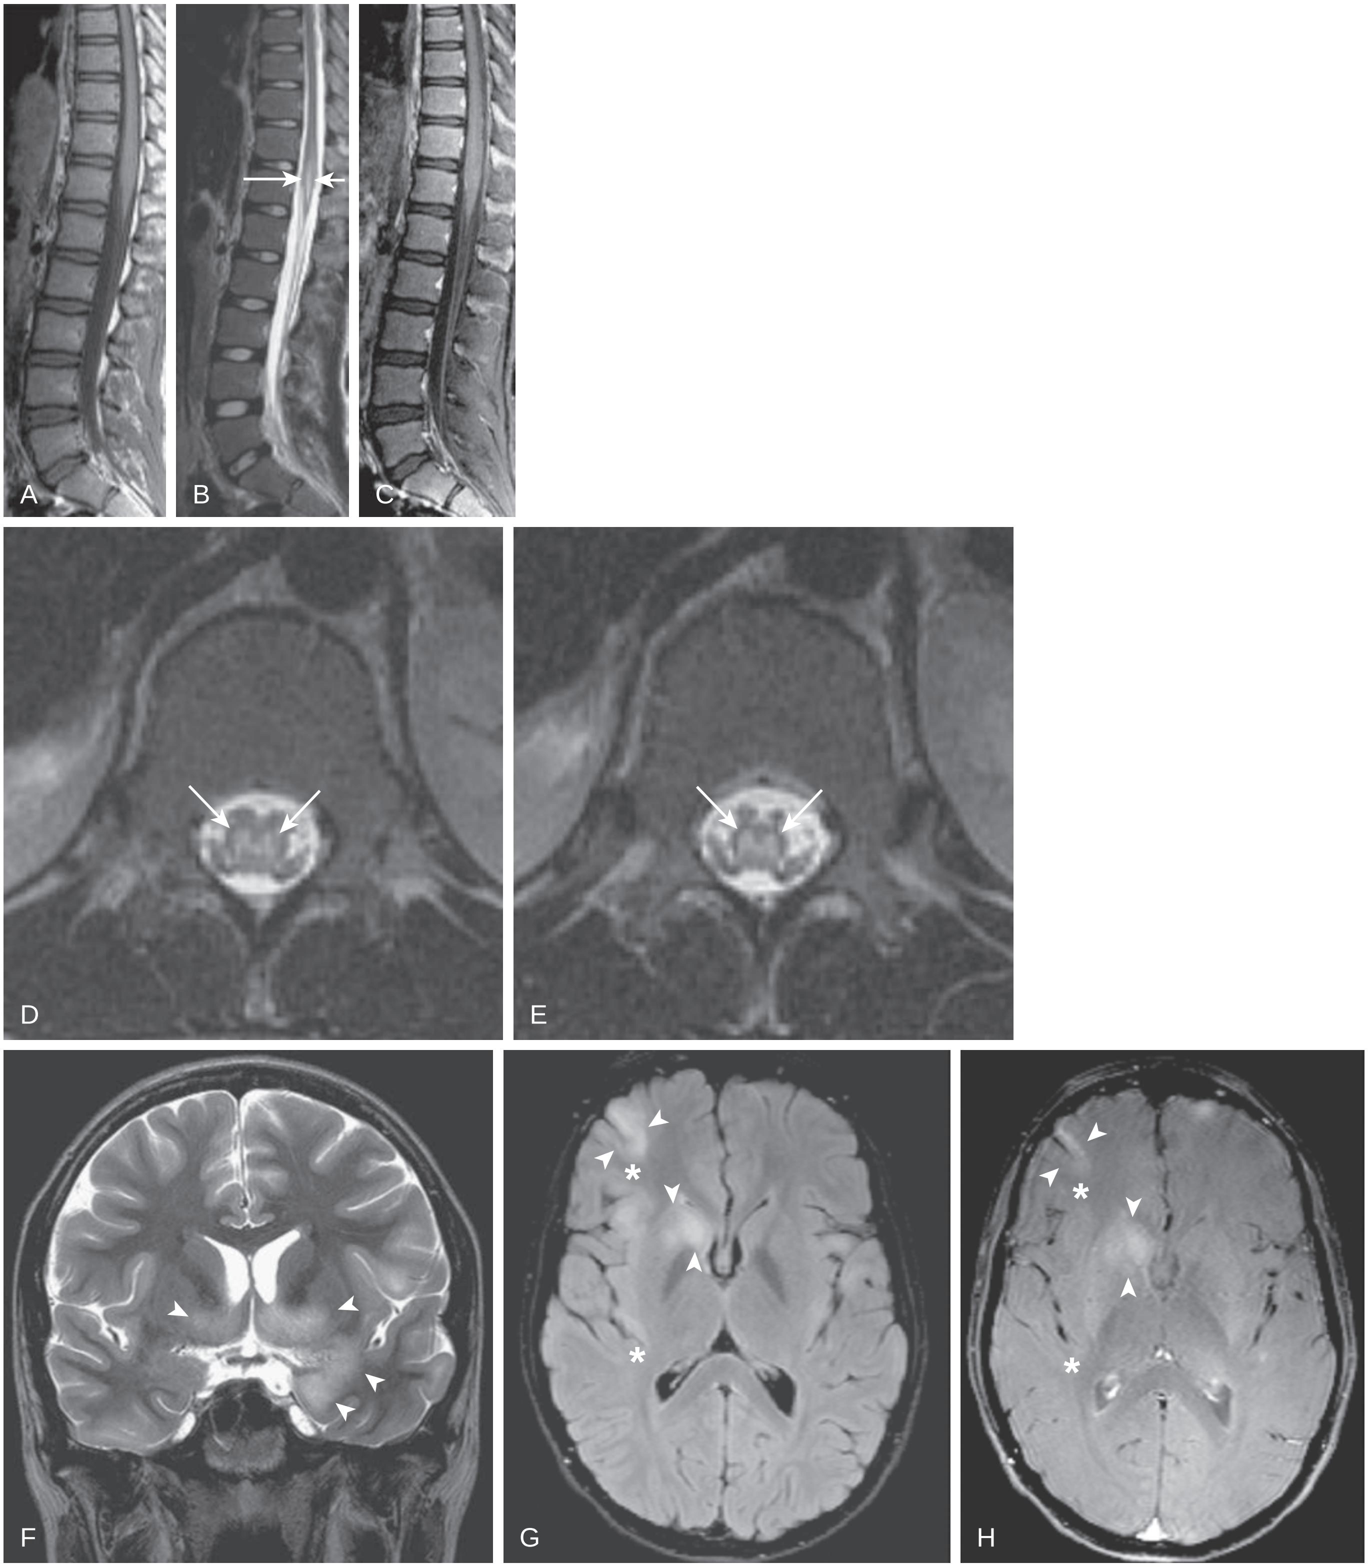

**Figure 44.13. Acute disseminated encephalomyelitis (ADEM).** A 16-year-old male history of constipation, urinary retention, lower extremity weakness, and numbness. Sagittal T1-weighted, sagittal T2-weighted, and sagittal postcontrast T1-weighted MR images (A–C, respectively), axial T2-weighted MR images through the lower thoracolumbar region (D and E), coronal T2-weighted MR image of the brain (F), axial FLAIR image through the brain (G), and axial postcontrast magnetization transfer T1-weighted image through the brain (H). Note the nonexpansive T2 prolongation *(arrows)* of the central spinal cord (D and E). In addition, there are areas of T2 prolongation within the brain (F and G), with involvement of both superficial gray and deep gray structures *(arrowheads)*, including the right insula *(asterisks)*.

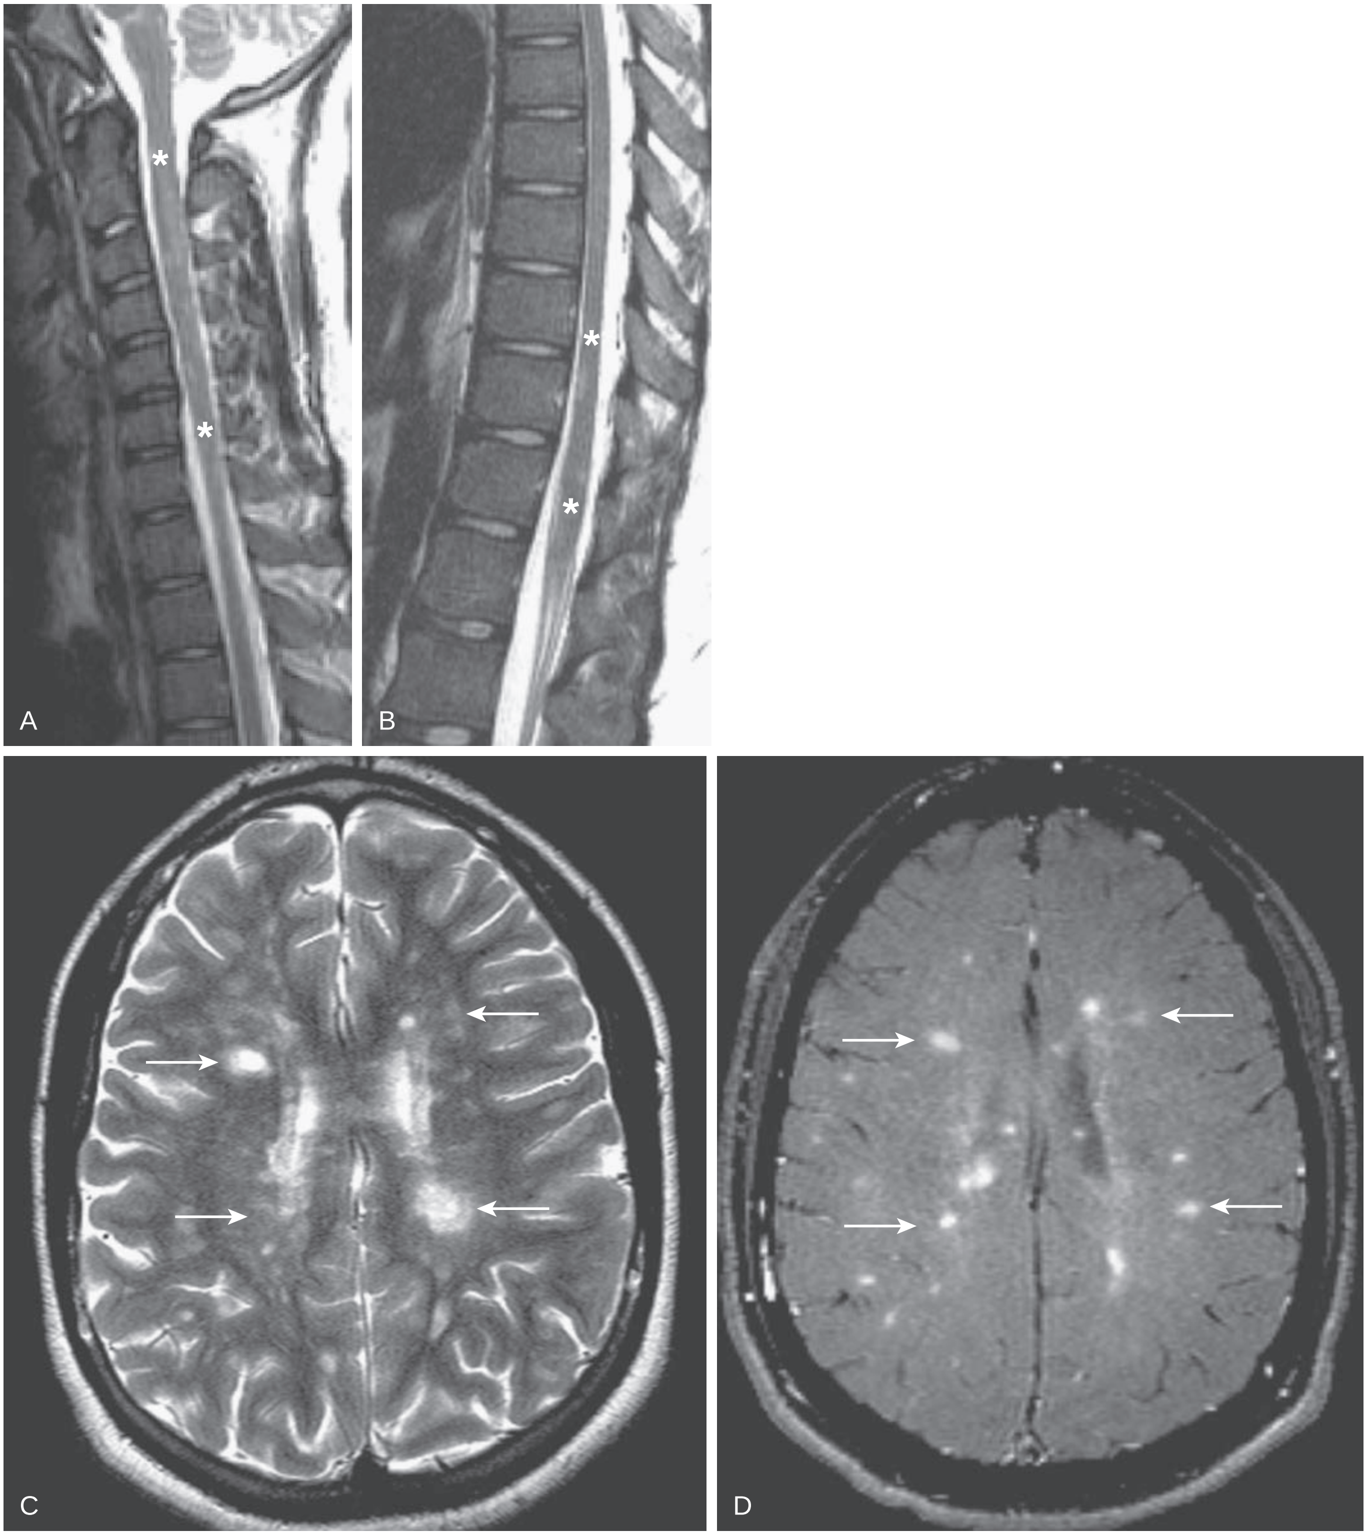

**Figure 44.14. Multiple sclerosis (MS).** Child with sensory changes and decreased vision. Sagittal T2-weighted MR images through the (A) cervical and (B) thoracic spine shows nonexpansive T2 prolongation *(asterisks)* of the spinal cord. (C) Axial T2-weighted and (D) axial postcontrast T1-weighted magnetization transfer MR images of the brain show multiple areas of T2 prolongation (*arrows* in C) within the deep white matter of the cerebrum, running perpendicular to the lateral ventricles (the so-called Dawson's fingers), associated with enhancement (*arrows* in D), suggesting acuity to the demyelinating plaques.

## KEY POINTS

- MRI is the imaging modality of choice for infectious and inflammatory conditions of the spine and spinal cord.
- *Staphylococcus aureus* is the most common infectious agent causing vertebral discitis and osteomyelitis.
- Guillain-Barré syndrome has become the most common cause of acute motor paralysis in children.
- Spinal cord lesions in transverse myelitis generally extend over three or more vertebral body segments, whereas those in multiple sclerosis generally extend over fewer than two vertebral body segments.

# Spinal Tumor and Tumor-like Conditions

*Lisa H. Hutchison and Kalie Adler*

## SPINAL NEOPLASMS

***Overview.*** Spinal tumors occur predominantly in young or middle-aged adults and are rare in children. The most common presentation is vague pain, gait disturbance, change in spinal curvature, motor weakness, and bowel and bladder dysfunction. In this chapter, general concepts regarding spinal neoplasms are discussed, followed by anatomic categories of lesions. Categories include neoplasms located in the intramedullary, intradural-extramedullary, or extradural compartments.[1]

***Imaging.*** The imaging features of spinal neoplasms are often nonspecific and findings overlap. Familiarity with age at diagnosis, key imaging findings, and associations can narrow the differential diagnosis, as summarized in Table 45.1.

Although osseous erosion can occur as a late finding with pediatric spinal cord tumors, plain radiographs are of limited utility. Computed tomography (CT) is helpful in imaging primary osseous lesions, but is less useful in cord evaluation. Instead, magnetic resonance imaging (MRI) is the study of choice to characterize and define spinal cord lesions. Differentiating intramedullary (within the cord) versus intradural-extramedullary (outside the cord, but inside the dura) versus extradural (outside the thecal sac) location is important to narrow the differential diagnosis. Intramedullary lesions show cord expansion, whereas extramedullary lesions will be separate from the cord in at least one plane. Baseline postoperative MRI is deferred for at least 12 weeks because surgical changes make early postoperative scans difficult to interpret.[2]

***Treatment.*** Treatment differs depending on the grade and type of neoplasm (see Table 45.1). The goal with lower-grade, noninfiltrative spinal neoplasms is complete excision of both the solid tumor and associated syrinx cavities. Although tumors may recur or have drop metastasis with suboptimal resection, they are generally amenable to repeat resection. In subtotal resection, adjuvant radiotherapy is useful in adults, but is controversial in children due to increased morbidity from damage to an immature cord.[3] Infiltrative or higher-grade neoplasms may preclude total surgical resection.[4]

Intraoperative ultrasound is often used to determine tumor margins during surgical planning and resection.[2] Electrophysiologic monitoring techniques can be helpful as the periphery of the tumor is approached to prevent damage to the uninvolved portions of the spinal cord.[3]

***Prognosis.*** Prognosis varies depending on tumor grade with high-grade tumors having the worst prognosis, presence or absence of cerebrospinal fluid (CSF) dissemination, and degree of resection. Preoperative neurologic deficits may persist postoperatively, but most tumors can be removed without causing new morbidity. With most cord neoplasms, contrast enhanced MRI of the entire cerebrospinal axis is warranted.

## INTRAMEDULLARY NEOPLASMS

***Overview.*** Pediatric intramedullary tumors occur most commonly in the cervicothoracic cord.[5] Nonspecific symptoms often lead to a delay in diagnosis. Younger children may present with spinal pain (dull and aching) or root pain, rigidity, persistent torticollis, and muscle spasm. Older children may present with gait disturbance and/or progressive scoliosis. Extremity weakness and paresthesias are common.[6] A subset of patients may present with symptoms of increased intracranial pressure (ICP) and hydrocephalus.

### Astrocytoma

***Overview and Origin.*** Up to 60% of intramedullary tumors in children are astrocytomas and the cervical cord is most commonly involved.[3] Spinal astrocytomas usually occur in children around 10 years of age, with an equal sex predilection. Spinal astrocytomas are rarely seen in neonates and infants and may present with irritability, torticollis, and loss or absence of developmental milestones.[6]

Astrocytomas arise from astrocytes and range from benign (grade I) to malignant (grade IV).[7] Spongioblastomas and pilocytic astrocytomas are at the benign end of the spectrum, and high-grade astrocytomas and glioblastoma multiforme tumors are at the malignant end of the spectrum.

Spinal astrocytomas may be cystic, mixed cystic and solid, solid, or contain necrotic components. Malignant astrocytomas can mimic spinal vascular malformations as a result of hypervascularity with possible intratumoral hemorrhage. Lesion size varies from focal to involvement of the entire spinal cord (holocord), which usually is seen during the first year of life.[8]

***Imaging.*** Key features of astrocytomas include cord expansion, eccentric location, hypointense to isointense T1 signal, heterogeneous hyperintense T2 signal, and variable enhancement, sometimes of a mural nodule, on postcontrast images (Figs. 45.1 and 45.2). T2 heterogeneity depends on the presence of solid, cystic, and necrotic components. Tumors may be small with associated syringohydromyelia and subarachnoid seeding.[5]

### Ependymoma

***Overview and Origin.*** Up to 30% of intramedullary tumors in children are ependymomas and the thoracic cord is most commonly involved. Ependymomas present in an older age group than do astrocytomas with a slight female predilection.[3] Ependymomas originate from ependymal cells within the central cord and frequently span multiple vertebral segments.[9] A variety of histologic subtypes exist, with cellular ependymoma being the most common.

Myxopapillary ependymoma occurs exclusively in the lower cord and filum terminale. When located in the cauda equina, this subtype may be associated with subarachnoid hemorrhage, back pain, lower extremity weakness, numbness, pain, and bowel and bladder incontinence.[10]

***Imaging.*** Ependymomas are distinguished by the findings of central cord location, cord expansion, heterogeneous signal intensity on all sequences, and a T2-hypointense hemosiderin cap along the cranial or caudal aspects of the tumor (Figs. 45.3 and 45.4). Contrast-enhanced spinal MRI is useful in the evaluation of drop metastasis, a common feature of ependymomas.[11,12] Multiple ependymomas should prompt consideration of neurofibromatosis type 2 (NF2).[13]

### Ganglioglioma

***Overview and Origin.*** Gangliogliomas contain both neoplastic glial and neuronal components. They present in the first three decades with an average presentation age of 12 years.[5,14]

**TABLE 45.1** Pediatric Spinal Neoplasms: Location, Key Imaging Features, and Other Comments

| Location | Neoplasm | Key Imaging Features | Other Comments |
|---|---|---|---|
| IM | Astrocytoma | Cervical most common<br>Tend to be eccentric in cord ± syrinx<br>Cystic with enhancing nodule | 10 years of age<br>Treatment: surgical debulking ± chemotherapy and radiation |
| | Ependymoma | Tend to be central in cord<br>Cervical most common<br>Hemosiderin cap on T2 sequences<br>Drop metastases | 13–14 years of age<br>If multiple lesions, consider NF2<br>Treatment: surgery ± radiation and chemotherapy |
| | Ganglioglioma | Similar imaging to ependymoma | 7 years; associated with NF2<br>Treatment: surgical resection |
| | Hemangioblastoma | Cystic with an enhancing mural nodule<br>Flow voids | Associated with von Hippel–Lindau disease<br>Treatment: surgery |
| EM | Leptomeningeal metastasis | Lumbosacral involvement<br>Variable size and number of lesions | Common with ependymomas, medulloblastomas, higher-grade astrocytomas<br>Treatment: depends on primary lesion |
| | Nerve sheath tumor (schwannoma, neurofibroma) | Target sign<br>Expansion of intervertebral foramina<br>Posterior vertebral body scalloping | Associated with NF1 and NF2<br>Treatment: conservative; rarely, debulking |
| | Meningioma | Isointense on noncontrast imaging<br>Homogeneous, vigorous enhancement | Teenagers; multiple lesions in setting of NF2<br>Treatment: surgical resection |
| ED | Osteoblastoma | Posterior element, solid, expansile, enhancing mass | 10–30 years; 40% occur in spine<br>Treatment: surgical resection |
| | Aneurysmal bone cyst | Posterior element, expansile, multicystic, fluid-fluid levels | 10–30 years; 20% occur in spine<br>Treatment: embolization, surgical curettage, and packing |
| | Osteoid osteoma | Posterior element lucent nidus with marked surrounding enhancement, ± central calcification | 90% <25 years of age; 10% occur in spine<br>Treatment: radiofrequency ablation |
| | Lymphoma | Vertebral body lesion with little or no loss of height; single > multiple | Spinal involvement with systemic disease; rarely primary lesion<br>Treatment: chemotherapy |
| | Leukemia | Vertebral body lesion with slight loss of height; multiple > single | Spinal involvement with systemic disease<br>Treatment: chemotherapy |
| | Langerhans cell histiocytosis | Vertebral body lesion(s) with severe loss of height (vertebra plana) and soft tissue mass; single > multiple | Ranges from single osseous lesion (histiocytosis X) to systemic disease<br>Treatment: usually chemotherapy |
| | Neuroblastoma | Paraspinous (adrenal is most common) mass encasing vessels with calcifications | 1–5 years of age<br>Treatment: chemotherapy and surgery |
| | Sacrococcygeal teratoma | Heterogeneous signal intensity; enhancement of solid tumor portions; ± osseous erosions; mature types are mostly cystic | 80% <6 months, found in utero; female > male; 4 types based on intrapelvic or extrapelvic location |

*ED,* Extradural (50%); *EM,* extramedullary (15%–20%); *IM,* intramedullary (30%–35%); *MRI,* magnetic resonance imaging; *NF1,* neurofibromatosis type 1; *NF2,* neurofibromatosis type 2.

Gangliogliomas are usually low grade with low malignant potential, but have a propensity for local recurrence.[14]

***Imaging.*** Gangliogliomas may be solid, cystic, calcified, or hemorrhagic. They demonstrate heterogeneous signal intensity on all sequences.[15] Notable features include a lack of peritumoral edema, and adjacent osseous erosion (Fig. 45.5). Given this lesion's similar appearance to an ependymoma on MRI and its association with patients who have NF2, it should be included in the differential diagnosis when ependymoma is a diagnostic consideration.[14]

### Hemangioblastoma

***Overview and Origin.*** Hemangioblastomas are most commonly intramedullary, but can be pial, subpial, or combined intramedullary-extramedullary.[16] Their presence should prompt consideration of von Hippel–Lindau disease and an appropriate workup should be initiated. Treatment includes chemotherapy and surgical resection.[17,18]

***Imaging.*** Hemangioblastomas are typically cystic masses with variable T1 signal, T2 hyperintensity, variable enhancement of mural nodules, and a syrinx in up to 50% of patients (Fig. 45.6). Flow voids are produced by the lesion's arterial and venous supply. Associated hemorrhage and peritumoral edema are common.[19]

## INTRADURAL-EXTRAMEDULLARY NEOPLASMS

***Overview.*** Intradural-extramedullary spinal neoplasms in children include various lesions such as neurofibromas/schwannomas, meningiomas, and leptomeningeal metastases.

### Nerve Sheath Tumors

***Overview and Origin.*** The two main spinal nerve sheath tumors are neurofibromas and schwannomas, with the focus in this chapter on neurofibromas.[20] Neurofibromas are derived from an intermediate cell or from a combination of Schwann cells and perineural fibroblasts. Most spinal neurofibromas are

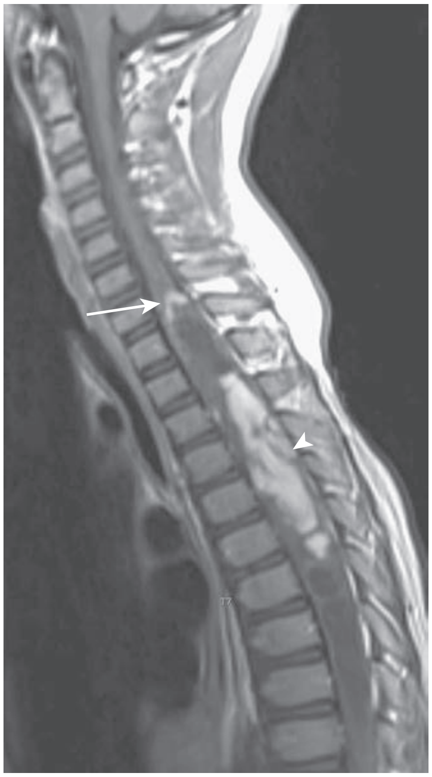

Figure 45.1. Astrocytoma in an 8-year-old boy with back pain. A sagittal T1-weighted contrast-enhanced image demonstrates an intramedullary cystic mass with dorsal nodular *(arrowhead)* and peripheral cranial *(arrow)* enhancement.

intradural-extramedullary lesions. The two morphologic types are fusiform (arising from a single nerve fascicle) and plexiform (involving multiple nerve branches). Lesions may be single, multiple, or diffuse. Neurofibromas are often encountered in children with neurofibromatosis type 1 (NF1), but they may occur as an isolated lesion.[21]

***Imaging.*** Neurofibromas have variable T1 signal, are T2 hyperintense, and enhance after contrast administration. Key imaging features include remodeling and expansion of the intervertebral foramina, indicative of slow indolent growth, and a target appearance (central low signal with peripheral high signal) on T2 images (Fig. 45.7). Rib erosion may be seen, and when extensive, may cause "ribbon ribs." Malignant degeneration into a neurofibrosarcoma is uncommon, but should be considered in large lesions with bone destruction or necrosis.

## Meningioma

***Overview and Imaging.*** Meningiomas of the spinal cord are rare in childhood.[22] When they are seen in patients with neurofibromatosis type 2 (NF2), they may occur intracranially and intraspinally. Meningiomas are T1 hypointense to isointense, T2 hyperintense, uniformly enhance after contrast, and may contain calcifications (Fig. 45.8).[23]

## Leptomeningeal Metastases

***Overview and Origin.*** Metastatic spread to the spinal canal occurs via CSF due to drop metastases from primary supratentorial and posterior fossa brain neoplasms, such as medulloblastoma, ependymoma, and atypical teratoid-rhabdoid tumors.[24]

***Imaging.*** CSF metastases may be solitary, multiple, or diffuse, coating the spinal cord and nerve roots. Metastatic nodules may range in size from 1 mm to a several cm, and may obstruct CSF flow (Fig. 45.9). The most common site is the distal thecal sac, followed by the thoracic, and lastly the cervical spine.[22] The spinal cord should be scanned before surgery for newly diagnosed brain tumors with a propensity to spread via the CSF. If preoperative

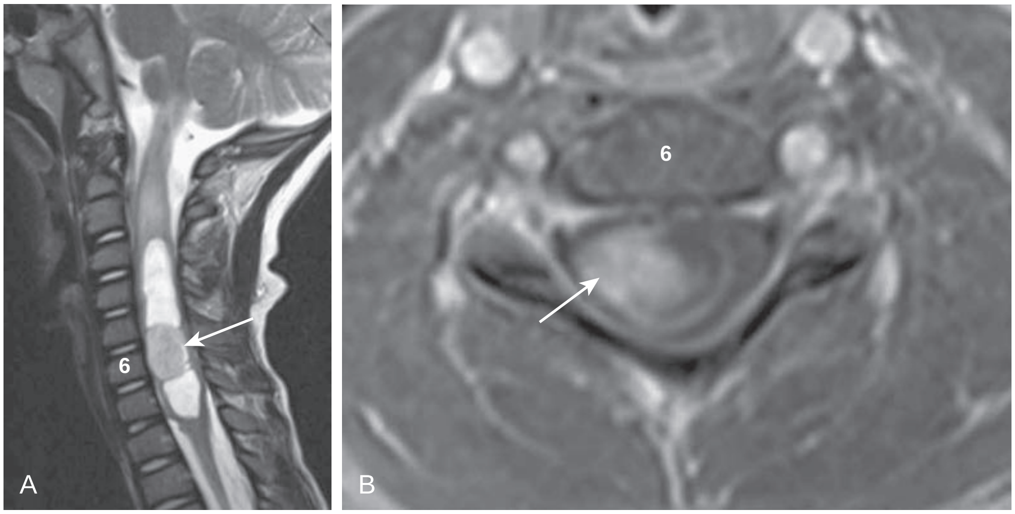

Figure 45.2. Astrocytoma in a 6-year-old boy with pain and decreased right arm use. (A) A sagittal T2-weighted image shows an intramedullary cystic cervical cord mass with a mural nodule *(arrow)*. Note T2 bright cord edema above the mass. (B) An axial T1-weighted postcontrast image through the enhancing nodule shows it is eccentrically located.

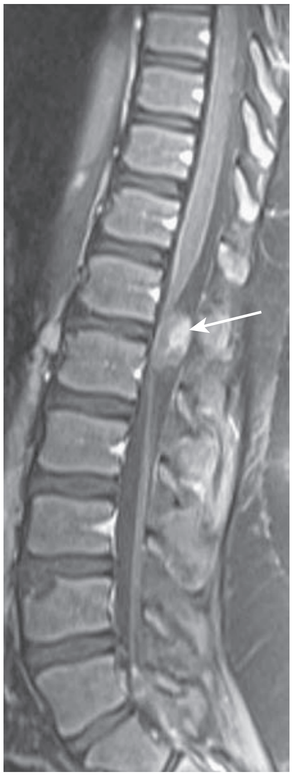

**Figure 45.3. Ependymoma in an 11-year-old boy with unexplained altered mental status.** A sagittal fat suppressed T1-weighted MR image demonstrates an extramedullary heterogeneously enhancing mass *(arrow)* at T12–L1 displacing the nerve roots ventrally.

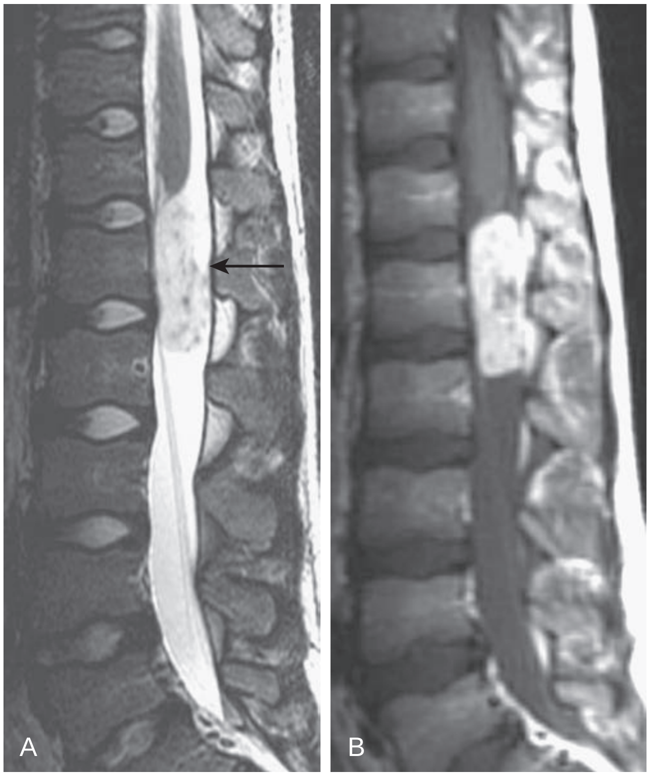

**Figure 45.4. Myxopapillary ependymoma in an 11-year-old girl with back pain.** (A) Sagittal T2-weighted MR image demonstrates a hyperintense, well-defined mass with internal flow voids just below the conus medullaris *(arrow)*. (B) A sagittal postcontrast T1-weighted image reveals avid enhancement.

MRI is not feasible, MRI should be delayed for 4 to 6 weeks after surgery to avoid confusion and possible false-positive results.[11]

## EXTRADURAL TUMORS

***Overview.*** Most childhood extradural neoplasms arise in the vertebral bodies or the paravertebral soft tissues and invade the spinal canal via the intervertebral foramina, such as neuroblastomas and sacrococcygeal teratomas. Primary osseous lesions, such as aneurysmal bone cysts, lymphoma, and Ewing sarcoma, as well as metastatic lesions, also may involve the vertebra and the spinal canal. Imaging is used to determine the extent of spinal involvement, the degree of neural element compression, and the degree of spinal column destabilization due to osseous destruction.[12,25]

### Neuroblastoma

***Overview and Origin.*** Tumors of neural crest cell origin include neuroblastomas, ganglioneuroblastomas, and ganglioneuromas. Neuroblastoma is by far the most common extracranial solid neoplasm, usually presenting between 1 and 5 years of age. Neuroblastomas are classified as primitive neuroectodermal tumors (PNETs) when they involve the central nervous system.

Neuroblastomas originate from neuroblasts along the sympathetic chain and arise most often in the adrenal gland. Metastatic spine involvement can be osseous or involve sympathetic chain ganglia. Spinal metastases may be single or multilevel, and may extend into the epidural space potentially causing cord compression. Larger lesions may have hemorrhage and necrosis. Ganglioneuroblastoma and ganglioneuroma are progressively less malignant forms of neuroblastoma that are composed of mature ganglion cells and nerve fibers. They are well encapsulated and similar in appearance to neuroblastoma, although usually smaller and better defined.

***Imaging.*** Neuroblastomas are paraspinal soft tissue masses, with frequent intraspinal extension. They are hypointense to isointense on T1-weighted images. On T2-weighted images, they range from hypointense to mildly T2 hyperintense and show variable contrast enhancement (Fig. 45.10). Hypointense areas on T1- and T2-weighted imaging may indicate calcifications. Fat-suppressed T2-weighted imaging is useful to determine the extent of disease. Evaluating for tumor extension across the midline is needed for staging.[1]

### Sacrococcygeal Teratomas

***Overview and Origin.*** Sacrococcygeal teratomas (SCTs) are neoplasms derived from all three germinal layers and may be benign or malignant. These neoplasms can contain neural elements, squamous and intestinal epithelium, skin appendages, teeth, and calcium. Four types of SCTs exist; type 1 is external to the pelvis, type 2 is predominantly external with a small intrapelvic portion, type 3 is predominantly intrapelvic with a small external component, and type 4 is completely intrapelvic. All four types may present as an extradural mass and may be associated with bony erosions. SCTs can be cystic, mixed cystic-solid, or solid lesions. Lesions with a more favorable prognosis are type 1 (external), those in younger or female patients, and those lesions that are cystic, homogenous, and contain calcifications.

***Imaging.*** CT is used to demonstrate osseous findings, as well as intrinsic calcifications. On MRI, cystic components of SCT are T1 hypointense and T2 hyperintense. The signal of hemorrhagic components will depend on the age of the hemorrhage. Solid components may enhance (Fig. 45.11).

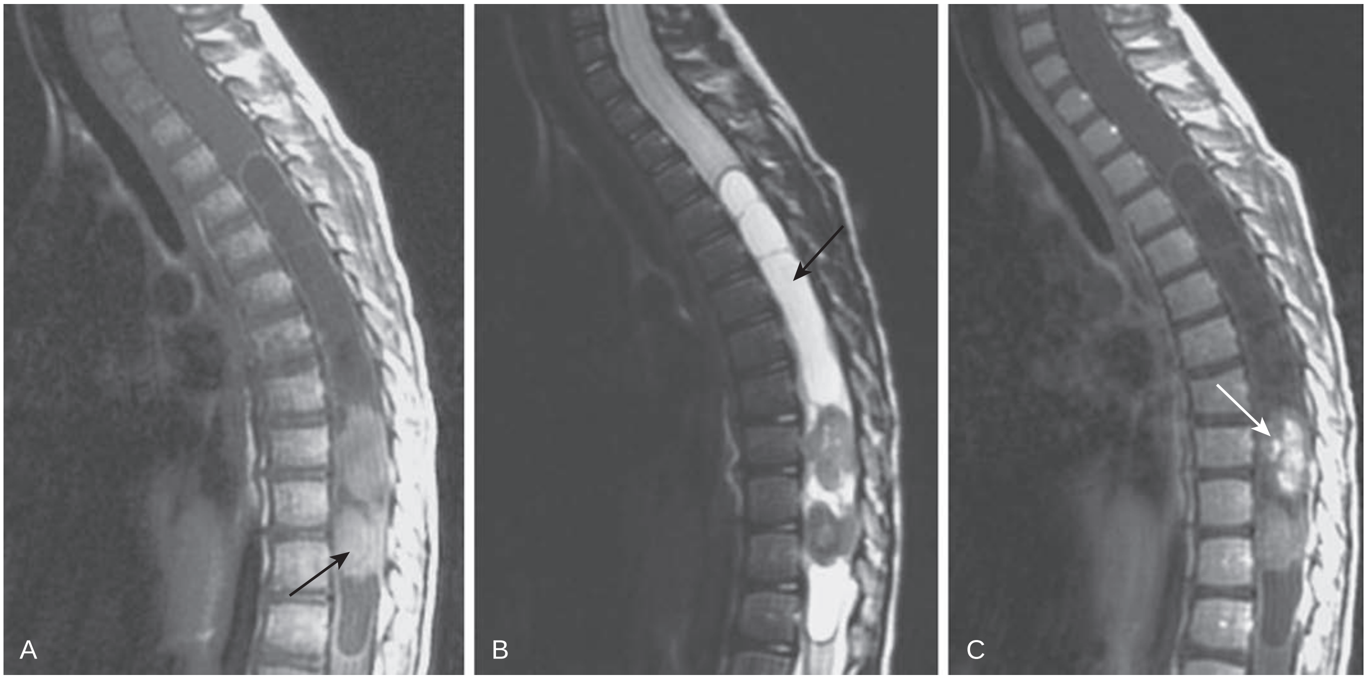

**Figure 45.5. Ganglioglioma.** (A) A sagittal T1-weighted MR image shows a holocord tumor. Rounded hyperintense elements at the thoracolumbar junction were found during surgery to represent hemorrhagic tumor components *(arrow).* (B) A sagittal fat-suppressed T2-weighted image shows the hemorrhagic components of the lesion as hypointense masses. Note the tumor cyst in the midthoracic cord *(arrow).* (C) A sagittal postcontrast T1-weighted image reveals enhancement of the caudal tumor *(arrow).*

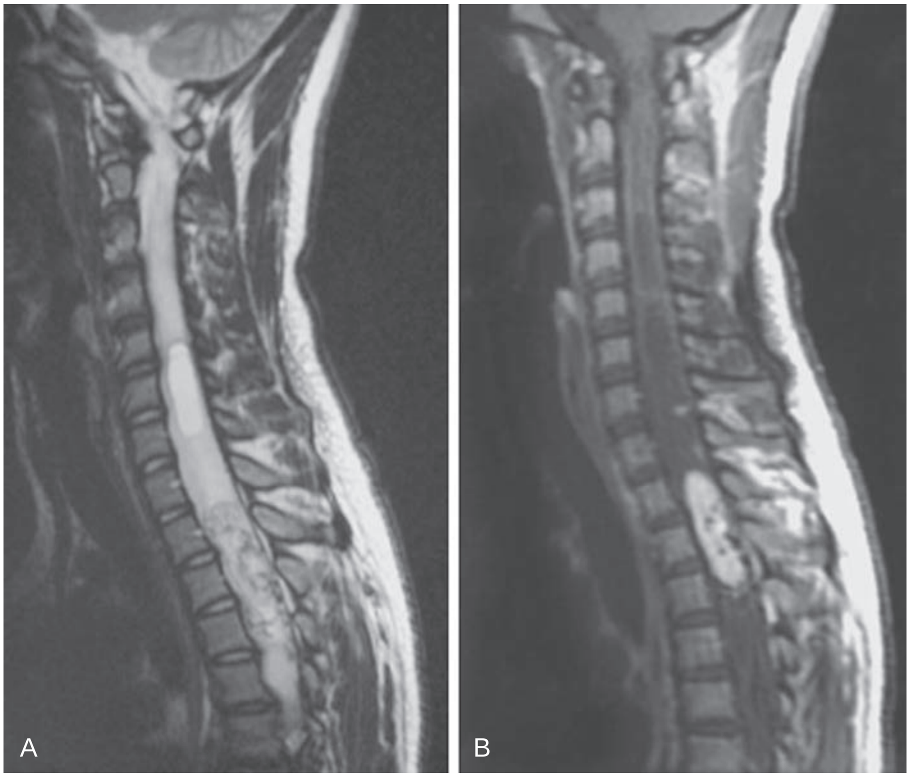

**Figure 45.6. Hemangioblastoma in a 14-year-old child with von Hippel–Lindau disease.** (A) A sagittal T2-weighted MR image shows a cystic component superior to the heterogeneous spinal cord lesion containing flow voids. (B) A sagittal postcontrast T1-weighted image demonstrates marked tumor enhancement and multiple bright foci of other hemangioblastomas in the cystic portion of the cord mass. A low signal cystic component is again seen.

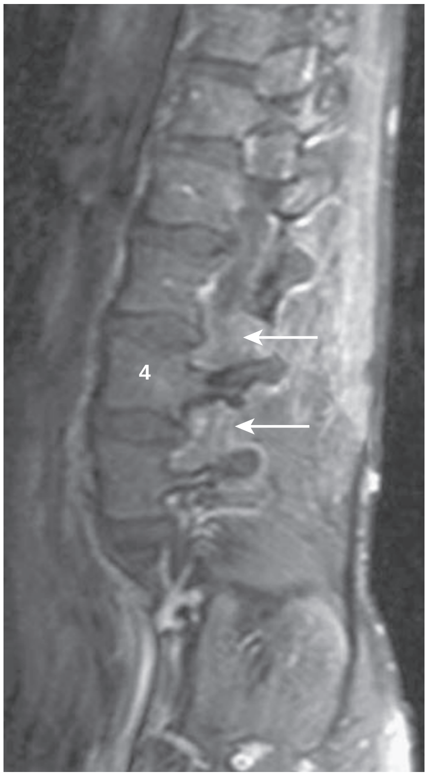

**Figure 45.7. Plexiform neurofibroma in a 13-year-old girl with NF1 and scoliosis.** Sagittal fat-suppressed T1-weighted MR image with contrast identifies neural foraminal stenosis at multiple contiguous lumbar levels *(arrows).*

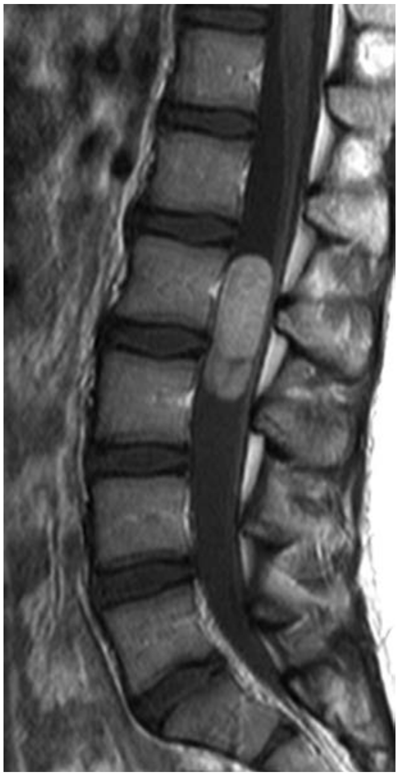

**Figure 45.8. Meningioma in a 15-year-old girl with leg and back pain.** Sagittal contrast-enhanced fat-suppressed T1-weighted MR image shows a well-defined enhancing mass in the lumbar spinal canal.

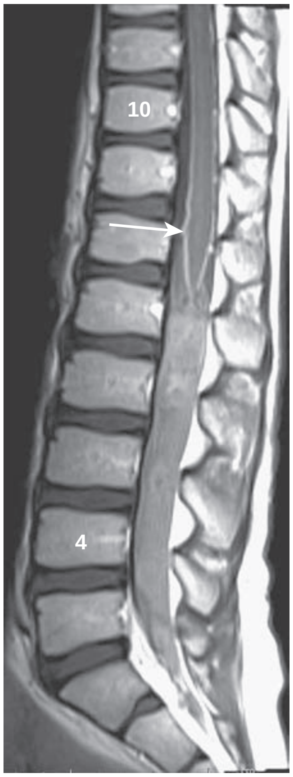

**Figure 45.9. Leptomeningeal metastases in a 9-year-old girl with an atypical rhabdoid teratoid tumor who has undergone radiation.** A sagittal postcontrast T1-weighted MR image demonstrates leptomeningeal enhancement *(arrow)* from the lower thoracic cord to the conus medullaris. Extensive enhancing solid tissue fills the distal thecal sac.

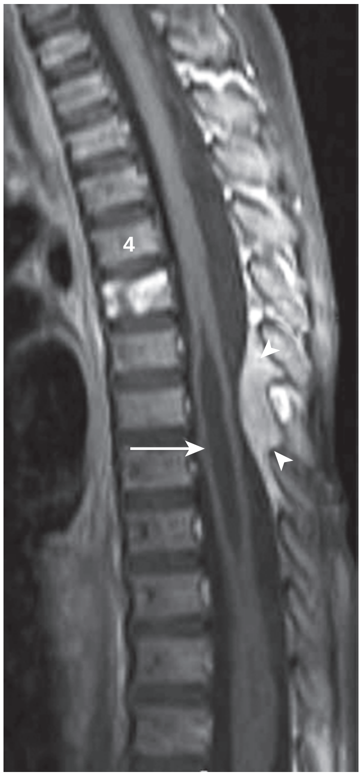

**Figure 45.10. Metastatic neuroblastoma in a 2-year-old boy with leg weakness and diarrhea.** A sagittal T1-weighted, fat-suppressed MR image identifies an enhancing metastatic lesion in the T5 vertebral body, a syrinx from T5 to T11 *(arrow),* and a hyperintense, enhancing dorsal epidural lesion *(arrowheads).* A primary right adrenal mass was found (not shown).

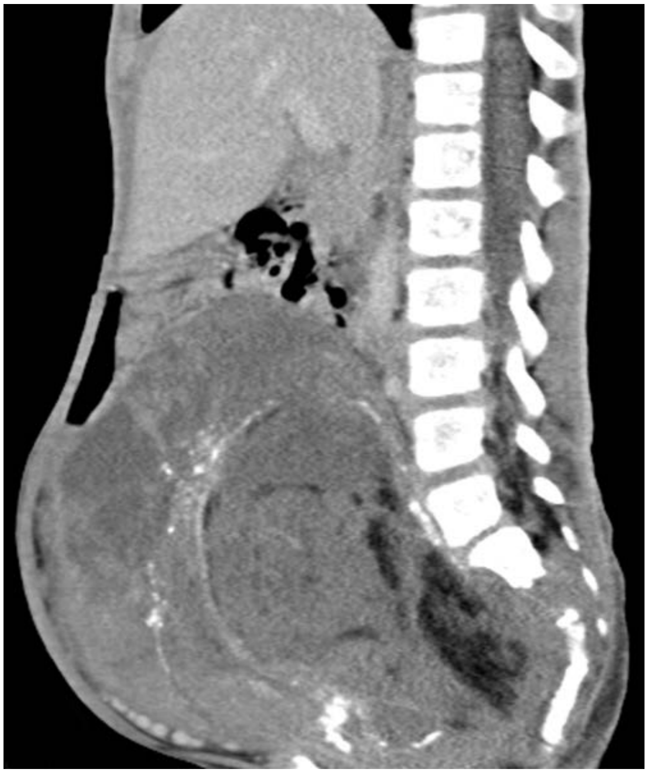

**Figure 45.11. Sacrococcygeal teratoma, type 4, in a 6-day-old girl with an abdominal mass.** Sagittal reconstructed postcontrast CT image shows a large mass anterior to and invading the sacrum. The heterogeneous mass contains low-attenuation fat, soft tissue, and scattered calcifications.

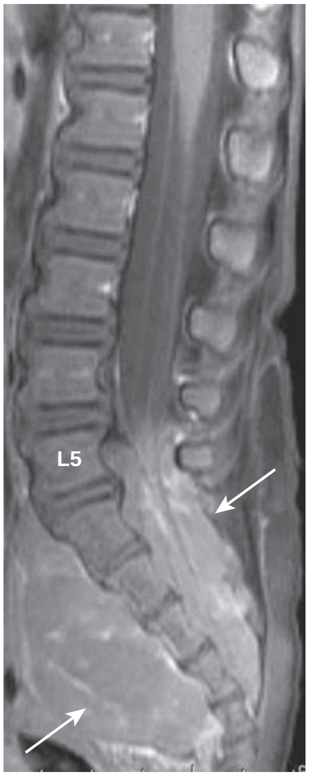

**Figure 45.13. Megakaryocytic leukemia in a 1-year-old boy with thrombocytopenia.** A sagittal T1-weighted postcontrast, fat-suppressed MR image identifies an enhancing mass arising from the sacrum with extensive lumbosacral epidural involvement *(arrows).*

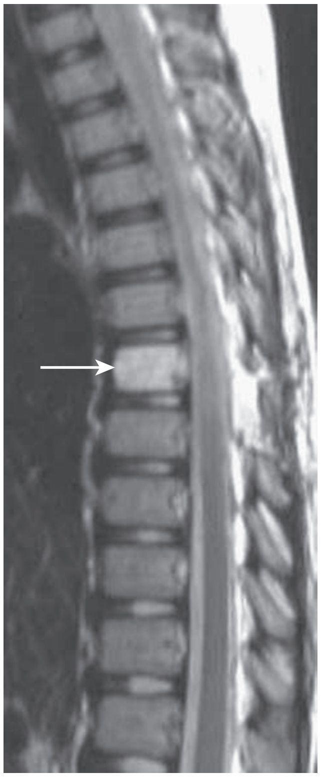

**Figure 45.12. Burkitt lymphoma in a 5-year-old boy with back pain and urinary retention.** A sagittal T2-weighted MR image demonstrates a hyperintense T7 vertebral body lesion. Note postsurgical changes of the posterior elements.

The location of the SCT in relationship to the gluteal fold helps differentiate this lesion from masses associated with spinal dysraphic conditions. Specifically, SCTs typically extend below the gluteal fold and masses associated with spinal dysraphism typically extend above the gluteal fold.[26]

## LYMPHOMA AND LEUKEMIA

***Overview and Origin.*** Lymphoma involves the spine less commonly than it does other reticuloendothelial system structures, such as lymph nodes. Single or multiple vertebral bodies may be involved, especially with non-Hodgkin–type lymphoma (Fig. 45.12). A diffuse epidural infiltration, a localized epidural mass, a primary osseous or paraspinal mass with epidural extension, or spinal cord masses may be present. Single or multiple vertebral levels may be involved. Epidural deposits from leukemia more commonly produce clinical symptoms in children than in adults, with myelogenous leukemia more likely presenting as a focal mass (Fig. 45.13).[27]

***Imaging.*** Epidural involvement in patients with lymphoma and leukemia is usually isointense on noncontrast T1-weighted, and slightly hypointense on T2-weighted sequences. Homogeneous enhancement is seen after contrast administration. A key imaging finding is the presence of normal vertebral body height and no osseous destruction despite abnormal marrow signal.[28]

### Leptomeningeal Melanosis

***Overview.*** Neurocutaneous melanosis is a rare, nonfamilial phakomatosis caused by melanocyte proliferation within the epidermis and leptomeninges. A forme fruste may occur in which only leptomeningeal involvement is present without cutaneous

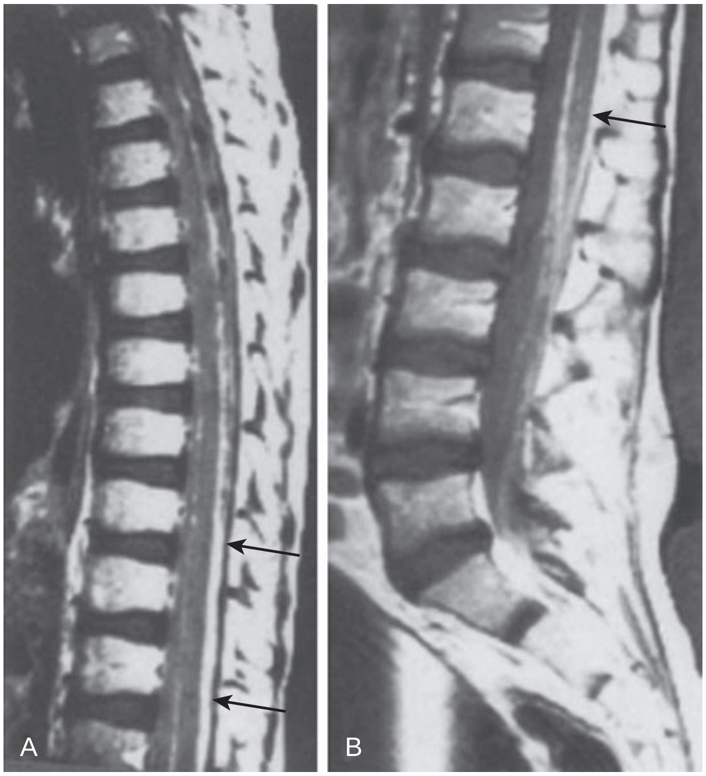

**Figure 45.14. Leptomeningeal melanosis.** A postcontrast sagittal T1-weighted MR image reveals diffuse enhancement *(arrows)* of the thoracic (A) and lumbosacral (B) spinal cord leptomeninges.

manifestations. In the pediatric population, leptomeningeal involvement may present with signs of raised ICP and hydrocephalus.

***Imaging.*** The most common finding is diffuse leptomeningeal thickening and enhancement after contrast administration, as can be seen with leptomeningeal metastases. However, hyperintense signal on noncontrast T1-weighted sequences, indicating melanin, should prompt consideration of melanosis (Fig. 45.14).[29]

## Extradural Bony Lesions

***Overview.*** Numerous vertebral osseous abnormalities may produce extradural mass effect. Spinal lesions tend to arise either from the posterior elements or vertebral bodies. Common posterior element lesions include osteoid osteomas, aneurysmal bone cysts, and osteoblastomas. Common primary pediatric vertebral masses include Ewing sarcoma (a peripheral PNET), lymphoma, leukemia, Langerhans cell histiocytosis, and metastatic disease, such as neuroblastoma.

***Imaging.*** Imaging findings vary depending on the specific type of lesion. CT plays a greater role in imaging osseous masses and is best used complementary to MRI. Posterior element lesions, which include osteoid osteomas, have a focal sclerotic nidus surrounded by a lucent halo on CT and show a "double density sign" on nuclear bone scintigraphy. On MRI, these lesions show impressive surrounding edema. Aneurysmal bone cysts are classically expansile, multilocular lesions with fluid-fluid levels due to internal hemorrhage (Fig. 45.15). Osteoblastomas are expansile solid masses of the posterior elements and rarely have fluid levels (Fig. 45.16). Lesions that involve the marrow space of a single vertebral body, such as Ewing sarcoma and lymphoma, tend to be T1 hypointense and T2 hyperintense with enhancement after contrast. They usually cause little, if any, loss of vertebral body height.[30]

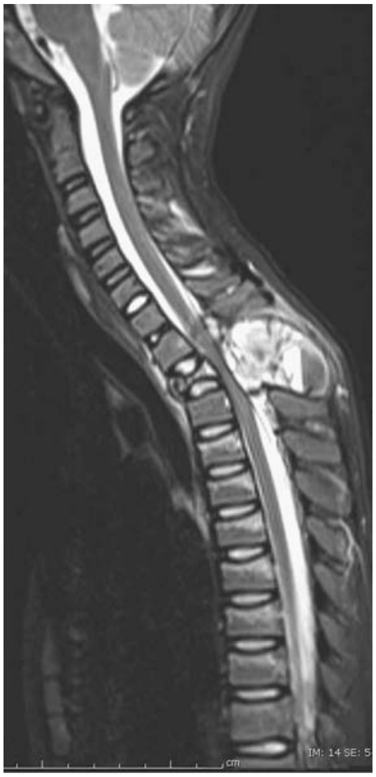

**Figure 45.15. An aneurysmal bone cyst in a 10-year-old girl with back pain.** A sagittal T2-weighted MR image demonstrates a multiloculated, expansile lesion with fluid levels in the T3 posterior elements. Compression of T3 causes effacement of the adjacent spinal canal.

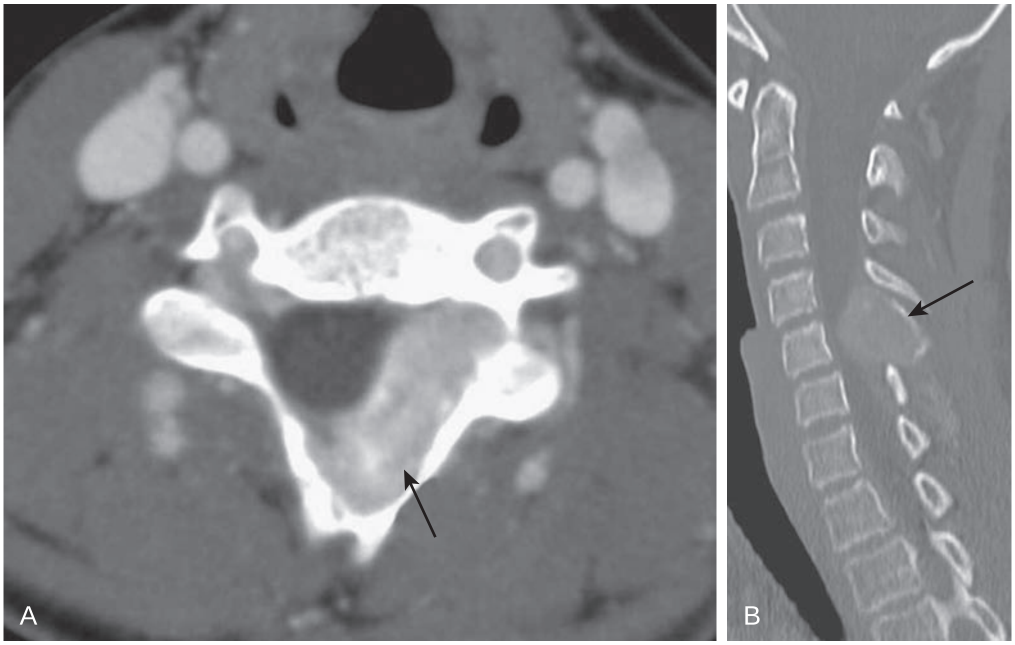

**Figure 45.16. Osteoblastoma in 14-year-old boy with left neck pain and paresthesias.** (A) Axial postcontrast CT image shows an enhancing epidural lesion *(arrow)* with rightward cord displacement. (B) Sagittal cervical spine CT demonstrates a C5 posterior element expansile mass *(arrow).*

## KEY POINTS

- The differential diagnosis of spinal neoplasms in children can be narrowed by determining the lesion compartment: intramedullary, intradural-extramedullary, or extradural.
- The most common pediatric spinal cord mass is astrocytoma, an intramedullary, expansile, infiltrative, often eccentric lesion with an enhancing component.
- The second most common pediatric spinal cord neoplasm is ependymoma, an intramedullary, often central, circumscribed mass often having a hemosiderin cap and necrosis.

# Vascular Lesions

*Joseph V. Loeb, Lisa H. Hutchison, and Kay North*

Vascular lesions of the spine are uncommon in children. Vascular lesions are subdivided into fast-flow lesions, such as arteriovenous malformations (AVMs) and arteriovenous fistulas (AVFs), and slow-flow lesions, such as venous (formerly "cavernous") malformations. Rarely, children suffer spinal cord infarcts. Several syndromes are associated with spinal cord AVMs and AVFs, including hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu), neurofibromatosis, and Parkes–Weber, Cobb, and CLOVES (congenital, lipomatous, overgrowth, vascular malformations, epidermal nevi, and spinal/skeletal anomalies or scoliosis) syndromes.[1,2,5]

## CLASSIFICATION

Vascular lesions of the spine have undergone various classifications,[1,6-10] in part because of the complexity of their diagnosis and features. The term *spinal arteriovenous shunt* is used to denote both types of high-flow lesions (AVMs and AVFs). Because AVMs and AVFs are found in various locations (i.e., intramedullary, intradural extramedullary, and extradural sites) with variable feeding vessels, structural features, drainage, and hemodynamic changes, additional subclassifications have been proposed.[6,8,9] Due to recent histopathologic discoveries, pediatric vascular anomalies have been classified using the International Society for the Study of Vascular Anomalies (ISSVA) system first published by Mulliken and Glowacki in 1996 and updated in 2014.[3,11,12] This system, which allows for correlation between lesion histology, clinical presentation, and treatment, is now used widely by pediatric subspecialists including dermatologists, interventional radiologists, plastic surgeons, and neurosurgeons.[10] The ISSVA classification system divides lesions into two broad categories: neoplasms and vascular malformations.[10-12] Vascular anomalies are further divided into simple, combined (containing more than one type of vessels), or associated with other anomalies.[3] This chapter discusses pediatric vascular anomalies, emphasizing the most common lesions, including AVMs and AVFs, and venous malformations. Spinal cord infarcts are also discussed in this chapter, though they fall outside the ISSVA system.

## ARTERIOVENOUS MALFORMATIONS

***Overview and Etiology.*** AVMs are high-flow malformations that contain a nidus (nest), or vascular network, that communicates between the arteries and veins. AVMs may be sporadic or seen in patients with various disorders. The high-flow dynamics within the AVM predisposes the involved arteries and veins to the formation of aneurysms and varices, respectively.[10] AVMs can be characterized further by the location of the nidus (intramedullary or extramedullary), as well as by morphology of the nidus (the central, tightly formed "glomus" type, or the diffuse, extensive, extramedullary "juvenile" or "metameric" type). In children, the glomus spinal cord fast-flow AVM is the most common. In one large series, twice as many children had AVMs as had AVFs.[6] AVMs may occur anywhere along the spine, and do so in approximate proportion with each segment, including 30% to 40% cervical and 60% to 70% thoracolumbar.

***Clinical Presentation.*** The initial clinical presentation varies from acute paraparesis to slowly progressive myelopathy with weakness, sensory loss, and bowel and bladder dysfunction. Hemorrhage is more common in children (78%) compared with adults, especially in cervical cord AVMs. In 56% of cases, children present acutely due to AVM hemorrhage.[6]

***Imaging.*** Magnetic resonance imaging (MRI) is the best noninvasive modality for initial diagnosis and follow-up of a spinal arteriovenous shunt.[6,13] Imaging findings of cord AVMs include tortuous dilated vessels within or on the surface of the cord that are identified by flow-voids. Hemorrhage has a variable appearance on T1-weighted and T2-weighted images depending on chronicity. T2-weighted images may demonstrate spinal cord edema and expansion.[3] MRI also documents the presence of cord cavitation, atrophy, and venous thrombosis. Images obtained after administration of gadolinium may reveal cord enhancement due to venous stasis, ischemia, or cord infarction[1] (Fig. 46.1). Distinguishing normal physiologic cerebrospinal fluid (CSF) pulsation and flow (particularly in the dorsal extramedullary midthoracic region) from vascular abnormalities requires optimization of spine imaging, which may include switching the phase and frequency encoding directions to decrease the effect of physiologic CSF pulsation. Computed tomography (CT) has a limited role in imaging AVMs, but may document bony changes, often seen in large, diffuse metameric-type lesions. Ultimately, spinal angiography remains the gold standard for diagnosis and delineation of AVMs.

***Treatment.*** Endovascular embolization is the primary line of treatment for fast-flow vascular anomalies, except for lesions at the conus, which are managed surgically.[1,3,6] In some patients, complete lesion embolization or resection is not possible because of unacceptably high risk of morbidity or mortality. In these cases, the treatment goal is to reach a hemodynamic equilibrium between the lesion and the spinal cord that will reduce the risk of ischemia and hemorrhage.[14,15]

***Prognosis.*** A spectrum of outcomes may occur depending on the lesion location, presentation, and treatment.[15] The severity of symptoms at the time of diagnosis is directly related to patient outcome, with most symptoms persisting partially or completely after treatment.[14]

## ARTERIOVENOUS FISTULA

***Overview and Etiology.*** The term *AVF* is used to describe fast-flow lesions with a direct artery to vein connection without a focal nidus, as seen in AVMs. Converse to AVMs, which are congenital lesions, AVFs are believed to be acquired anomalies resulting from microvascular injury and reparative healing.[8,16] In a large combined pediatric and adult series, a higher percentage of multiple cord fistulas were observed in pediatric (46%) compared with adult patients (27%).[6] AVFs are divided by location into two groups, spinal cord and spinal dural. Spinal cord AVFs are perimedullary in location and one-third as common as AVMs in children. Spinal dural AVFs are extremely rare in the pediatric population.[6]

***Clinical Presentation.*** The clinical presentation of AVFs is similar to AVMs, including slowly progressive weakness, sensory loss, and bowel and bladder dysfunction due to venous congestion, venous hypertension, and resultant myelopathy. However, AVFs hemorrhage less than AVMs, and acute presentations are uncommon.[6]

***Imaging.*** Imaging findings of pediatric spinal cord AVFs are virtually identical to spinal cord AVMs.[1] Dural AVFs, which are common in adults, are uncommon in children.[6]

## Abstract:

Spinal vascular lesions in children are rare, but have significant neurologic presentations and sequelae. The lesions can be subdivided into fast flow lesions, such as AVM's and AVF's, and slow flow lesions, such as venous malformations. Rarely, children suffer spinal cord infarcts.

## Keywords:

Vascular malformations
Arteriovenous malformation
Arteriovenous fistula
Venous malformations
Spinal infarcts

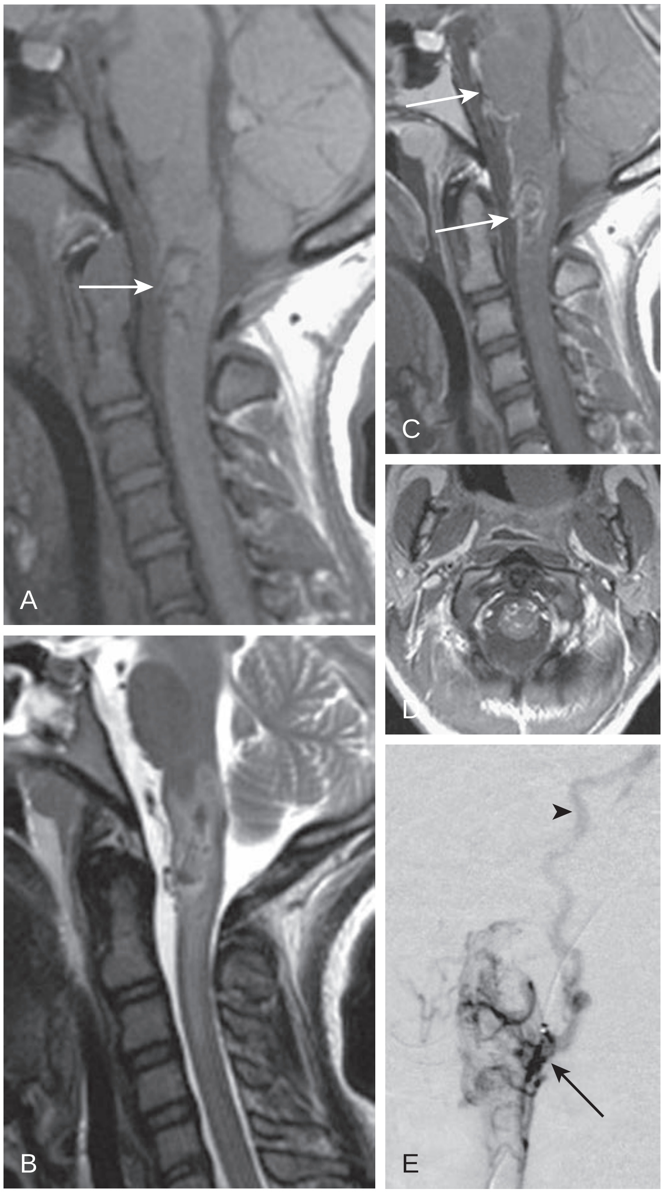

**Figure 46.1. AVM in a 14-year-old girl with sudden severe headache, left-sided weakness, and loss of consciousness.** Head CT (not shown) revealed intraventricular hemorrhage. (A) Sagittal T1-weighted MRI shows a hypointense lesion with subtle foci of high signal hemorrhage *(arrow).* (B) Sagittal T2-weighted MRI confirms low-signal central hemorrhage with hyperintense surrounding edema. (C and D) Postcontrast T1-weighted sagittal and axial MRI demonstrates enhancing superficial serpiginous vessels and peripheral intramedullary enhancement *(arrows).* (E) A catheter angiogram injection of the vertebral artery reveals an intramedullary nidus *(arrow)* with arterial supply from anterior and lateral spinal artery contributors. Venous drainage is toward the jugular bulb via a recurrent perimedullary vein *(arrowhead).*

***Treatment.*** Because each spinal AVF is unique, treatment must be tailored to the specific lesion, taking into account location, size, number of fistulous sites, and associated symptoms.[3] Therapies are the same as for other fast-flow anomalies, including endovascular embolization, microsurgical resection, radiation therapy (used rarely), or a combination of these therapies.[1,3,17] Endovascular embolization has the advantage of being less invasive than the other therapies, but the feeding arteries may not be accessible, and thus open surgery is needed in some cases.[18]

***Prognosis.*** Early diagnosis of AVFs is essential to preserve neurologic function. Patient outcome is proportional to the severity of symptoms at the time of diagnosis. Patients who are nonambulatory and those with poor bladder or bowel function before treatment are unlikely to regain neurologic functions after therapy.[17,18]

## VENOUS MALFORMATIONS

***Overview.*** Slow-flow venous (formerly known as cavernous) malformations (VMs), also previously termed *cavernous angiomas* and *cavernomas*, are congenital vascular malformations composed of dysmorphic venous channels lined by a single layer of endothelial cells with no intervening neural tissue.[19] Per the ISSVA classification system, VMs of the spinal cord have been reclassified as simple vascular malformations III. Rather than the misnomer cavernoma, the term *venous (cavernous) malformation* is used to avoid confusion with true neoplasms that enlarge through cell division (mitosis). VMs increase in size by distention of vascular channels, often due to inflammation or hemorrhage. Spinal cord VMs are less common than similar lesions found in the brain, with one study showing that 5% of pediatric VMs located within the spine.[20]

***Etiology.*** The specific etiology of spinal VMs is unclear. However, the presentation of multiple brain and/or spinal VMs in any child should prompt a careful history and genetic analysis. Associated mutations predisposing patients to multiple VMs have been found on chromosomes 3 and 7, with an autosomal dominant variable penetrance pattern of inheritance.[20] Deep venous anomalies are associated with sporadic VMs in up to 40% of cases. Patients who previously have undergone radiation therapy, typically of the craniospinal axis, are predisposed to the development of VMs. Approximately 12% to 16% of pediatric patients have multiple VM lesions.[20,21]

***Clinical Presentation.*** The clinical presentation of VMs is variable, often resulting from hemorrhage. They may present at any age with variable symptoms, from being nearly asymptomatic to having severe neurologic symptoms. Pediatric patients are more likely to have a sudden clinical onset compared with adults, with up to 75% presenting acutely.[20]

***Imaging.*** MRI findings of spinal cord VMs are similar to their intracranial counterparts, with T1-weighted signal heterogeneity within the lesion caused by blood products of varying age. On T2-weighted imaging, a classic hypointense rim representing hemosiderin is key, with an internal heterogeneous T2 signal. Cord edema may be seen if recent hemorrhage has occurred (Fig. 46.2). On T2* gradient recalled echo imaging and susceptibility-weighted imaging (SWI), a prominent blooming effect is noted because of hemorrhage degradation products.[22] SWI has been shown to be significantly better than T2* gradient imaging to detect hemorrhage.[22] Distinguishing a spinal cord VM from other pathologies can be difficult in some cases, but usually is based on identification of the classic hemosiderin rim (or ring), and the absence of other morphologic features that would suggest a neoplasm, such as an enhancing mass.[19] Because VMs are very slow-flow lesions, they are not seen on catheter angiography. Therefore catheter angiography has no role in the imaging evaluation of VMs.

***Treatment.*** Asymptomatic VMs and those located in delicate regions are treated conservatively. Although symptomatic VMs located elsewhere in the body may be treated initially with sclerotherapy, this treatment is not an option for intramedullary spinal cord lesions. Instead, patients with symptomatic spinal cord lesions may undergo surgical resection or, rarely, radiotherapy when the lesions are in hard-to-reach locations.[19,21]

***Prognosis.*** The immediate postoperative outcome after VM resection in one study showed that 11% of patients had worse symptoms, 83% were the same, and 6% were improved. At 5-year follow-up, the percentages of patients who were the same and

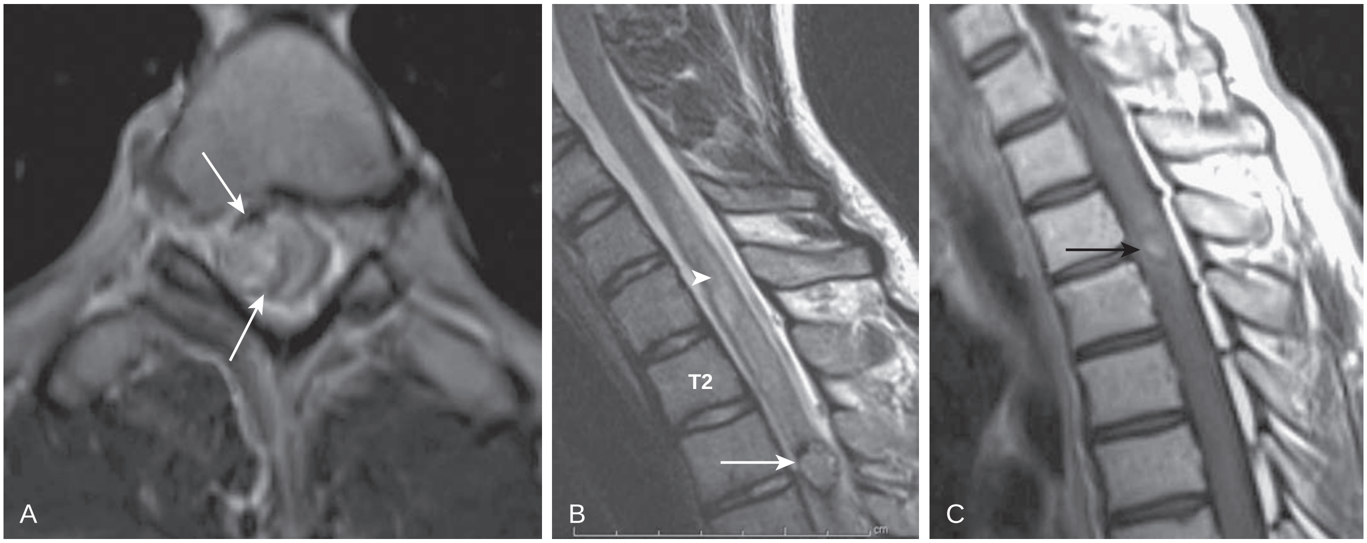

**Figure 46.2. Vascular malformation in a 16-year-old boy with arm weakness.** (A and B) Axial and sagittal T2-weighted MRI demonstrates a centrally hyperintense intramedullary lesion with a hypointense rim *(arrows).* Central bright signal cord edema is noted proximally as well *(arrowhead).* (C) Postcontrast T1-weighted MRI shows no enhancement. Central hyperintense hemorrhage within the lesion *(arrow)* also was seen on precontrast images (not shown).

improved were 68% and 23%, respectively,[23] showing a moderate response to treatment.

## SPINAL CORD INFARCTION

***Overview.*** Infarction of the spinal cord is uncommon, particularly in children. The most vulnerable region of the spinal cord is the anterior half, which is supplied by the single anterior spinal artery. The posterior spinal cord is supplied by paired paramedian posterior spinal arteries, allowing more extensive collateral circulation.

***Etiology.*** Trauma and infection (e.g., meningitis) are the most common causes of cord infarction in children.[24] Other causes of spinal cord infarction include thrombotic and/or embolic phenomena from cardiac disease, hypercoagulable states, umbilical arterial lines, or fibrocartilaginous embolization, as well as hypoperfusion and cardiac arrest.[24,25,29]

***Clinical Presentation.*** Spinal cord infarction most often presents with acute paraparesis or quadriparesis depending on the level of cord involvement.[26]

***Imaging.*** Because the single anterior artery supplies the anterior two-thirds of the spinal cord, infarction often shows anterior cord involvement of both gray and white matter, seen as T1 hypointensity and T2 hyperintensity (Fig. 46.3). T2 hyperintensity may not be seen initially if MRI is performed in the hyperacute (first few hours after the event) setting. Cord edema and swelling can be seen acutely, and contrast enhancement can occur in the subacute (>5 days) phase.[27] Current MRI techniques allow diffusion-weighted imaging (DWI) of the spinal cord as a supplement to standard sequences to confirm ischemia[27,28] (Fig. 46.4). In the differential diagnosis of cord infarction is transverse myelitis, which is more common than cord infarction (see Chapter 44). Isolated involvement of the spinal cord gray matter suggests an infectious or postinfectious autoimmune process rather than infarction. Careful review of the patient's history, spinal fluid, and anatomic distribution of signal abnormality in spinal gray and/or white matter are helpful to distinguish cord infarct from transverse myelitis.[24,29]

***Treatment.*** Supportive care is largely the only treatment for spinal cord infarct (Fig. 46.5). Methylprednisone may be given in the acute setting to help limit cord edema, but its utility is questionable.[25,29]

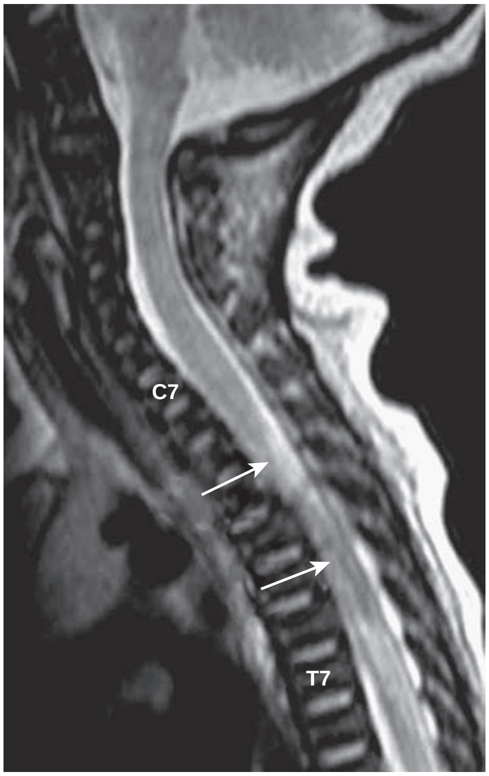

**Figure 46.3. Spinal cord infarct in a newborn male with paraplegia due to traumatic delivery.** Sagittal T2-weighted MRI reveals a large region of heterogeneous signal intensity *(arrows)* due to thoracic cord transection. Proximal hyperintense edema also is seen. Labeled are the seventh cervical (C7) and thoracic (T7) vertebrae.

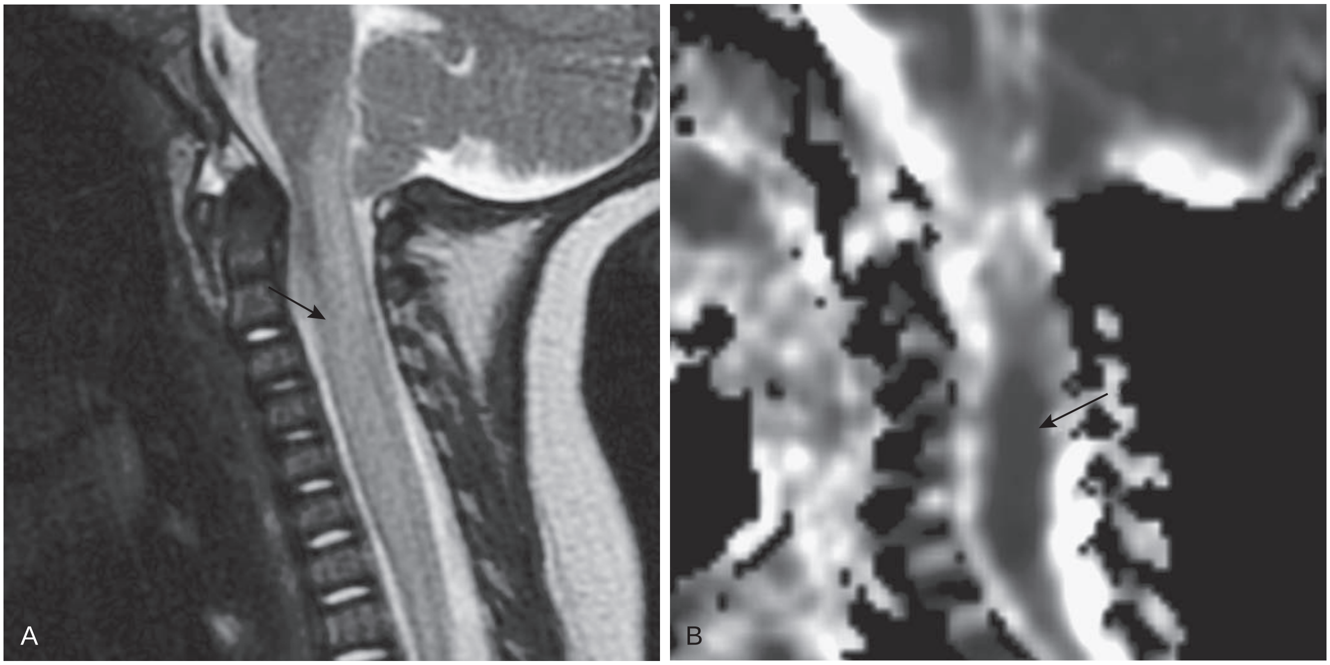

**Figure 46.4. Cord ischemia due to herpes simplex virus type 6.** (A) A sagittal fast spin echo T2-weighted MRI shows T2 hyperintensity and cord swelling because of edema *(arrow).* (B) Apparent diffusion coefficient (ADC) map of a sagittal echo planar diffusion-weighted image shows hypointensity representing cytotoxic cord edema *(arrow).* The findings are consistent with necrotizing myelitis.

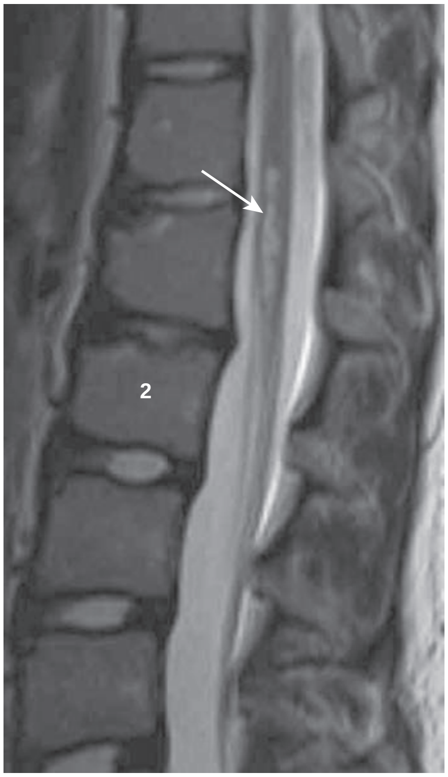

**Figure 46.5. Lumbar spinal cord infarct in a 13-year-old girl with pain and leg weakness for 2 weeks.** Sagittal T2-weighted MRI reveals a well-defined region of oblong hyperintensity *(arrow).* Irregularity at the anterior superior margin of L1 and L2 are consistent with Schmorl nodes suggesting possible fibrocartilaginous etiology.

***Prognosis.*** The outcome of cord infarction depends on the initial symptoms. Unfortunately, symptoms such as paraparesis and paraplegia seen at presentation often persist.[25,26]

## KEY POINTS

- Spinal vascular lesions in children are rare, but have significant neurologic presentations and sequelae. Diagnosis of such a lesion should prompt evaluation for an underlying cause, syndrome, or genetic predisposition.
- Advances in histopathologic knowledge have led to development of the ISSVA classification system, which allows consistent correlation between the type of pediatric vascular anomaly, lesion treatment, and outcome.
- Newer MRI techniques, such as SWI and DWI, can help characterize fast-flow spinal cord arteriovenous shunts, as well as slow-flow vascular lesions and spinal cord infarcts.

# 47

# Trauma

Peter Winningham and Lisa H. Hutchison

The mortality rate of spine-related trauma in children is higher than in adults and is estimated at 25% to 32%.[1] Fortunately, children with incomplete neurologic lesions fare better than adults, with up to 90% having partial recovery and 60% having full recovery.[1,2]

## ETIOLOGY

Motor vehicle accidents (MVAs), falls, and sports injuries are the most common causes of pediatric spinal trauma. Young athletes are at higher risk than adults for developing stress-related injuries.[3,4] Congenital spine anomalies such as os odontoideum, block vertebrae, Klippel–Feil syndrome, and Down syndrome increase the risk of cervical spinal injury. Nerve root avulsion may result from birth trauma, MVAs, or penetrating injury (Fig. 47.1).[5]

Younger children are more susceptible to upper cervical injuries because of their relatively large-sized, heavy craniums and weaker neck muscles.[6] This anatomy causes a more cranial fulcrum of movement at C2–C3 in younger children versus C5–C6 in older children and adults.[1] Injuries in younger children, especially those younger than 8 years, differ from those in older children. Because of greater cervical mobility and ligament laxity in the spine of younger children, they tend to have injuries at higher levels (occiput to C3). These injuries are more likely associated with a neurologic deficit and extend through synchondroses.[7]

## SPINAL CORD INJURY WITHOUT RADIOGRAPHIC ABNORMALITY

The unique biomechanical properties of young children causes increased occurrence of spinal cord injury without radiographic abnormality (SCIWORA).[8] With the introduction of magnetic resonance imaging (MRI), injuries in children with SCIWORA could be visualized and the general prognosis predicted on the basis of the findings.[9,10] MRI can show the findings of cord contusion, hemorrhage, and transection (Fig. 47.2).[11] The presence of intramedullary hemorrhage and transection portend a poor prognosis.[8]

## ATLANTO-OCCIPITAL DISASSOCIATION

Because of their relatively small occipital condyles and more horizontal atlanto-occipital joints, young children are at increased risk for atlanto-occipital disassociation.[2,9,12] Devastating spinal cord injury often occurs, and many cases are fatal. A diagnosis is made by measuring a condylar gap greater than 5 mm (Kaufman condylar gap) or a basion-to-axis interval (BAI) greater than 12 mm (Fig. 47.3).[2] One pitfall is that in children under 13 years, the BAI is less reliable.[12] See Table 47.1 for pediatric cervical spine measurements.[13] Atlanto-occipital disassociation requires urgent stabilization.

## ATLAS OR JEFFERSON FRACTURE

Cervical spine compression loading forces can result in a C1 burst, or Jefferson, fracture. This injury is most common in adolescents from MVAs and diving accidents. Jefferson fractures show between one and four defects in the C1 ring. The fracture may be stable or unstable, depending on whether or not the transverse ligament is intact or ruptured, respectively. A single C1 ring defect is usually stable, whereas three or four defects are unstable.[9] A dens to C1 lateral mass distance greater than 8 mm suggests instability. Forty percent of Jefferson fractures have an associated C2 fracture.[12] Lateral cervical spine radiographs are of little value, and the diagnosis is made on the odontoid view or computed tomography (CT) by showing offset of the C1 on C2 lateral masses (Fig. 47.4).[13] Pitfalls to avoid include head rotation on the open-mouth view, which may cause the lateral mass to appear laterally displaced; hypermobility in young children that may have minimal normal lateral displacement of C1 on C2; and the normal developmental offset of C1 lateral masses in children less than 2 years of age because of differential C1 versus C2 growth.[9]

## ATLANTOAXIAL ROTATORY FORCE INJURY

The atlantoaxial joint is responsible for 50% of the normal neck range of motion. Temporary ligamentous laxity after neck infection or surgery may cause mild atlantoaxial rotatory subluxation (AARS), or Grisel syndrome. A similar situation, referred to as “wry neck,” occurs in normal children who simply awaken with a stiff neck unable to turn their head to one side.[9] Grisel syndrome and wry neck represent a mild, self-limiting form of C1 on C2 rotatory subluxation caused by muscle spasm. In frank rotatory dislocation, children present with torticollis, holding their heads in a peculiar “cock robin” position (head rotated to one side and tilted to the other).[2] The duration of subluxation is proportional to the risk of morbidity. When rotatory injury is fixed, the term *atlantoaxial rotatory fixation (AARF)* is applied. Atlantoaxial rotatory injury is classified into four types, according to Fielding and Hawkins (Table 47.2).[14] Mild rotatory anomalies are treated with muscle relaxers and physical therapy, but more aggressive management may include traction and, rarely, surgery, to prevent C1–C2 osseous fusion.[2] An imaging diagnosis of AARS is suggested by the presence of asymmetry in the dens to C1 lateral mass distance on open-mouth odontoid radiographs and CT (Fig. 47.5). CT signs of rotatory disorders include loss of articulation of the occiput and C1, as well as sclerosis on both sides of the joint with impending fusion (Fig. 47.6).

## ODONTOID (DENS) FRACTURES

Dens, or odontoid, fractures are common in children. The rigid, upright nature of dens makes it susceptible to a variety of flexion, loading, and extension forces.[9] In young children, the odontoid is separated from the body of C2 by a cartilaginous synchondrosis, which fuses between 5 and 7 years.[9] The presence of the synchondrosis in infants and young children allows fractures to occur frequently through this growth plate, but fortunately these fractures heal readily (Fig. 47.7). In adults these fractures are often complicated by nonunion or pseudoarthroses.[1] Dens fractures are classified into three types with type 2 being unstable. Type 1 is through the tip of the dens, type 2 is through the base of the dens, and type 3 is through the body of C2.[2,9]

A pitfall of odontoid fractures is the presence of an os odontoideum. This variant is a well-corticated ossicle of variable size in the expected location of the odontoid process. Small os odontoideums are normal variants of no significance; however, when large enough to extend inferior to the annular ligament, they may be unstable and susceptible to injury.[9] The origin is

## Abstract:

This chapter reviews spine related trauma in children. Specific diagnoses covered with accompanying images include: atlanto-occipital disassociation, Jefferson fracture, atlantoaxial rotatory force injury, odontoid fracture, hangman fracture, chance and burst fractures. The concept of spinal cord injury without radiographic abnormality (SCIWORA) is discussed. Tables within the chapter include the Fielding classification of atlantoaxial rotatory subluxation and typical radiographic measurements used in pediatric cervical spine trauma.

## Keywords:

Jefferson fracture
atlantoaxial rotatory subluxation
odontoid fracture
hangman fracture
chance fracture
burst fracture
SCIWORA

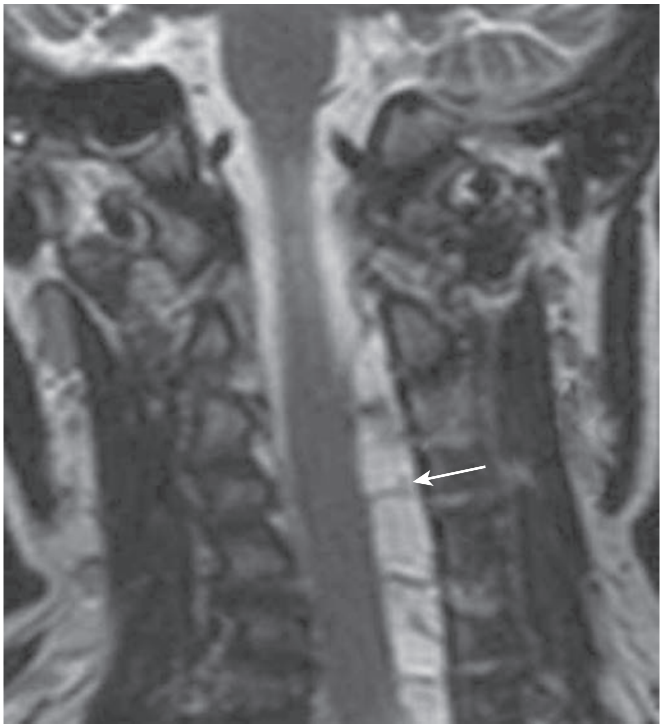

**Figure 47.1. Avulsed nerve roots in a 13-year-old girl unable to use her left arm after an all-terrain vehicle accident.** Coronal T2-weighted MRI shows an extensive intradural cerebrospinal fluid collection *(arrow)* shifting the spinal cord to the right due to C2 to T1 nerve root avulsions.

**Figure 47.2. **Figure 47.3. Atlantoaxial dissociation in a 5-year-old unrestrained girl after a motor vehicle accident.** Lateral cervical spine radiograph demonstrates abnormally increased basion to dens distance of 15 mm *(white line).* The C1–C2 interspinous distance is also increased at greater than 12 mm *(arrow).*

controversial, but they are likely both posttraumatic and congenital.[2,15]

## HANGMAN FRACTURE

Hyperextension forces may cause fractures through the C2 pars interarticularis, known as *hangman fractures*. Often, these fractures are complex in morphology being associated with flexion and extension forces in the same patient.[9] The C2 fracture lucency is diagnostic, but may be difficult to visualize on lateral radiographs (Fig. 47.8). They are more easily detected with flexion views. Application of the posterior cervical line (see Table 47.1) is helpful to diagnose the injury.[9] Hangman fractures may be unilateral or bilateral, in which case they are stable or unstable, respectively. In infants, one must be aware of the pitfall of congenital defects of C2 being confused with a hangman fracture. Congenital defects are distinguished by smooth, sclerotic, narrow margins.[9,16]

## THORACIC AND LUMBAR SPINE FRACTURES

Cervicothoracic junction injuries are associated with breech delivery often presenting as SCIWORA or brachial plexus injuries.[2] Associated T1 and T2 transverse process fractures also occur.

Lower thoracic and upper lumbar spine injuries are most often caused by MVAs, with up to 50% having associated small bowel injury from seatbelt trauma.[2,17] Common lower thoracic and lumbar fractures include anterior column compressions, which are typically stable, and posterior column burst fractures, which are typically unstable (Fig. 47.9). Burst fractures occur with axial compression forces, causing endplate fracture extending into the anterior and posterior column (Fig. 47.10). Chance, or seatbelt, fractures are

**TABLE 47.1** Cervical Spine Measurements Useful in Evaluation of Pediatric Trauma

| Imaging Sign | Definition | Normal | Injury |
|---|---|---|---|
| Predental distance | Distance between posterior inferior C1 arch to anterior dens | Age 0–8years: <5 mm<br>Age 8+ years: <3 mm<br>Flexion/extension: <2 mm change | C1–C2 ligamentous injury |
| C1–C2 interspinous interval | Distance between C1–C2 spinous processes | <12 mm | C1–C2 ligamentous injury |
| Basion dens interval | Distance between basion to superior tip of dens | <12 mm | Atlanto-occipital distraction |
| Condylar gap | Distance between occipital and C1 condyles | <5 mm | Atlanto-occipital distraction |
| Dens to C1 lateral masses | Distance from dens to bilateral lateral C1 masses | Must be symmetric right to left<br>>8 mm suggests instability | AARS, AARF, Jefferson fracture |
| Spinolaminar line | Line between C1 and C3 anterior spinous process cortex | Anterior spinous process cortex of C2 is missed by <1.5 mm | Hangman fracture |

*AARF,* Atlantoaxial rotatory fixation; *AARS,* atlantoaxial rotatory subluxation.

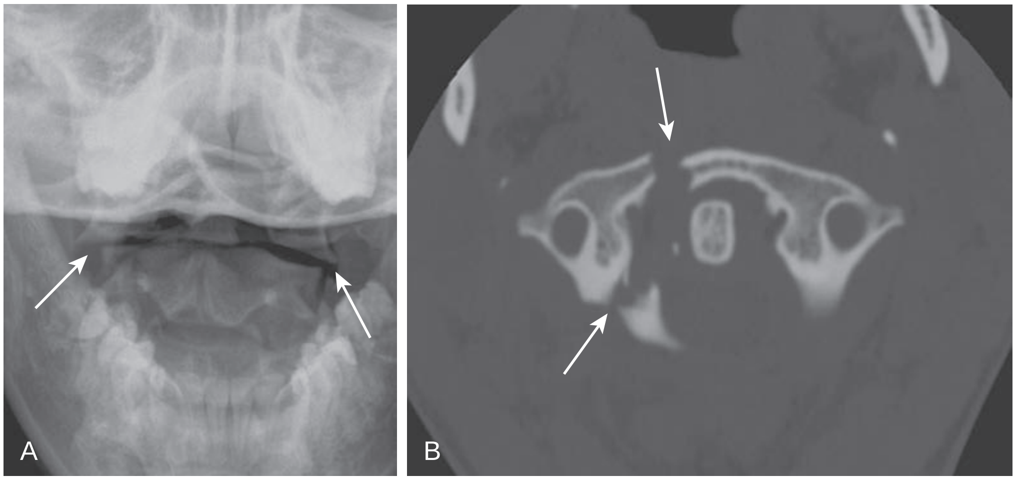

**Figure 47.4. Jefferson fracture in an adolescent with unspecified trauma.** (A) Open-mouth odontoid view shows asymmetric bilateral offset of the lateral masses of C1 on C2 *(arrows).* (B) An axial CT image reveals fracture lucencies in the right anterior and posterior C1 arches *(arrows).*

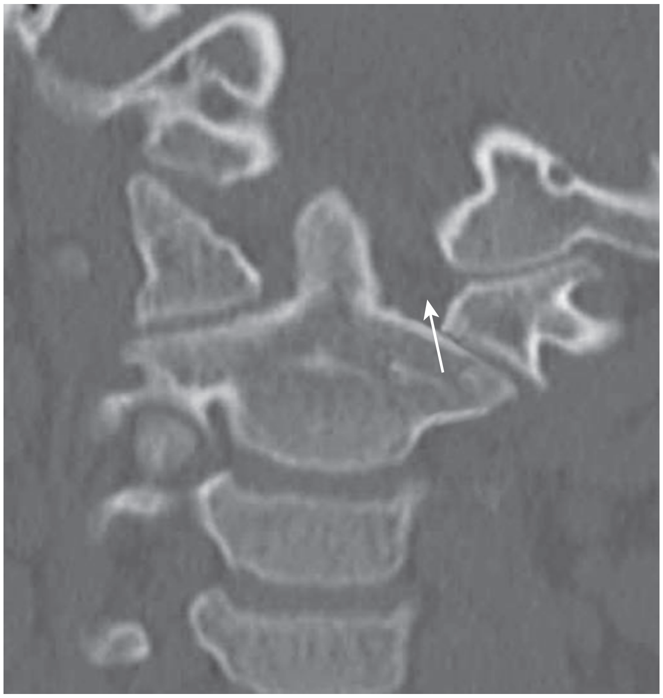

**Figure 47.5. Atlantoaxial rotatory subluxation in a 13-year-old girl with torticollis for 2 weeks and no history of infection or trauma.** Coronal reconstructed cervical spine CT shows widening of the atlantodental distance on the left *(arrow)* compared with the normal right side. This distance widened and narrowed when turning the head to the left and the right, respectively (dynamic CT not shown).

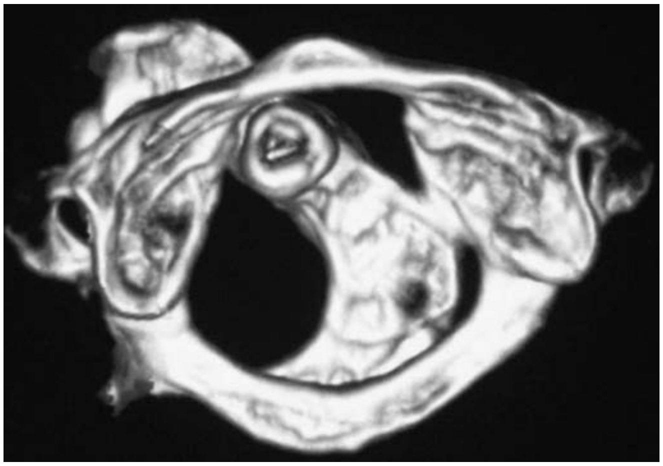

**Figure 47.6. Atlantoaxial rotatory fixation (Fielding type 1) in a 15-year-old girl with rigid torticollis for 4 weeks after spinal manipulation.** Axial three-dimensional cervical CT reveals rotation of C1 on C2 with loss of articulation of the condyles, but without anterior displacement of C1. Note normal distance between C1 and dens, which indicates a Fielding type 1 injury.

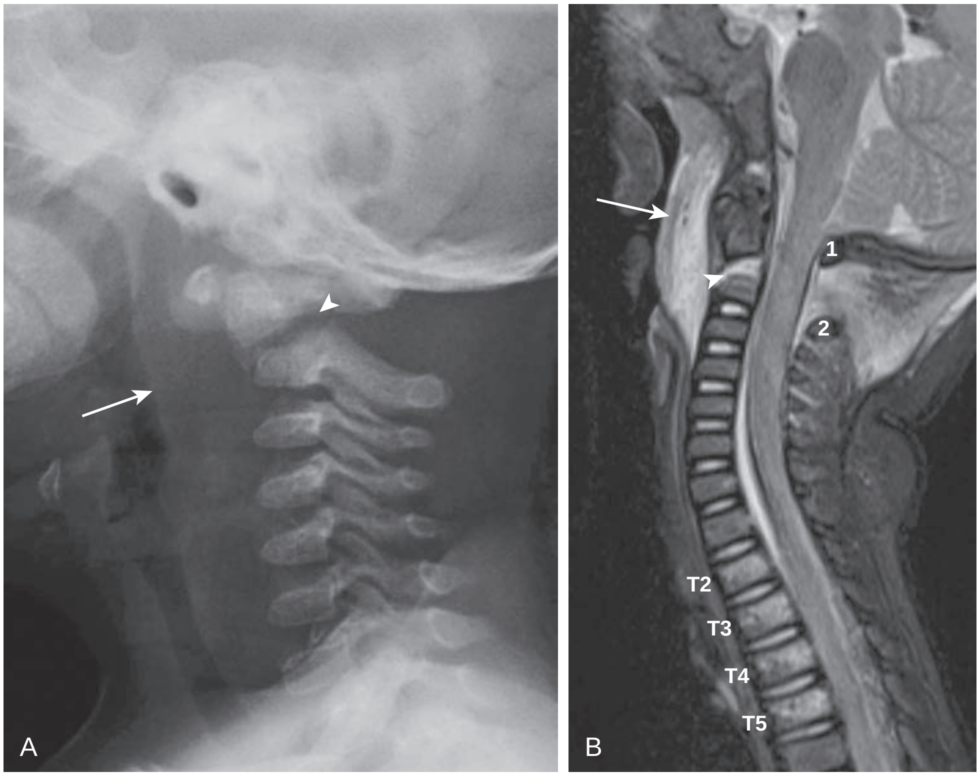

**Figure 47.7. Odontoid fracture in a 12-month-old girl after a motor vehicle accident.** (A) Lateral cervical radiograph shows prevertebral soft tissue swelling *(arrow),* widening of the C2 synchondrosis *(arrowhead),* and anterior subluxation of the dens on the body of C2. (B) Sagittal T2-weighted fat-suppressed MRI confirms the radiographic findings and also reveals additional vertebral contusions as hyperintense marrow signal of T2–T5. Ligamentous injury is seen as increase in the C1–C2 interspinous interval, which contains T2 bright soft tissue edema.

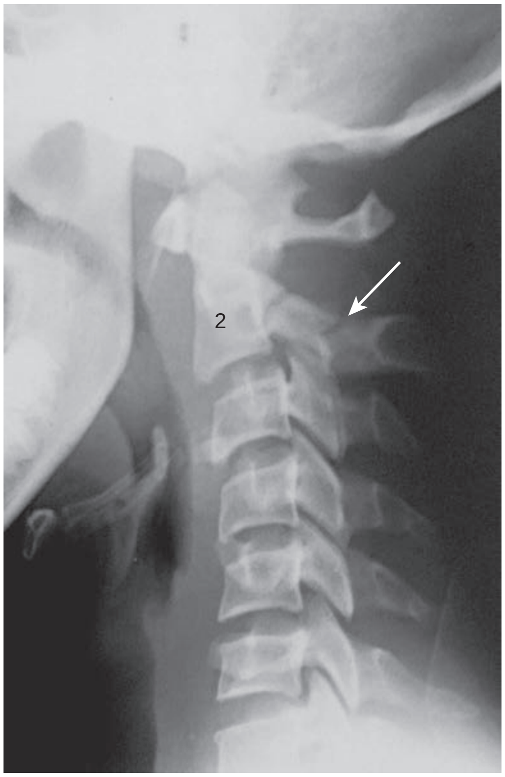

**Figure 47.8. Hangman fracture in a 15-year-old boy after an accidental fall.** A lateral cervical spine radiograph identifies lucency through the C2 posterior elements *(arrow).*

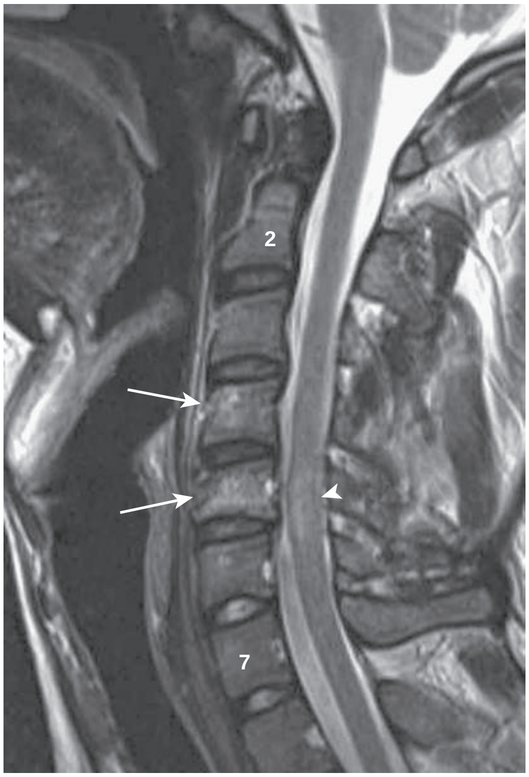

**Figure 47.9. Cervical spine compression fractures and cord contusion in a 17-year-old boy after an all-terrain vehicle accident.** Sagittal T2-weighted MRI shows hyperintense signal and decreased height of the anterior C4 and C5 vertebral bodies *(arrows).* T2 bright signal cord contusion is seen at the C5 level *(arrowhead).*

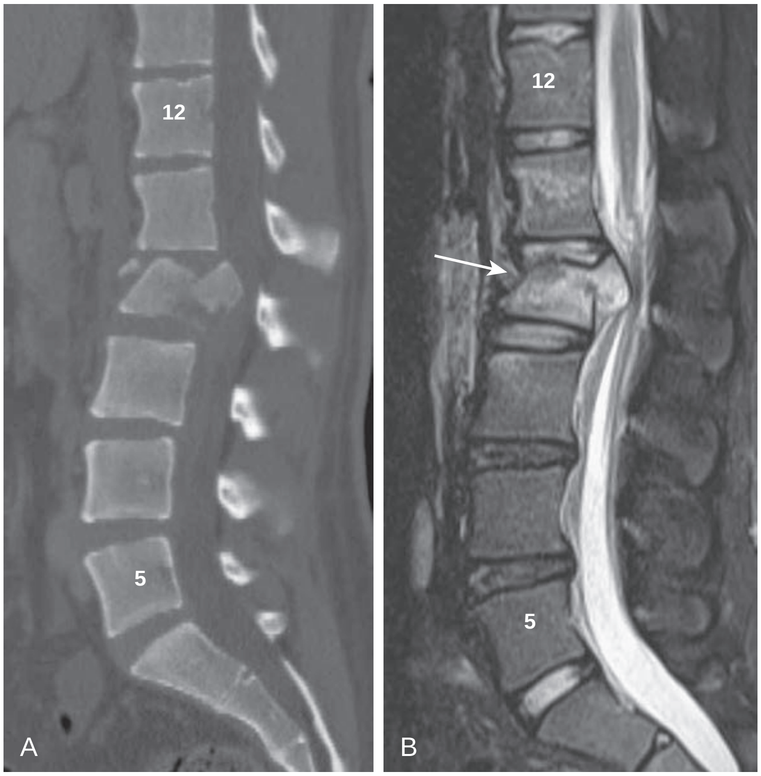

**Figure 47.10. Burst fracture in a 16-year-old boy with leg pain and weakness after a motor vehicle accident.** (A) Sagittal reformatted CT identifies a comminuted L2 fracture with a retropulsed fragment in the spinal canal. (B) Sagittal short tau inversion recovery (STIR) MRI confirms the fracture with retropulsed fragment compressing the cauda equina *(arrow).* In addition, T2 bright signal contusions in the adjacent L1 and L3 vertebral bodies are present.

**TABLE 47.2** Fielding Classification of Atlantoaxial Rotatory Subluxation

| Type | Description |
|---|---|
| I | Rotatory displacement of C1 on dens without anterior displacement; most common type |
| II | 3–5 mm of anterior C1 displacement with rotation centered on the lateral facets possibly disrupting the transverse ligaments |
| III | >5 mm anterior C1 displacement with rotation centered on lateral facets possibly disrupting the transverse ligament, alar ligament, and facet capsule |
| IV | Posterior C1 displacement on C2 of both lateral facets; rarely seen in adults with rheumatoid arthritis |

caused by flexion injury with horizontal extension through the posterior vertebrae (Fig. 47.11).[2]

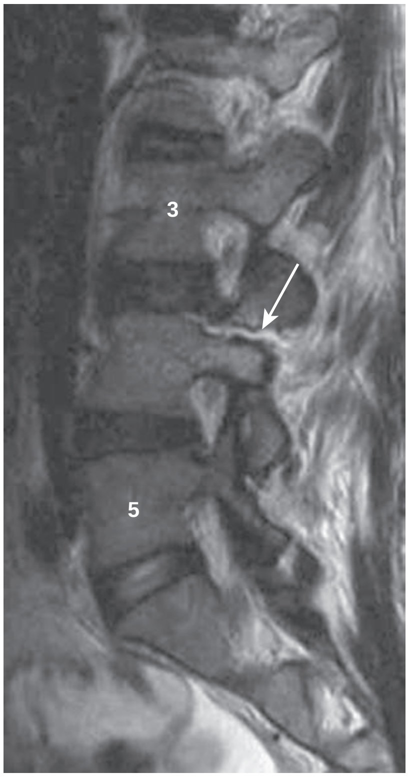

**Figure 47.11. Chance fracture in a 5-year-old-boy unable to move his legs after a motor vehicle accident.** Sagittal T2-weighted MRI shows a horizontal fracture through the superior endplate and pedicles of L4 *(arrow).* Associated surrounding T2 bright soft tissue edema is also seen.

## SPONDYLOLYSIS

Spondylolysis may be a congenital deformity or an acquired stress fracture extending through the pars interarticularis. It is believed due to repetitive flexion and extension of the adolescent spine and is often seen in athletes, having been reported in 11% of female gymnasts.[18] Defects extend through the pars on radiography, CT, and MRI. Spondylolysis without spondylolisthesis is treated conservatively. Spondylolisthesis may require stabilization depending on severity.

## SPINAL CORD CONTUSIONS AND TRANSECTIONS

Spinal cord contusions and transections are a continuum of injuries occurring alongside fractures, ligamentous injuries, or both.

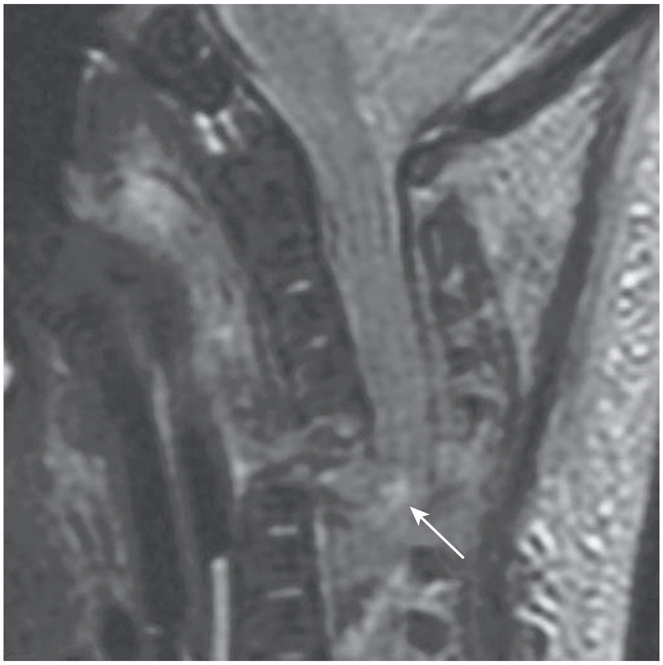

**Figure 47.12. Cord transection in a newborn with distractive birth injury.** Sagittal STIR MRI shows disruption of the cervical vertebral column at C5–C6, transection of the spinal cord, and focal hyperintense signal within cord consistent with hyperacute edema and hemorrhage *(arrow).*

Contusions are areas of edema secondary to shearing injuries. Severe cases have rupture of intramedullary vessels with cord hemorrhage and vascular compromise.[17] Complete cord transection results from extreme distraction or severe shear injury, and has a very poor prognosis (Fig. 47.12).[10]

### KEY POINTS

- Infants and young children have a higher likelihood of upper cervical injury with greater risk of permanent morbidity.
- MRI is used to detect spinal cord and ligament injuries, including SCIWORA.
- In the evaluation of spinal cord injury, MRI is able to determine the extent of intramedullary hemorrhage, which correlates with patient outcome.

# 48 Embryology, Anatomy, and Neonatal Lung Pathophysiology

Beverley Newman

## OVERVIEW

The respiratory system consists of conducting and gas exchange components, with the bifurcating airways and accompanying pulmonary arteries (PAs) bringing air and blood to peripheral capillary-lined airspaces for gas exchange. In understanding and evaluating pulmonary pathologic processes, it is useful to view the lung as consisting of multiple sets of branching trees including airways, arterial and venous pulmonary vasculature, systemic vasculature, and lymphatics.[1] This chapter reviews the developmental biology, clinical anatomy, and pathophysiology of the respiratory system. Medical lung diseases in the neonate are used as illustrative examples, although the relevance of the discussion extends to the entire pediatric age group and beyond.

There are a large number of causes of newborn respiratory distress. They have been classified as congenital and acquired, medical versus surgical, and intrapulmonary versus extrapulmonary/extrathoracic.[2–4] Chest radiographic findings are often nonspecific (Table 48.1); close clinical correlation is needed for intelligent interpretation.[3] This chapter will not exhaustively review neonatal lung disorders but rather selected conditions not covered elsewhere in this book that are relevant to the anatomy/physiology discussed.

## DEVELOPMENTAL BIOLOGY AND PATHOPHYSIOLOGY

### Airways

The larynx, trachea, and bronchi develop from a ventromedial diverticulum of the foregut known as the laryngotracheal groove. Proliferation of the laryngeal mesenchyme produces arytenoid swellings that grow toward the tongue, converting the primordial glottis into a T-shaped laryngeal inlet. In the infant, the larynx is high in location, with its inferior border located at the C4 level. During childhood, the larynx descends and eventually reaches its adult location at the C6–C7 level by age 15 years. Functions of the larynx include breathing, phonation, and protection of the lower airway against aspiration.[5–7]

The laryngotracheal groove grows caudally, forming the trachea. It lies ventral and parallel to the dorsal foregut, which becomes the esophagus. The separation of the trachea and esophagus progresses cranially and is complete by 6 weeks' gestation. The endodermal lining will produce the epithelium and glandular structures of the trachea, whereas the connective tissue, cartilage, and smooth muscle come from the surrounding splanchnic mesenchyme.[5–7] Faulty separation of the trachea and esophagus gives rise to esophageal atresia/tracheoesophageal fistula (see Chapter 96). Disproportionate growth of the esophagus at the expense of the trachea may give rise to tracheal stenosis or, in the most severe form, tracheal agenesis (see Chapter 52).

### Lungs

The lung bud arises from the caudal end of the laryngotracheal groove by the end of the fourth week and soon divides into two bronchial buds.[5,8,9] The bronchial buds grow laterally into the pericardioperitoneal canals. Early in the fifth week, the connection of the bronchial buds to the trachea enlarges to form the mainstem bronchi. The right main stem bronchus bifurcates into a superior secondary bronchus, supplying the right upper lobe and an inferior secondary bronchus that subdivides into two bronchi, supplying the right middle and lower lobes. The left main stem bronchus divides into two secondary bronchi that supply the upper and lower lobes of the left lung. The bronchi continue to divide, and all airway divisions are complete by 16 weeks' gestation (Fig. 48.1). Cartilage appears at 10 weeks in the trachea and is found in the segmental bronchi by 16 weeks. Unequal growth of the lung buds can lead to the development of unilateral pulmonary agenesis or hypoplasia. Prolonged oligohydramnios, space-occupying thoracic or abdominal lesions that compress one or both hemithoraces, chest wall deformities, neuromuscular disorders, and conditions producing PA hypoperfusion are associated with pulmonary hypoplasia.[5,8,10,11]

Lung development has been divided into five stages (Table 48.2). After completion of tracheobronchial and peripheral airway branching during the embryonic (26–52 days) and pseudoglandular (52 days–16 weeks) stages, the bronchi and terminal bronchioles enlarge during the canalicular stage (17–28 weeks). The capillary bed begins to approximate the future air spaces, and gas exchange is possible. Type I and type II pneumocytes can be identified in the fetal lung by 20 to 22 weeks, but the capillary-alveolar interface is not adequate for extrauterine survival until 23 to 24 weeks of gestation.[5,8,9,12]

The saccular stage (29–36 weeks) is characterized by the development of terminal air sacs with flattening of the epithelium in the distal air spaces. The type II pneumocytes produce surfactant, which is stored as lamellar bodies. During the alveolar stage (36 weeks to infancy), the size and number of alveoli increase. When birth occurs at full term, it is estimated that 50 million alveoli are present. Alveolar formation continues postnatally until about 8 years, with most development in the first 2 years of life. The mature human lung ultimately has 300 million alveoli. Further lung growth occurs via enlargement of existing lung components (Table 48.3).

Acinar or alveolar dysplasia and alveolar capillary dysplasia (ACD) are rare, usually lethal disorders with early lung developmental arrest with lack of normal formation of terminal air spaces and distal vessels resulting in markedly impaired gas exchange. In ACD, there is often misalignment of the pulmonary veins centrally adjacent to pulmonary arterioles and bronchioles instead of their normal peripheral interlobular location[11,13,14] (see Chapter 56).

## Surfactant

Surfactant is composed of phospholipids, protein, and neutral lipids (e-Fig. 48.2). Surfactant lines the alveoli and decreases surface tension, which leads to decreased work of breathing and stabilizes the terminal air spaces, preventing alveolar atelectasis, especially at low lung volumes.[15] Surfactant can be detected as early as 24 to 26 weeks' gestation, although mature surfactant usually is not present until 34 to 36 weeks' gestation. Surfactant maturation can be affected by a variety of substances. Insulin delays surfactant maturation (propensity for infants of diabetic mothers to have surfactant deficiency), whereas other substances, such as glucocorticoids and thyroid hormone, accelerate it.[16] Administration of glucocorticoid to mothers 24 to 48 hours before preterm delivery accelerates surfactant maturation and results in a significant decrease in the incidence and severity of respiratory distress syndrome of the newborn (RDS), also known as hyaline membrane disease or

**TABLE 48.1** Common Medical Diseases of the Newborn Chest[2]

| Pattern | Lung Disease* |
|---|---|
| Hazy granular | RDS<br>Pneumonia<br>CHF |
| Confluent alveolar | RDS<br>Pneumonia<br>Hemorrhage<br>CHF |
| Patchy opacities | Aspiration<br>Pneumonia<br>Hemorrhage |
| Streaky interstitial | TTN<br>Pneumonia<br>CHF |

*RDS, CHF, and TTN tend to be symmetric. Aspiration and hemorrhage tend to be asymmetric. Pneumonia can mimic almost all patterns.

*CHF*, Congestive heart failure; *RDS*, respiratory distress syndrome; *TTN*, transient tachypnea of the newborn.

**TABLE 48.2** Classification of Phases of Human Intrauterine Lung Growth

| Phase | Time of Occurrence | Significance |
|---|---|---|
| Embryonic | 26–52 days | Development of trachea and major bronchi |
| Pseudoglandular | 52 days to 16 wk | Development of remaining conducting airways |
| Canalicular | 17–28 wk | Development of vascular bed, framework of acinus; flattening of epithelium |
| Saccular | 29–36 wk | Increased complexity of saccules |
| Alveolar | 36 wk to term | Presence and development of alveoli |

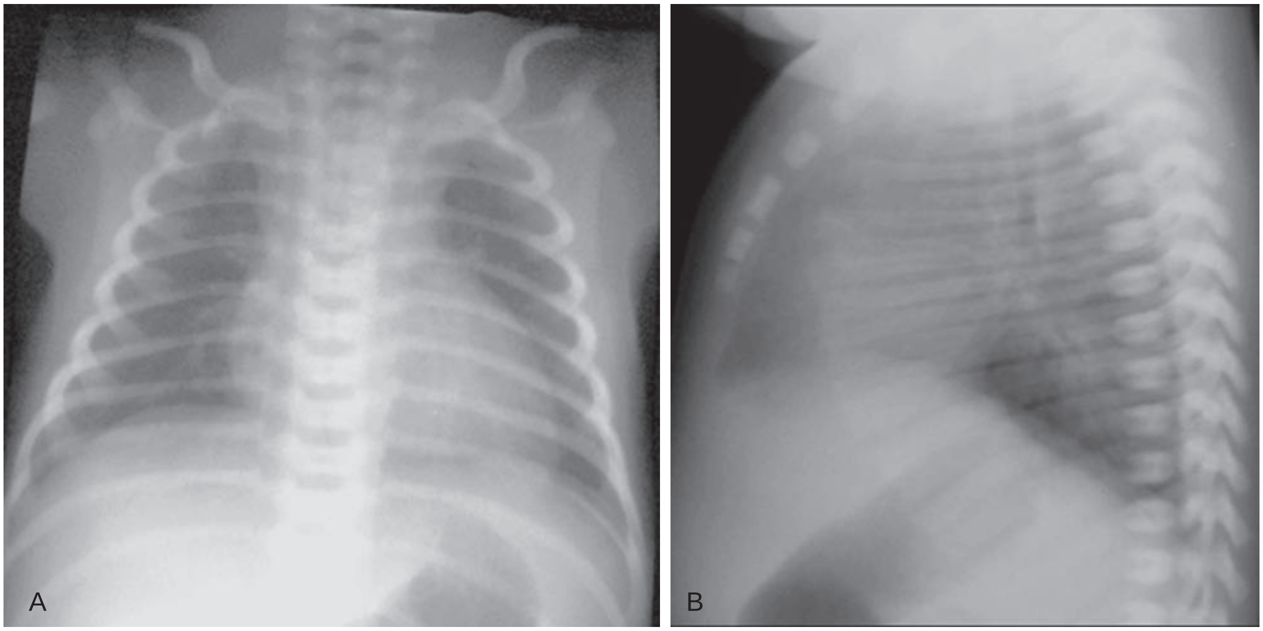

**Figure 48.3. Normal newborn chest radiograph.** Normal frontal (A) and lateral (B) newborn chest radiographs. Aeration is typically six to eight anterior ribs. The central pulmonary vessels are distinct and not enlarged. The lungs are symmetric and clear, and the airways are visible. The superior mediastinum often appears wide due to normal thymus, but there is no mass effect. Similarly, the cardiac silhouette may look slightly prominent on frontal view (due to thymus) but not on lateral (thymus anterior). The bony structures are normal, and the ribs horizontal.

surfactant deficiency disease.[12] RDS is largely encountered in premature infants less than 36 weeks' gestation related to absence or immaturity of pulmonary surfactant. Other risk factors include maternal diabetes, multigestation, and caesarian section. Secondary surfactant insufficiency also may accompany asphyxia, infection, and meconium aspiration.[3] RDS of prematurity is characterized clinically by cyanosis, tachypnea, and retractions within a few hours of delivery. As opposed to the normal radiographic appearance of the newborn chest radiograph (Fig. 48.3), the lungs in RDS are underinflated and without therapeutic intervention exhibit diffuse ground glass opacity ranging from mild fine granularity to complete lung opacification with air bronchograms (Fig. 48.4) (see Table 48.1).[2–4,12] Tracheal instillation of exogenous surfactant can ameliorate the natural course of RDS significantly.[3,17] With early treatment including continuous positive airway pressure (CPAP) and surfactant at birth, underaeration may be less apparent radiographically, and a more coarse granular lung pattern is seen due to partial reaeration of alveoli. Because of nonuniform distribution of surfactant, lung involvement may become patchy or asymmetric (Fig. 48.5).[2,3,12] Other complications including atelectasis, air leak such as pulmonary interstitial emphysema, pneumomediastinum, pneumothorax and pneumopericardium, as well as pulmonary edema related to shunting through a patent ductus arteriosus, pulmonary hemorrhage, and superimposed infection may occur during the course of the disease and its treatment. The incidence and severity of these are somewhat modified with modern management.[2,3,12] Progression of neonatal lung disease (not confined to RDS) to chronic lung disease is less common and less severe than was encountered previously, especially in more mature infants. However, the survival of very small premature infants, as young as 23 to 24 weeks with very immature lungs, has resulted in a different pattern of chronic lung disease, reflecting arrested and disordered alveolar and pulmonary vascular development (see Chapter 56).[12,13]

In addition, there are a number of rare congenital genetic disorders of surfactant production and metabolism that may be causes of respiratory distress and diffuse hazy lung opacification, usually in the term neonate (see Chapter 56).[13]

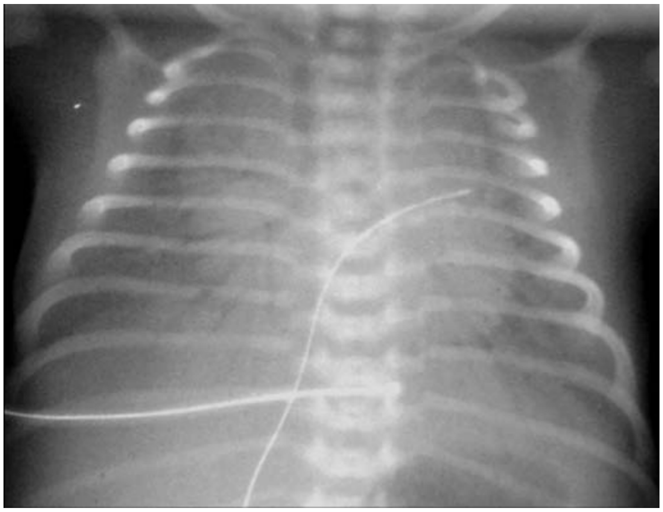

**Figure 48.4. RDS in a premature 29-week-gestation newborn infant.** The lungs are underaerated with symmetric ground-glass opacification. Note central air bronchograms.

## Fetal Lung Liquid

The fetal lung is filled with fluid during gestation. This fluid is produced by pulmonary epithelial cells, and its composition is different from that of amniotic fluid.[18] As the fetus matures, surfactant can be found in this lung fluid. Fetal lung liquid is under higher pressure than amniotic fluid, and efflux of lung liquid into the amniotic fluid occurs, forming the basis of amniotic fluid analysis for surfactant to determine fetal pulmonary maturity.

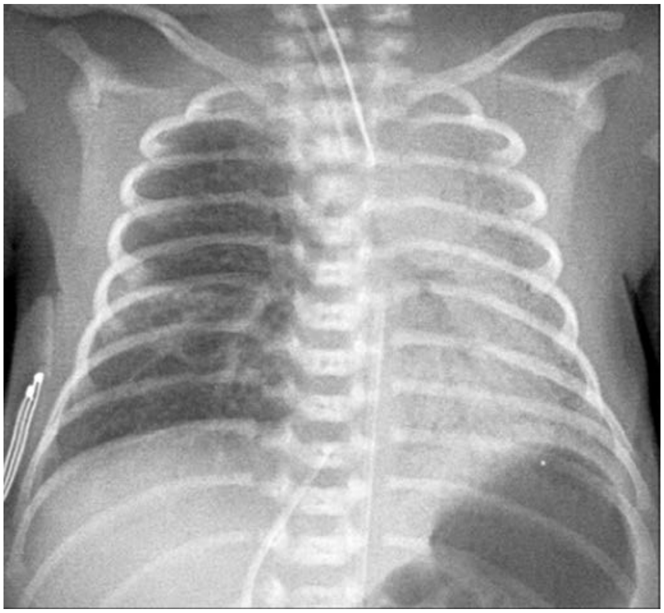

**Figure 48.5. RDS with asymmetric clearing post surfactant in a 26-week-gestation infant.** Note UA and UV lines in place with tips in the descending aorta and IVC/right atrial junction, respectively. A hazy granular pattern is seen on the left consistent with persistent RDS, with partial reaeration on the right with a more coarse streaky appearance. The hyperlucent right lung raises the question of possible airleak such as anterior pneumothorax. No pneumothorax was present on a later decubitus view *(not shown)*. However, the right perihilar linear lucencies may represent mild interstitial emphysema.

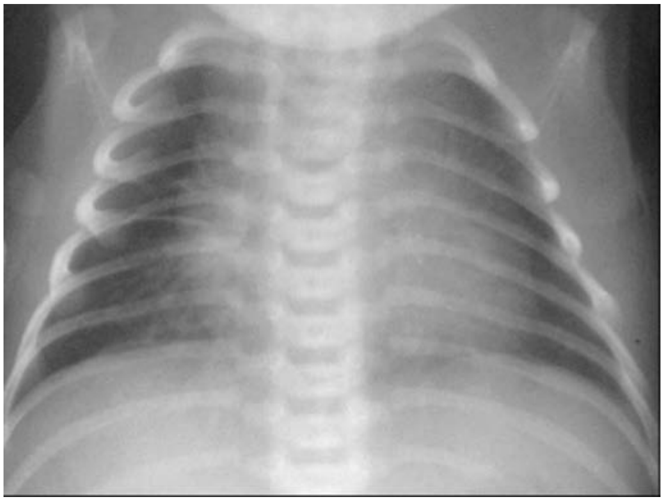

**Figure 48.6. Transient tachypnea of the newborn (TTN) in a full-term infant born by cesarean section.** There are mild streaky interstitial markings, right greater than left, with fluid in the minor fissure. Note prominent thymus with thymic wave appearance at margins. The lungs cleared by day 2 of life *(not shown)*.

Removal of liquid from the lung begins shortly before delivery and continues for several hours after delivery. The majority of the lung fluid is expelled during passage through the birth canal. The major routes for postnatal clearance of fetal lung fluid are the pulmonary circulation and lymphatics. Delayed clearance of fetal lung fluid results in mild to moderate respiratory distress and is seen more commonly in infants delivered by cesarean section. This disorder, also known as transient tachypnea of the newborn, is predominantly seen in full-term infants and is characterized radiographically by transient abnormality (usually normalizes in 24–48 hours) with a similar appearance to mild pulmonary edema including mild hyperinflation, increased perihilar markings, and small pleural effusions, features likely related to the presence of fluid in lymphatic channels (Fig. 48.6).[2–4]

## Pulmonary Vasculature/Circulation

The fetal lung is the only organ that does not perform its postnatal function before birth. All gas exchange occurs via the placenta and oxygenated blood returns to the fetus via the umbilical vein to the ductus venosus, inferior vena cava (IVC), and right atrium (RA). Most of the IVC return entering the RA crosses the foramen ovale into the left atrium. The remaining IVC and superior vena cava (SVC) blood flow to the RA enters the right ventricle. Most of the right ventricle output crosses the ductus arteriosus (DA) into the aorta. These shunts at the foramen ovale and DA result in most of the fetal cardiac output bypassing the lungs (see Chapter 70).[19]

Dramatic pulmonary circulatory changes occur at delivery. The lungs expand with air, the partial pressure of oxygen rises, and the umbilical cord is clamped. These changes result in a decrease in pulmonary vascular resistance, ductal constriction, and functional closure of the foramen ovale so that all of the blood entering the RA passes through the lungs. In term and near-term infants, this process may go awry with the persistence of high pulmonary vascular resistance and continued shunting of blood away from the lungs via the foramen ovale and DA. This mechanism results in hypoxemia and is known as persistent pulmonary hypertension of the newborn. It usually is seen in infants with underlying pulmonary hypoplasia (e.g., congenital diaphragmatic hernia) or with perinatal stresses such as asphyxia, often associated with meconium aspiration, infection, or hypoglycemia.[2,3] Management of persistent pulmonary hypertension of the newborn currently is aimed at treating the underlying disease and promoting pulmonary vasodilatation. Inhalation of nitric oxide often results in relaxation of the pulmonary vasculature with improved oxygenation. Infants who do not respond to conventional treatment or nitric oxide frequently require extracorporeal membrane oxygenation. Persistent pulmonary hypertension in and of itself does not produce characteristic radiographic findings; the lungs may be clear or exhibit oligemia. Radiographs may show cardiomegaly and congestion in the presence of significant myocardial ischemia. In meconium aspiration, typical findings include hyperinflation and asymmetric patchy opacities with or without airleak (Fig. 48.7). Acute infection (e.g., group B Streptococcus) can have a variable appearance ranging from streaky interstitial or scattered patchy to diffuse granular changes mimicking many other neonatal lung conditions (Fig. 48.8) (see Table 48.1).[2–4]

# CLINICAL ANATOMY

## Airways

Basic airway anatomy to the level of the terminal bronchiole (the last purely conducting, i.e., nonalveolated, airway) is not substantially different in children compared with adults except in size. The right lung has three lobes, and the left lung has two lobes (Fig. 48.9). The pleural fissures separating the lobes of the lungs often are anatomically incomplete. Portions of the fissures occasionally are radiographically visualized as fine lines in healthy infants. The lungs are subdivided further into 8 to 10 segments on the left and 10 on the right, each served by a segmental bronchus (Figs. 48.10 and 48.11).[20–22]

The trachea, which is the largest of the conducting airways, is a fibromuscular tube lined principally by ciliated columnar

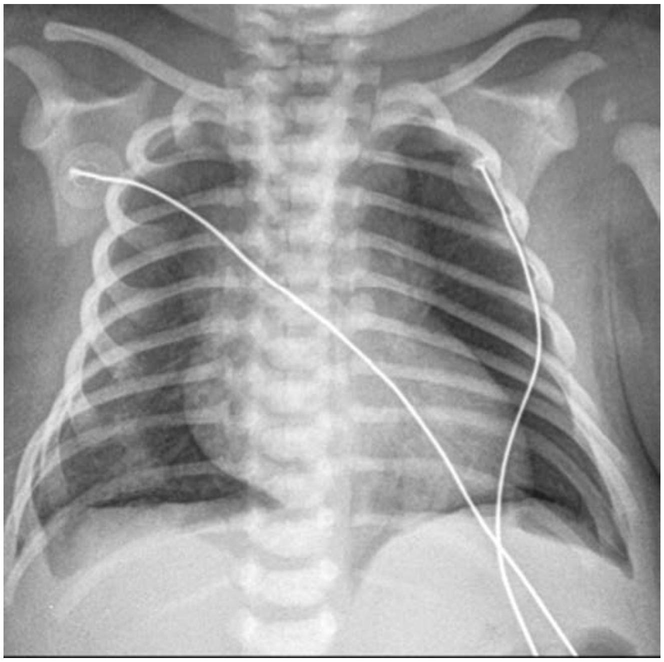

**Figure 48.7. Perinatal asphyxia and meconium aspiration during delivery in a full-term newborn with respiratory distress at birth.** There are streaky increased interstitial markings with patchy opacities at both lung bases consistent with meconium aspiration. In addition, there are bilateral pneumothoraces as evidenced by the hyperlucent left and medial right hemithoraces, subpulmonic air bilaterally, with accentuation of the inferior pleural margins.

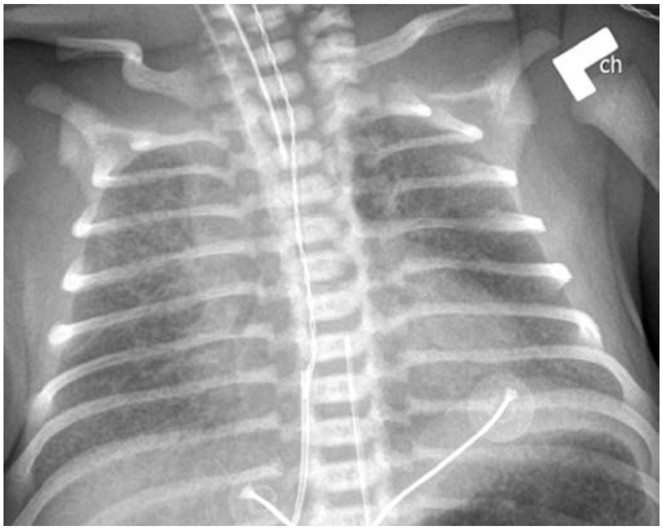

**Figure 48.8. Group B streptococcal pneumonia in a full-term newborn.** The lungs are mildly underaerated with diffuse hazy to streaky bilateral opacities. No pleural effusion is evident (a common finding in neonatal pneumonia).

epithelium and mucous cells. The trachea is supported by 16 to 20 cartilaginous rings, which are incomplete posteriorly, where the tracheal wall is composed of fibrous, muscular, and elastic tissue. The trachea extends from the cricoid cartilage at the C4 level to the carina near the T4 level at birth and at a lower level with increasing age. Congenital tracheal stenosis is characterized by complete cartilaginous rings; a short or long segment may be affected (see Chapter 52). The tracheal cross-sectional area has been analyzed by computed tomography (CT) and grows predictably with age.[23,24] The cross-sectional shape may vary considerably in the normal population and depending on the phase of respiration.[25]

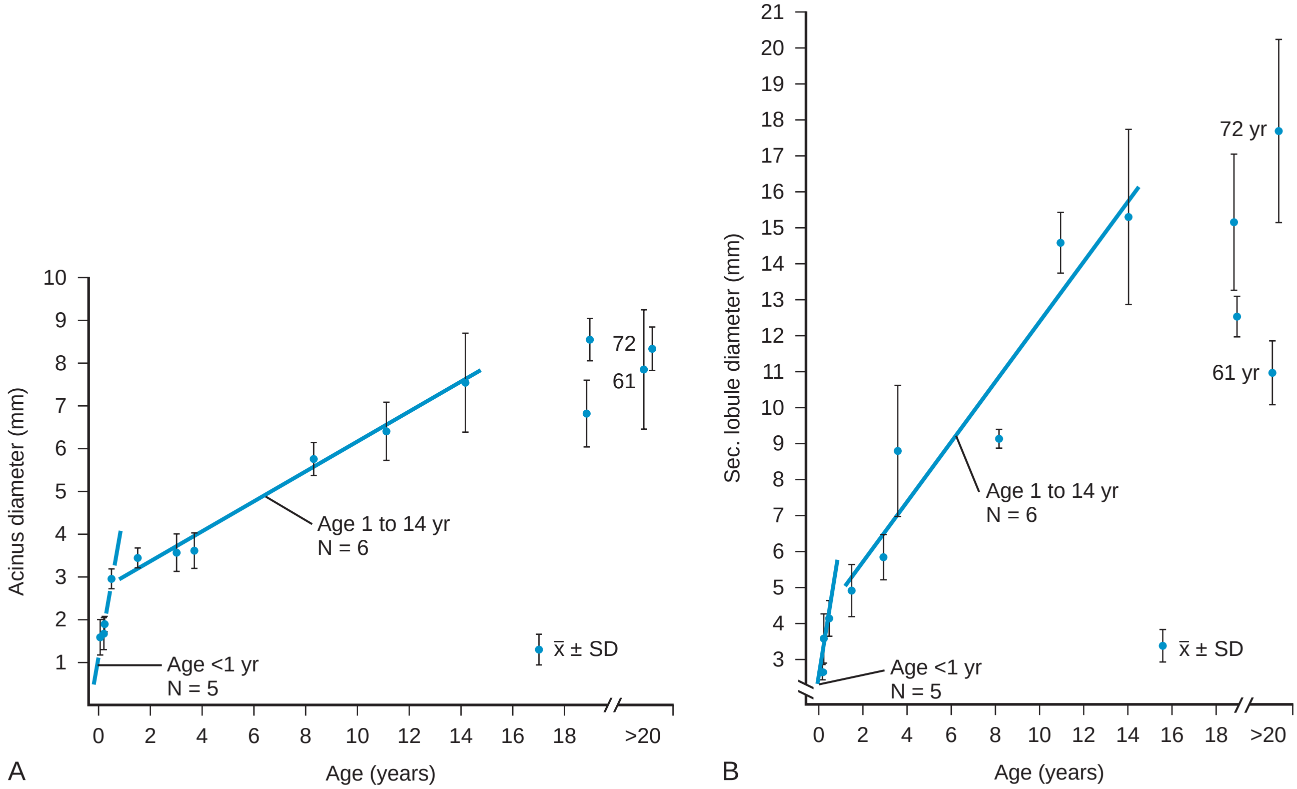
The first four bronchial generations (through the segmental branches) are strongly supported by cartilaginous plates that aid in keeping the bronchi patent. The smaller cartilaginous bronchial branches, from the fifth to the eleventh generation, double in number with each branching generation and decrease in size down to approximately 1 mm in diameter (Fig. 48.12).[26] They are in a common fibrous sheath with an accompanying PA branch.

The bronchioles are the conducting airways that extend to the sixteenth generation and lack cartilage in their walls. They are dependent for their patency on the support of the surrounding lung parenchyma. As the lung expands, the bronchioles dilate. Unless they are abnormal, bronchioles are usually not visible on imaging beyond the eighth generation (1.5 mm) (see Fig. 48.12). The last purely conducting branch of the airway is the terminal bronchiole, which arborizes into three generations of respiratory bronchioles, each giving rise to progressively greater numbers of alveoli. The alveoli and the alveolar ducts and sacs that give rise to them constitute the gas-exchange portion of the lung (see Fig. 48.12).

## The Respiratory Portion of the Lungs

The two subunits of the peripheral airspaces that are most important to the radiologist are the acinus and the secondary pulmonary lobule. The alveolus, which in an adult averages approximately 200 to 300 µm in diameter, is below the limits of visibility on imaging. The acinus is the unit of lung tissue peripheral to the terminal bronchiole and consists of a cluster of 50 to 400 alveoli. It occasionally is visible in the pediatric lung and typically ranges in diameter from 1 to 2 mm in infants younger than 1 year old to 7 to 9 mm in adolescents and adults (Fig. 48.13 and e-Fig. 48.14).[27]

The secondary pulmonary lobule is a cluster of about 3 to 24 acini that are separated from other lobules by interlobular septa composed of fibrous tissue. The secondary lobules and their septa are much better developed in the periphery of the lung than in the center. The mean diameter of the secondary lobule at birth is 3 mm and by 12 years measures 15 mm (see e-Fig. 48.14).[27] The pulmonary veins and lymphatics course through the interlobular septa, and the PAs and bronchioles are positioned centrally within the lobule (see Fig. 48.13). Thickened septa are visible on



**e-Figure 48.14. Size of the pulmonary acinus and secondary lobule in children.** The relationship of mean acinar diameter (A) and secondary lobular diameter (B) with respect to age. *SD,* Standard deviation. *(From Osborne DRS, Effmann EL, Hedlund LW. **Figure 48.11. Bronchopulmonary segments as seen on the surface of the lungs.** (A) Lateral surface. (B) Medial surface. (C) Base or diaphragmatic surface. *(Adapted from Boyden EA.* The segmental anatomy of the lungs, *New York: McGraw-Hill; 1955; and from Rosse C, Gaddum-Rosse P.* Hollingsched's textbook of anatomy, *5th ed, Philadelphia: Lippincott-Raven; 1997:457.)*

chest radiographs as Kerley B lines and directly on high-resolution CT (Fig. 48.15).

Multiple imaging modalities have been used to determine prenatal and postnatal lung volumes and growth. CT postprocessing tools can provide accurate measurement of lung volume as well as sizes of airway wall/lumen and arterial area from an axial multidetector CT dataset.[28–30]

Mean CT density decreases with age and increases in an anterior to posterior gradient in a quietly breathing supine child.[31] Patient age, anterior versus posterior location, and apical versus basal location are significant predictors of regional lung density at inspiratory and expiratory volumes.[32]

Collateral ventilation can occur across pulmonary segments because no pleurae separate them. It also may occur between lobes when fissures are incomplete. There are three routes of collateral ventilation: (1) alveolar pores of Kohn (2- to 10-microns circular apertures in the alveolar walls); (2) canals of Lambert (epithelial-lined tubular structures between preterminal, terminal, or respiratory bronchioles and the alveoli surrounding them); and (3) direct small airway anastomoses.[21] Collateral ventilatory pathways are less well developed in young infants than in older children and adults.

## Pulmonary Vasculature/Circulation

The pulmonary circulation develops in concert with the airways, as the two systems are strongly interdependent (see Chapter 53). The development of the vascular system of the lung requires exquisite regulation of cell migration, proliferation, and differentiation; complex molecular pathway interactions are just beginning to be elucidated.[14] The lung has a dual blood supply consisting of a PA and a systemic arterial supply. The main PA arises from the right ventricle distal to the pulmonic valve and forms a segment of the left heart border before it bifurcates at the level of the carina. The left PA curves superiorly and posteriorly to the left hilum anterior to the left main bronchus, where it divides into two branches. The lower branch is directed posteriorly and crosses over the left upper lobe bronchus, descending parallel with but lateral to the left lower lobe bronchus. This vessel gives branches to the lingula segment, to the superior segment of the lower lobe, and to the basilar segments. The smaller superior branch divides, and its branches parallel the bronchial divisions to the upper lobe. The right PA is almost horizontal and divides into its two major branches while still within the pericardium. It lies posterior to the ascending aorta and SVC, and anterior to the right main bronchus. The main upper lobe branch, the truncus anterior, ascends anterior to the right upper lobe bronchus and subdivides into three branches that parallel the three segmental bronchi to the right upper lobe. The largest branch of the right PA is the interlobar artery, which passes anterior to the bronchus intermedius and descends lateral to it, giving branches, in order, to the middle lobe, the superior segment of the lower lobe, and four branches to the basilar segments of the right lower lobe.

In the lung parenchyma, the PA branches travel and divide with the bronchial branches, although they also give off unaccompanied supernumerary branches. There are approximately 23 divisions of airway branching and approximately 28 divisions of PA branching. These vessels can be visualized on high-resolution CT to about the level of the sixteenth generation, which is a few millimeters from the pleural surface and corresponds to the level of the terminal bronchioles, allowing identification of the secondary pulmonary lobule (the parenchyma supplied by three to five or more terminal bronchioles). The arterioles continue to divide until they form a dense capillary network surrounding the alveolus. This network ultimately consists of 280 billion capillary segments with a total blood volume of 140 mL; pulmonary blood volume can nearly double during exercise.[33]

The primary role of the pulmonary circulation is to transport deoxygenated blood from the heart to the alveolar capillaries, where oxygenation occurs, and then transport oxygenated blood through the pulmonary veins back to the left atrium. The pressure in the pulmonary circuit is about one-sixth that of the systemic circuit; total pulmonary blood flow is determined primarily by cardiac output, although the control of pulmonary blood flow is complex and also depends on the relative systemic and pulmonary pressures, gravity, and local pulmonary factors. Large numbers of lung capillaries normally are not perfused or are only minimally perfused, which allows for increased arterial flow without increased PA pressure. Gravity is an important determinant of regional pulmonary blood flow, with the more dependent regions receiving

**Figure 48.12. Bronchial generations.** The bronchi and airways from the fourth generation (the segmental bronchus) to the last generation (the alveolar sacs and alveoli) are represented. Bronchi contain cartilage within their walls, to the level of small (3-mm diameter) subsegmental branches. They are readily visible on high-resolution computed tomography (HRCT). Bronchioles, which do not contain cartilage but rather an extensive network of fibers within their walls, are seen only to the eighth generation, which corresponds to a diameter of about 1.5 mm. Beyond the eighth generation, the bronchiolar walls are not visible by HRCT unless they are abnormal. The terminal bronchioles are the sixteenth-generation bronchioles and conduct air into the lobules. Beyond the terminal bronchioles, four to eight respiratory bronchioles lead to distal acini. Respiratory bronchioles are characterized by the presence of outpouchings representing alveolar ducts and terminal groupings of alveolar sacs. *(From Armstrong P. The normal chest. In: Armstrong P, Wilson AG, Dee P, et al, eds.* Imaging of Diseases of the Chest, *3rd ed, London: Mosby; 2000:26.)*

a greater volume of blood. The smaller, muscular PA branches vasoconstrict under conditions of hypoxia in an attempt to maintain the ventilation-perfusion balance. When lung disease becomes severe enough, this protective mechanism is overwhelmed, and poorly ventilated alveoli are perfused, which results in right-to-left shunting and systemic desaturation. Hypoxemia and accompanying acidosis increase pulmonary vascular resistance, which leads to right ventricular hypertrophy and eventually to cor pulmonale.

The vast pulmonary capillary bed serves the function of gas exchange. Its endothelial cell lining has important metabolic functions and is quite sensitive to toxins, including infectious agents and high oxygen concentrations. When endothelial cells are damaged, increased permeability pulmonary edema often results.[2]

The pulmonary venous radicles arise distal to the capillary meshwork and travel in the interlobular septa, which form the walls of the secondary pulmonary lobules; the veins do not accompany the PA and bronchial branches. They drain toward the hilum and gradually increase in size. Usually two large central pulmonary veins are found on each side. The upper lobe veins are more vertical in orientation, and the lower ones are more horizontal before they enter the left atrium. The right superior vein is located posterior to the SVC and anterior to the right interlobar PA. The left superior pulmonary vein is located anterior to the left main PA and is just anterior to the left upper lobe bronchus. The right inferior branch enters the left atrium anterior to the right lower lobe bronchus, and the left inferior pulmonary vein enters the left atrium at a point just anterior to the descending aorta and posterior to the left lower lobe bronchus.

The systemic circulation to the lung is via two to four (most commonly one right and two left) bronchial arteries that are branches of the thoracic aorta. These vessels provide blood supply to the airways and central mediastinum. In the presence of PA obstruction, collateral circulation to the pulmonary capillaries can develop through precapillary anastomotic channels.

## Lymphatics

Pulmonary lymphatics are essential to removal of initial fetal lung liquid and to the removal of protein and water outside the vascular space.[34,35] This fluid is returned to the circulation via the right lymphatic duct and the thoracic duct. Lymphatic vessels travel beside blood vessels in the bronchovascular spaces and in the connective tissues of the pleura. No lymphatics are present within the alveolar walls, but juxta-alveolar lymphatics represent the initial part of the lung lymphatic system. Enlargement of lymphatic channels in secondary lobular septa may be visualized on chest radiography and with CT (see Fig. 48.15). Lymphangiectasia and lymphatic malformations may be primary, congenital, or acquired related to

(B) A 15-year-old girl with mixed connective tissue disease shows moderately severe septal thickening and patchy distribution of ground-glass opacities within some lobules.

absent, malformed, obstructed, congested, or disrupted lymphatic channels.[13,36] Some genetic syndromes especially Turner, Noonan, and Down syndrome are associated with lymphatic abnormalities. Dilated pulmonary/pleural and/or mediastinal lymphatics, focal lymphatic collections, and chylothorax may produce mild to severe respiratory distress (see Chapters 55 and 56).

## KEY POINTS

- An understanding of normal airway and pulmonary development, physiology, and anatomy is essential in appreciating the clinical and imaging findings in pulmonary pathologic conditions.
- Airway, lung, and vascular development and physiologic function are interdependent and follow an orderly progression. Arrest or disruption of these processes often results in newborn respiratory distress with a wide variety of conditions including genetic disorders, congenital lung anomalies, thoracic compressive lesions, lung disease of prematurity, abnormal retention of fetal lung liquid, perinatal asphyxia, meconium aspiration, and pulmonary infection.
- The number of alveoli increases sixfold after birth with the process accelerated in early life and completed by age 8 years, with further lung growth by enlargement of existing lung components.
- Two clinically useful subunits of airspace disease are the acinus and secondary pulmonary lobule. The acinus is the unit of lung peripheral to the terminal bronchiole and consists of 50 to 400 alveoli, whereas the secondary lobule is a cluster of 3 to 24 acini separated by interlobular septa.
- The peripheral pulmonary vasculature divides and accompanies bronchial branching. It may be visualized to at least the sixteenth generation of division within a few millimeters of the peripheral surface and corresponds to the level of the terminal bronchioles.

# Imaging Techniques

*Hyun Woo Goo, Laura A. Drubach, and Edward Y. Lee*

## OVERVIEW

Various imaging modalities—conventional radiography, fluoroscopy, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine studies—are used to assess the pediatric respiratory system. Although having abundant air in the respiratory system is beneficial when performing conventional radiography, fluoroscopy, and CT, it complicates assessment of the respiratory system with ultrasound and MRI.

When answers to specific clinical questions are sought, radiologists and clinicians ideally should work together to select appropriate imaging modalities. Up-to-date knowledge about the advantages and disadvantages of each imaging modality should be carefully considered when making a selection because the imaging techniques for the pediatric respiratory system are continuously evolving. Furthermore, the imaging techniques should be tailored to the individual pediatric patient for optimal results. This chapter discusses indications, contraindications, benefits, risks, and other relevant issues pertaining to each imaging modality currently being used.

## CONVENTIONAL RADIOGRAPHY

Conventional radiography is the creation of a projection image with the use of x-rays to view parts of the human body. This primary, cost-effective imaging method currently is the modality used most frequently for evaluation of the respiratory system in children. Conventional radiography is associated with a very low level of ionizing radiation exposure (in the range of 0.01–0.02 mSv for chest posteroanterior [PA] radiography).[1,2] Soft tissue neck study and chest radiography are the two radiographic imaging studies used most frequently to assess the pediatric respiratory system.

### Soft Tissue Neck Study

Inspiratory stridor resulting from an upper airway obstruction is the most frequent indication for a soft tissue neck study in pediatric patients.[3] The common causes of inspiratory stridor in infants and children include croup, epiglottitis, a foreign body, and an upper airway mass. To obtain optimal diagnostic quality, the neck of the patient should be extended and images should be obtained at full inspiration. The standard views consist of both an anteroposterior (AP) view and a lateral view. An additional expiratory lateral view of the neck subsequently may be obtained; this can be helpful in differentiating a fixed large airway disorder (e.g., subglottic stenosis) from a dynamic large airway disorder (e.g., tracheomalacia).

Use of the high-kilovoltage technique with added filtration and coned magnification may facilitate visualization of the upper airway and adjacent soft tissue. Immobilization may be necessary for infants and young children (<5 years) who may not be able to follow verbal instructions. However, great care should be taken not to exacerbate airway obstruction when positioning a child with respiratory distress. For instance, the upright position is preferred and the supine position is contraindicated in the setting of acute epiglottitis. When necessary, careful manual immobilization of the head and neck during the study by the child's parents or by an experienced technologist may be considered. A clinician should accompany the child with respiratory distress, and an emergency kit should be available in the examination room. In most conditions resulting in upper airway obstruction in pediatric patients, a soft tissue neck study is sufficient to make the diagnosis. However, when the underlying cause of upper airway obstruction is not evident, fluoroscopy, CT, or MRI may be necessary as a next step in the imaging evaluation.

### Chest Radiography

Chest radiography is the imaging study obtained most frequently to evaluate the respiratory system in pediatric patients. Immobilization is usually required in uncooperative infants and young children (<5 years) to achieve consistent image quality by decreasing motion artifacts and poor positioning.[4] Chest radiography is obtained during quiet inspiration in uncooperative infants and young children, and during full inspiration in cooperative older pediatric patients. The standard chest radiographic views consist of the AP view in infants and young children (<5 years) and either AP or PA views in older children, in addition to a lateral view. AP, PA, and lateral views of the chest can be obtained with the patient in the supine or erect position. Exposure parameters for chest radiography should be appropriately optimized. Unnecessary radiation to nonthoracic structures such as the lower neck, proximal upper extremity, and upper abdomen should be avoided by using appropriate collimation and shielding.[5,6]

In contrast to a radiographic screen-film system, image acquisition and display are decoupled in digital radiography, which allows increased versatility of image manipulations.[7,8] Recently, optimization of digital radiographic techniques has been emphasized to reduce unnecessary overexposure to pediatric patients.[6,9] The increased likelihood of overexposure in digital radiography, the so-called *dose creep*, is attributed not only to the lack of a standardized exposure index but also to the difficulty in recognizing overexposed radiographs by radiologic technologists and radiologists. Fortunately, a new standardized exposure index for digital radiography was proposed recently.[10]

Optimized techniques of digital chest radiography in children often are different from those in adults. For instance, automatic exposure control and grids are not particularly helpful in small pediatric patients. Additional views such as expiratory, decubitus, and oblique views sometimes are necessary to clarify abnormalities detected on standard AP or PA views or to solve unanswered clinical questions. Expiratory views may be used to confirm air trapping due to an underlying airway obstruction. The lateral decubitus view generally is used to detect freely shifting pleural effusion or air; it is used infrequently to demonstrate an air-fluid level in an intraparenchymal cavitary lesion. In addition, the lateral decubitus view may be used to demonstrate air trapping in the dependent lung or to clarify poorly defined lung opacities in the nondependent lung in uncooperative infants and young children.[11,12] Oblique views may be helpful for evaluating rib, soft tissue, hilar, carinal, and peripheral lung abnormalities.

## FLUOROSCOPY

Fluoroscopy can be used to evaluate dynamic large airway and lung abnormalities, such as airway obstruction, air trapping, and diaphragmatic paresis/paralysis. Use of fluoroscopic techniques and equipment should be optimized to minimize radiation exposure

## Abstract:

Various imaging modalities—conventional radiography, fluoroscopy, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine studies—currently are available and are used to assess the pediatric respiratory system in clinical practice. The presence of air in the airways and lungs can be beneficial and challenging with regard to imaging the respiratory system. Although having abundant air in the respiratory system is beneficial when performing conventional radiography, fluoroscopy, and CT, it complicates assessment of the respiratory system with ultrasound and MRI.

of both the patient and operator by following the “imaging gently” and “step lightly” principles.[13]

## Fluoroscopy-Guided Airway Study

A fluoroscopy-guided airway study may be helpful in demonstrating dynamic airway abnormalities, such as laryngomalacia, tracheomalacia, obstructive sleep apnea, and vocal cord dysfunction syndrome.[14-16] Additionally, a fixed airway disorder such as stenosis or stricture can be identified and differentiated from a dynamic airway disorder. Compared with endoscopic procedures, a fluoroscopy-guided airway study generally is inexpensive and less invasive.[17] In recent years, fluoroscopy-guided airway studies have begun to be replaced by dynamic airway CT with a low radiation dose technique.[18] Dynamic airway CT is more accurate than a fluoroscopy for evaluation of the location, degree, and extent of both the dynamic and fixed airway abnormalities. Furthermore, dynamic airway CT can provide additional information about other intrathoracic structures, which is a valuable benefit.[18]

## ULTRASOUND

Ultrasound (US) is a valuable and commonly used imaging modality for evaluating the chest in pediatric patients, because it is widely available, is relatively easy to perform, and does not expose patients to radiation.[19,20] Its real-time evaluation capability and portability are important additional benefits. Furthermore, crucial information regarding associated vascular structures or underlying blood flow also can be obtained with color Doppler US.[19,20] US is useful in assessing and triaging selected lung and pleural lesions, as well as juxtadiaphragmatic and mediastinal structures, as long as there is a sonographic window without intervening aerated lung.

### Evaluation of Lungs and Mediastinum

The main clinical indication for ultrasound of the lungs in pediatric patients is to characterize a peripheral lung opacity (i.e., parenchymal versus pleural disease) that has been detected with chest radiography.[19] Frequent underlying etiologies include atelectasis, consolidation, lung necrosis, a lung abscess, congenital lung lesions, and a primary or metastatic lung neoplasm (Fig. 49.1).[19,20] For evaluation of these abnormalities, conventional chest radiography should be carefully reviewed to localize the area of interest so the clinical question can be specifically answered with the US evaluation.[19,20] Lung US has shown utility as a primary imaging modality to diagnose pediatric pneumonia, and is also being used to assess for interstitial disease, whether from edema, inflammatory, or fibrotic processes.[21]

Ultrasound evaluation of the lungs typically is performed with the patient in the supine or upright position. However, to improve the visualization in some selected situations, the lateral decubitus view or the supraclavicular and/or suprasternal notch view may be beneficial. Optimal views can be achieved by placing a pillow or blanket on the dependent side or behind the shoulder to help extend the neck of the patient.[19] The choice of US transducer depends primarily on three factors: the age of the patient, the size of the patient, and the location of the abnormality.[19,20] Although curved or linear array transducers typically are used to evaluate peripheral lung opacity, smaller sector or vector transducers may be necessary for imaging in infants or young children who have a small available acoustic window (such as between the ribs). High-frequency transducers (e.g., 7.5–15.0 MHz) are helpful in evaluating the chest in infants and young children who do not have substantial subcutaneous tissue and provide higher resolution images.[19] Conversely, use of low-frequency transducers (e.g., <5 MHz) may be necessary when evaluating older children who required greater soft tissue penetration, although image resolution is decreased.[19] Color Doppler US is useful for evaluating lung lesions with underlying vascular structures in cases of pulmonary sequestration or blood flow in cases involving a neoplasm.

Mediastinal lesions can also be evaluated initially by US, especially in small children. One of the major uses of US is to differentiate normal thymus from a mediastinal mass and prevent further unnecessary CT or MRI. Characterizing lesions as cystic or solid is also useful.

### Evaluation of Pleura

In emergent and critical care settings, US can reliably detect a pneumothorax, and may be more sensitive than radiography in supine patients.[20,22] US can be useful in differentiating pleural fluid from atelectasis and/or consolidation when the diagnosis is equivocal on the basis of conventional radiography. Furthermore, US is more sensitive and accurate than conventional radiography or CT for characterizing pleural fluid, which may be simple or complex (Fig. 49.2).[19] US evaluation of patients in both the erect and lateral decubitus positions can be useful for differentiating between freely flowing and loculated pleural fluid. In addition, ultrasound can visualize the internal debris, septations, and pleural thickening often associated with parapneumonic collections. Such complex pleural effusion often requires a drainage procedure that can be facilitated with ultrasound guidance.

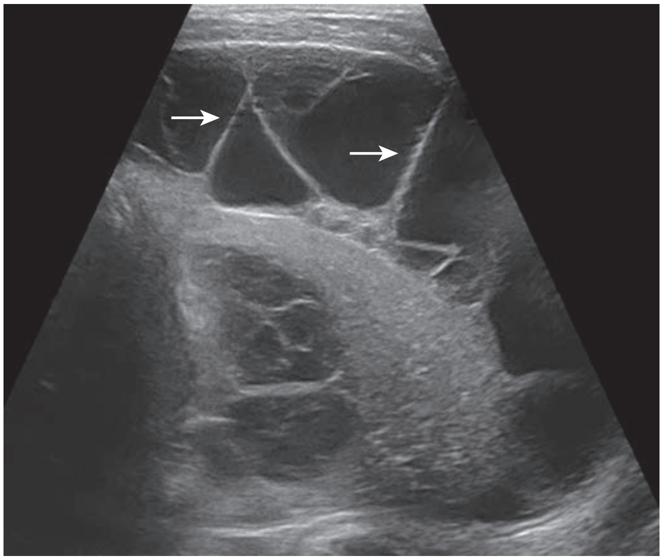

**Figure 49.2. Ultrasound for pleural fluid in a 5-year-old boy with recurrent pneumonia in the right lung.** Longitudinal sonogram of the right hemithorax shows a complex pleural effusion with thick septations *(arrows)*.

## COMPUTED TOMOGRAPHY

CT is a valuable cross-sectional imaging study for evaluating the pediatric chest, mainly because its images provide excellent air-tissue contrast. Current multidetector CT allows short scan times with a decreased rate of sedation, and has increased the role of CT assessment of pediatric airways and lungs.[23] Respiratory motion artifacts can degrade CT image quality in infants and young children who breathe freely during the scan. These artifacts can be reduced with the use of general anesthesia and controlled ventilation.[24,25] These techniques also can be used to control either the inspiratory or expiratory phases of respiration.[24-26] In addition, newer high-pitch dual-source spiral CT scanning is very helpful in reducing motion artifacts on non–breath-hold chest CT scans in children.[27] Virtual monoenergetic dual-energy CT with energy domain noise reduction can provide higher iodine contrast-to-noise ratio compared with conventional single-energy CT further improving image quality (Fig. 49.3).[28]

Reducing the CT radiation dose while maintaining diagnostic image quality is of critical importance in pediatric patients because of the greater radiosensitivity and longer life expectancy of children, coupled with increasing CT use. Low-dose, body size–adapted chest CT protocols using variable tube voltages and tube currents have been established, usually on the basis of body weight.[29,30] However, recent studies demonstrate that cross-sectional dimensions provide better CT dose adaptation to body habitus.[30-34] The tube current always should be modulated if applicable because this allows CT dose reduction without degrading image quality.[35-37] Electrocardiogram-triggered sequential scanning may be used in CT of the chest in children to achieve fewer motion artifacts and a lower radiation dose.[25,38]

CT image quality may be further improved by adjusting kilovolt levels and reconstruction algorithms: a low kilovolt level for contrast-enhanced CT and a high kilovolt level for unenhanced CT, a high-frequency reconstruction algorithm for lung evaluation, and a standard reconstruction algorithm for mediastinal evaluation. In addition to axial CT images, postprocessed and reconstructed images such as multiplanar reformatted (MPR) and

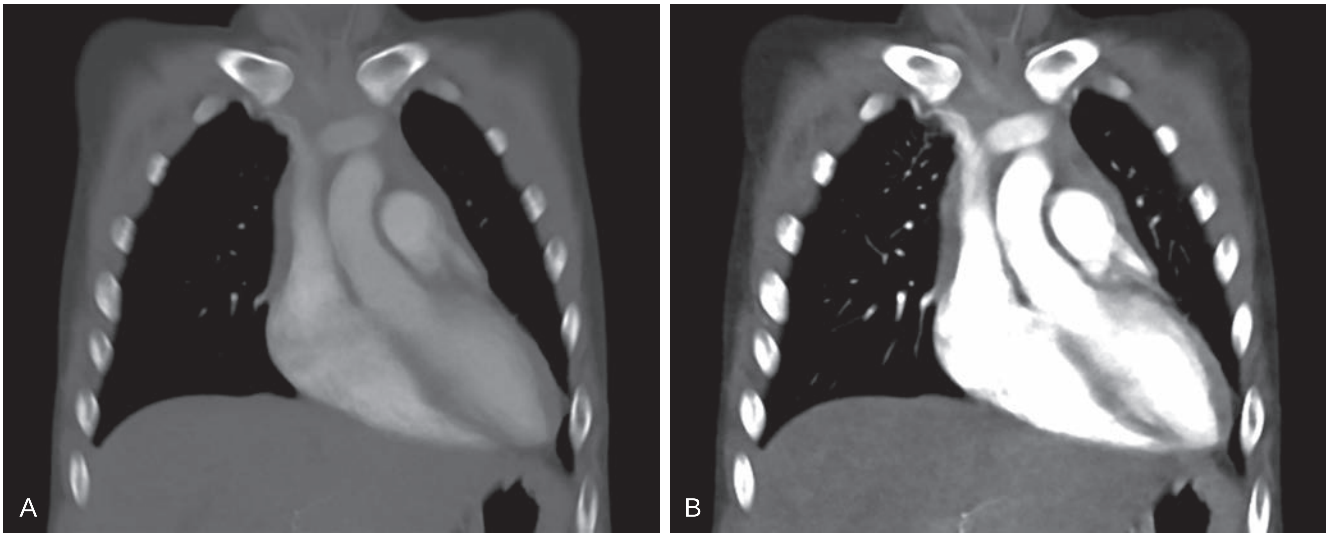

**Figure 49.3. Coronal dual-energy enhanced chest CT (window level, 200 HU; window width 1000 HU) using dual-source technique (80 kVp and 140 kVp with tin filter).** Compared with linear blending image (A) with mixed ratio of 0.4 (40% from 80 kVp data), virtual monoenergetic 40 keV image (B) with energy domain noise reduction demonstrates markedly increased iodine contrast-to-noise ratio.

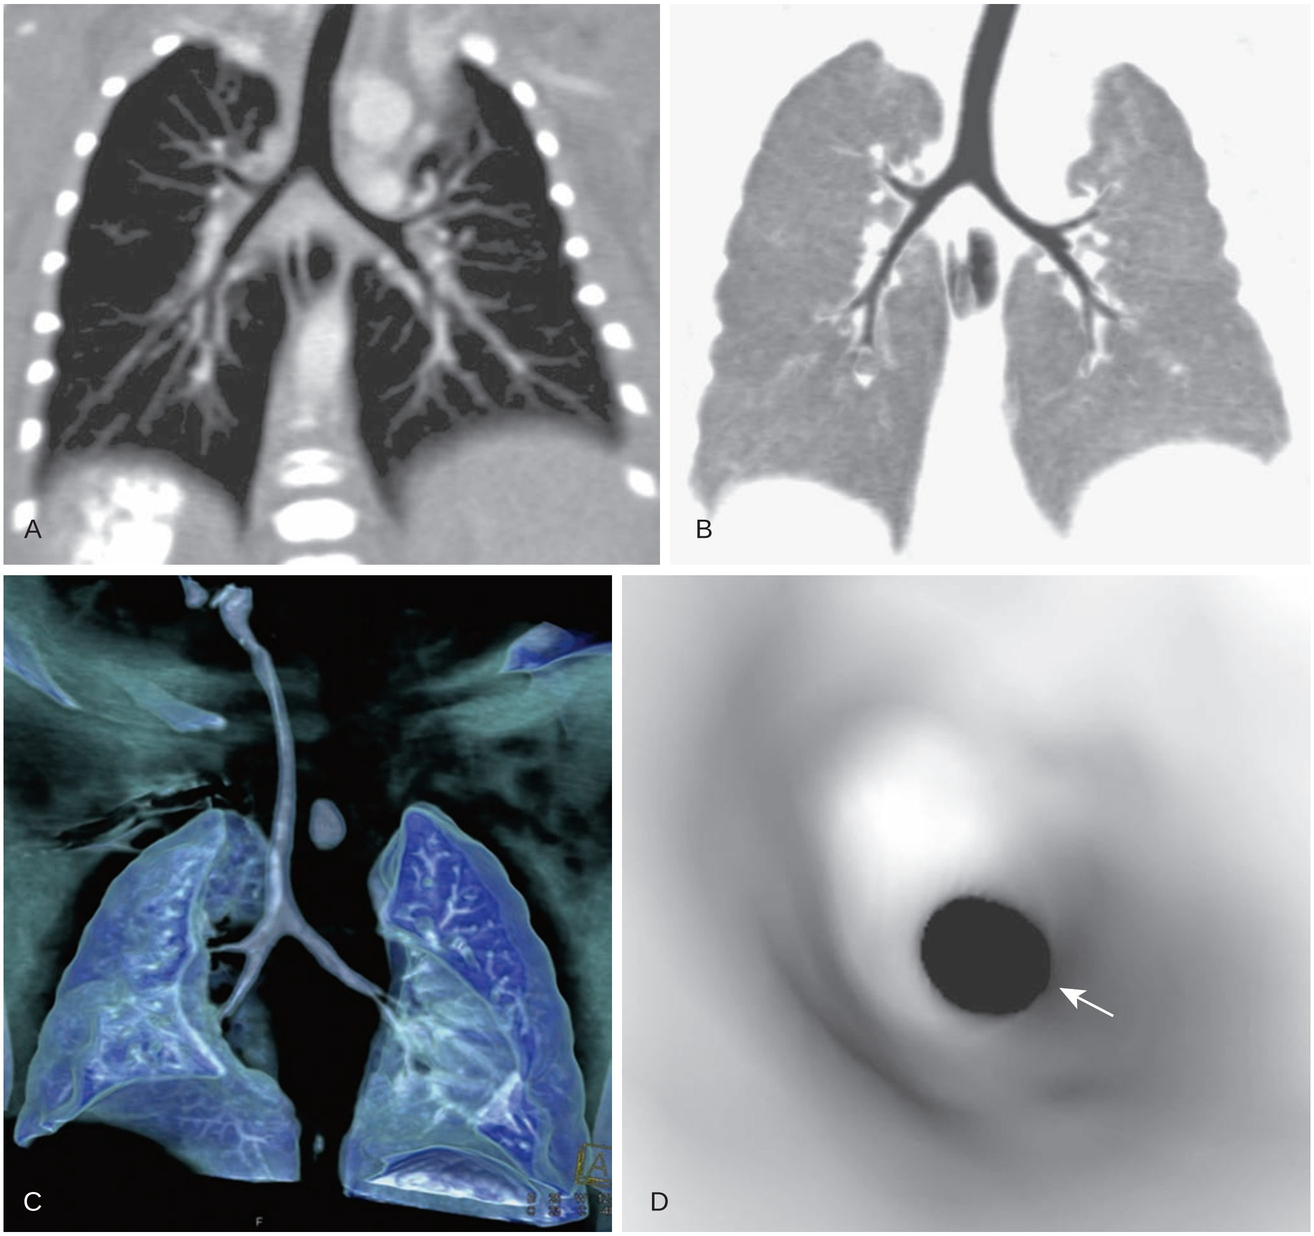

**Figure 49.4. Multiplanar reformatted and 3D CT imaging.** (A) Coronal thin-slab CT image shows normal relationships between the airway and the pulmonary artery, indicating thoracic situs solitus. (B) Coronal minimum-intensity projection CT image shows anatomic details of the central airways. (C) Volume-rendered CT image shows the 3D appearance of the lungs and airways. (D) Virtual bronchoscopic image providing an endoscopic view of the trachea shows concentric narrowing *(arrow)* from a tracheal web.

three-dimensional (3D) images considerably increase diagnostic accuracy of pediatric chest CT (Fig. 49.4).[39] CT scanning with thinner collimation (<1 mm) offers better-quality MPR and 3D images. Various visualization techniques including maximum intensity projection, minimum intensity projection, volume rendering, and virtual bronchoscopy can help further visualize thoracic abnormalities (see Fig. 49.4).

## Evaluation of Airways

Anatomic details of the pediatric airways can readily be imaged with CT.[40,41] However, small airways distal to the subsegmental level (i.e., airways <0.5–1.5 mm in diameter) often are invisible on CT. CT is less invasive than bronchoscopy in evaluating pediatric airways and provides cross-sectional imaging without superimposition. Various airway abnormalities, including fixed or dynamic obstruction, bronchiectasis, and wall thickening, can be diagnosed. Contrast-enhanced CT allows for evaluation of airway/vascular relationships. MRI may be used to evaluate large airways with comparable diagnostic accuracy, but MRI is inferior to CT in evaluating small airways because of lower spatial resolution and lower signal/noise ratio.

### Static Airway Computed Tomography Study

A static airway CT study is performed mainly to assess a fixed airway narrowing or stenosis. Axial CT data are acquired in infants and young children while they breathe freely and in older children while they hold their breath at the end of an inspiration (Fig. 49.4C). Anatomic details of the airway typically are well visualized,

**TABLE 49.1** Tube Current and Kilovoltage by Patient Weight for Central Airway Multidetector Computed Tomography

| Weight (kg) | Tube Current (mAs) Inspiration/Expiration | Kilovoltage |
|---|---|---|
| <10 | 40/20 | 80 |
| 10–14 | 50/25 | 80 |
| 15–24 | 60/30 | 80 |
| 25–34 | 70/35 | 80 |
| 35–44 | 80/40 | 80 |
| 45–54 | 90/40 | 90 |
| 55–70 | 100–120/40 | 100–120 |

For tube current and kilovoltage by patient weight for end-expiratory multidetector computed tomography (MDCT) examination, mAs should be reduced by 50% to a maximum of 40 mAs while maintaining the same level of kilovoltage for end-inspiratory MDCT examination.

*From Lee EY, Boiselle PM. Tracheobronchomalacia in infants and children: multidetector CT evaluation.* Radiology. *2009;252(1):7–22.*

even in free-breathing studies, because of the fast scan speed of multidetector CT. The extent and cause of airway abnormalities can be better evaluated with MPR and 3D CT images than with axial CT images alone.

### Dynamic Airway Computed Tomography Study

A paired inspiratory and expiratory CT study is performed for the dynamic evaluation of a large airway disorder, most commonly tracheobronchomalacia.[18] Expiratory CT is performed with a low radiation dose technique during this dual-phase study (Table 49.1). The resultant effective dose from this paired study typically is in the range of 3.5 to 7.5 mSv.[18] Expiratory CT can be obtained with two different respiratory maneuvers: (1) holding the breath at the end of an expiration during end-expiratory CT and (2) forced exhalation during dynamic expiratory CT. In uncooperative infants and young children, general anesthesia with intubation, controlled ventilation, or respiratory triggering can be used.[18,24,25,41]

### Cine Airway Computed Tomography Study

In cine airway CT, axial sequential scans are acquired continuously at predefined noncontiguous slices with high resolution and low radiation dose technique throughout the respiratory cycle.[42] This technique allows changes in the cross-sectional area and shape of the airway to be demonstrated throughout the entire respiratory cycle, thus making the diagnosis of tracheobronchomalacia possible. To achieve the high temporal resolution required for cine airway CT, the fastest gantry rotation speed is used. The total scan time should be tailored to a range of one to two respiratory cycles to minimize the radiation dose. As a result, the radiation dose of cine airway CT is quite low—in the range of 0.2 mSv to 0.3 mSv.[25] Cine airway CT is performed in infants and young children as they breathe freely or with a coughing maneuver in cooperative older children.[18,43] Coughing exaggerates the expiratory collapse of the airway because it produces a higher intrathoracic extra-airway pressure than does normal or forced exhalation, and thus it is the preferred technique for a cine airway CT study. In addition to dynamic airway evaluation, cine airway CT also can be used to detect pulmonary air trapping, which often is a secondary sign of underlying small airway disease.[42]

### Four-Dimensional Airway Computed Tomography Study

Increased longitudinal coverage of up to 16 cm with modern CT makes four-dimensional (4D) airway CT study feasible.[44] As in a cine airway CT study, an axial sequential CT scan is continuously acquired without table movement throughout the respiration cycle in 4D airway CT. The major difference from cine airway CT is the real-time volumetric coverage of almost the entire central airway in infants and young children (Fig. 49.5).

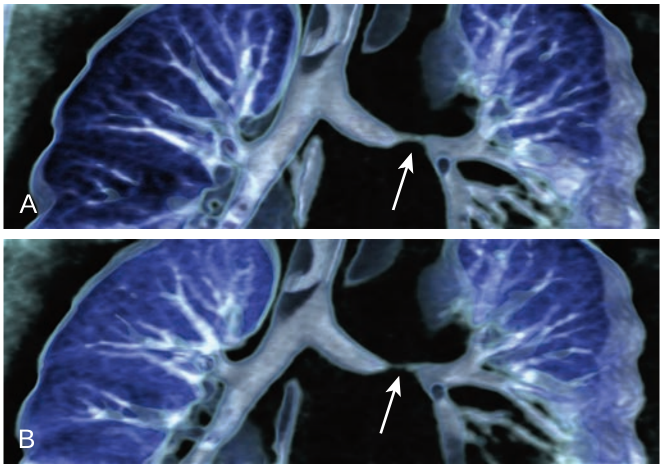

**Figure 49.5. Four-dimensional airway CT study.** (A) Peak inspiration. (B) Peak expiration. A fixed narrowing *(arrow)* is noted at the distal left main bronchus.

## Evaluation of Lungs

CT is valuable in evaluating not only the air spaces, but also interstitial and vascular abnormalities, and parenchymal nodules or masses in the lung. In addition, mediastinal, hilar, and chest wall abnormalities also can be assessed. However, soft tissue contrast resolution of CT is inferior to that of MRI, and MRI is better in evaluating intraspinal and paraspinal regions.

Expiratory CT is necessary to confirm air trapping accurately.[42,45] To obtain proper expiratory CT data, patient cooperation or anesthesia is required. In uncooperative infants and young children, lateral decubitus CT may be used as an altenative.[46] In this position, dependent and nondependent lungs show different lung volumes that mimic inspiration and expiration, respectively (Fig. 49.6A). A drawback of the lateral decubitus CT technique is the need to change the position of the patient, different location between the dependent and nondependent lungs, and exaggerated respiratory motion artifacts in the nondependent lung. Cine CT in the supine position can overcome some of the limitations of lateral decubitus CT (Fig. 49.6B and C).[42] Recently, dual-energy chest CT has been used in pediatric patients to assess regional lung perfusion and ventilation.[47-53] Quantitative analysis to determine lung volume or density can be performed using 3D CT data.

### Routine Chest Computed Tomography Study

Routine chest CT is performed without or with intravenous administration of an iodinated contrast agent, depending on the clinical questions being addressed. High tube voltage should be used for an unenhanced chest CT scan, whereas low tube voltage should be selected for an enhanced chest CT scan. The use of precontrast and postcontrast (dual-phase) chest CT should be avoided in pediatric patients as much as possible to minimize exposure to radiation. Virtual unenhanced CT imaging using the dual-energy technique may substitute for real unenhanced CT imaging, reducing radiation dose.[53]

### High-Resolution Computed Tomography Study

High-resolution CT (HRCT) originally was developed in the 1980s as a special technique in which noncontiguous thin sections,

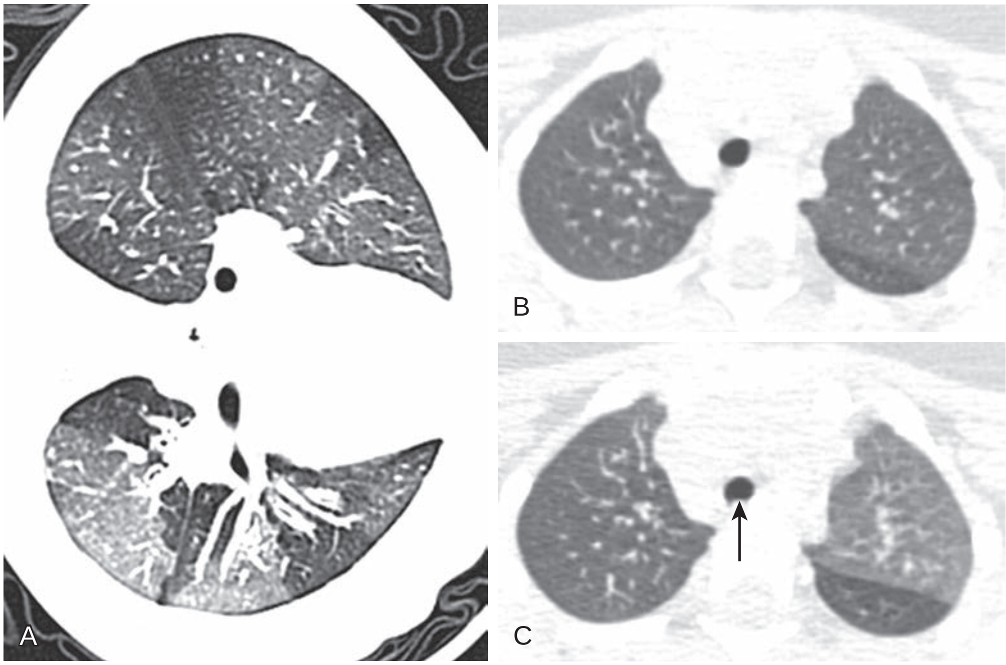

**Figure 49.6. Expiratory CT techniques in children breathing freely.** (A) Left-side-down lateral decubitus CT scan shows geographic hyperlucent areas due to trapping of air, so-called mosaic lung attenuation, in the dependent left lung of a child with bronchiolitis obliterans. Inspiratory (B) and expiratory (C) cine CT images show the normal left upper lobe and the abnormal right upper and left lower lobes with trapping of air. The normal posterior flattening of the trachea *(arrow)* is noted at expiration (C).

approximately 1 mm in slice thickness, are acquired at 5- to 20-mm intervals depending on the size of the patient.[54] To illustrate fine details of the lung anatomy and pathology, a high spatial frequency reconstruction algorithm is used. This classic HRCT study has been used principally as a follow-up imaging study of diffuse lung abnormalities, such as interstitial lung disease or cystic fibrosis, while delivering a very low radiation dose. The development of MDCT allows contiguous thin sections of the entire lung to be viewed with a reasonably low radiation dose and MPR capabilities, which changes the technical concept of HRCT of the lung. MDCT with thin collimation (<1 mm), single spiral CT scanning can provide both thick sections (for a routine chest CT with standard reconstruction algorithm) and thin sections (for HRCT of the lung with high spatial frequency reconstruction algorithm) without additional scanning radiation exposure. It has been reported that reconstructed HRCT images from volumetric MDCT acquisition have significantly less motion artifact than images obtained with traditional axial HRCT acquisition in pediatric patients.[54-57] Nonetheless, the classic HRCT technique still may be used in pediatric patients because of the overall decreased radiation exposure compared with volumetric data acquisition.

## MAGNETIC RESONANCE IMAGING

Chest MRI has inherent limitations because of the low signal-to-noise ratio of the lung, cardiac and respiratory motion artifacts, and susceptibility artifacts that occur at air-tissue interfaces in the lung. A lengthy examination time is another important disadvantage of MRI, leading to a greater requirement for sedation or anesthesia in pediatric patients. However, recent technical advances in MRI, such as parallel imaging and multichannel body-array coils, allow substantial reduction of examination time. In addition, vector electrocardiogram triggering, respiratory triggering, and navigator gating may be used separately or together to suppress motion artifacts.

Lack of ionizing radiation exposure and excellent soft tissue contrast are advantages of MRI. Different tissue characteristics can be evaluated with T1- and T2-weighted imaging and, more recently, balanced steady-state free precession imaging. Fat saturation may be added to the pulse sequence if necessary. The use of gadolinium contrast agents can further improve tissue characterization on T1-weighted imaging. A variety of functional thoracic assessments, including perfusion, ventilation, and respiratory mechanics, can be performed with MRI.[58-60] Water diffusivity or cellularity of thoracic masses may be evaluated with diffusion-weighted imaging (Fig. 49.7). Hyperpolarized gas MRI allows excellent static and dynamic visualization of the lung and airway and may overcome the limitations of proton MRI of the thorax.[61] However, hyperpolarized gas MRI has markedly limited availability, which is the main obstacle to its clinical use and the primary reason it remains in the research realm. Chest MRI examination cannot be performed in some circumstances (e.g., when contraindications for MRI exist, such as the presence of a permanent cardiac pacemaker, the presence of a cardioverter-defibrillator, or claustrophobia).

### Evaluation of Airways

Central airways and their relationships to adjacent cardiovascular structures can be assessed with noncontrast black-blood MRI (Fig. 49.8).[62] Tracheobronchomalacia can be diagnosed with real-time dynamic airway MRI. CT is generally preferred for airway evaluation as the detailed delineation of the airway, especially smaller peripheral airways on MRI, is somewhat limited because of lower spatial resolution.

### Evaluation of Lungs

Despite the inherent limitations of lung MRI, magnetic resonance is rapidly advancing as a viable lung imaging modality. One study

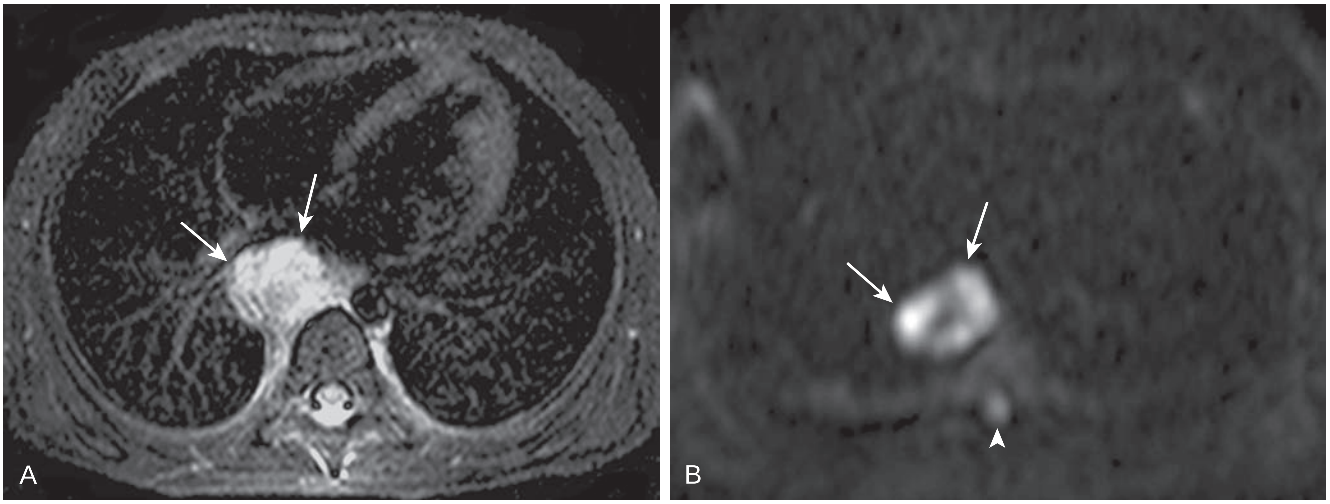

**Figure 49.7. Diffusion-weighted MRI.** (A) Axial T2-weighted chest MRI using a short tau inversion recovery sequence shows a metastatic neuroblastoma involving a paraesophageal lymph node *(arrows).* (B) On axial diffusion-weighted MRI (b-value, 800 sec/mm$^2$), hyperintense areas are predominant in the lesion *(arrows),* indicating restricted water diffusion or hypercellularity. Of note, the normal spinal cord *(arrowhead)* appears modestly hyperintense.

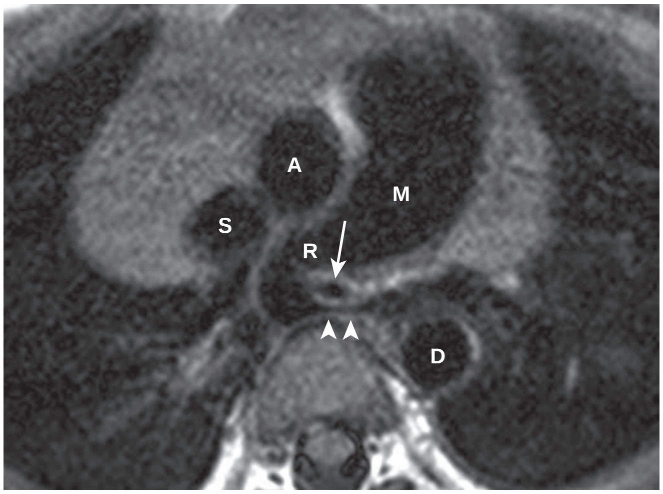

**Figure 49.8. Black-blood MRI.** An axial T1-weighted, electrocardiogram-triggered chest MRI using spin-echo echo-planar imaging and the black-blood technique shows an intimate relationship between the left pulmonary artery sling and congenital tracheal stenosis *(arrow),* the so-called “sling-ring” complex. Note a severe focal stenosis *(arrowheads)* of the left pulmonary artery between the trachea and the spine. *A,* Ascending aorta; *D,* descending aorta; *M,* main pulmonary artery; *R,* right pulmonary artery; *S,* superior vena cava.

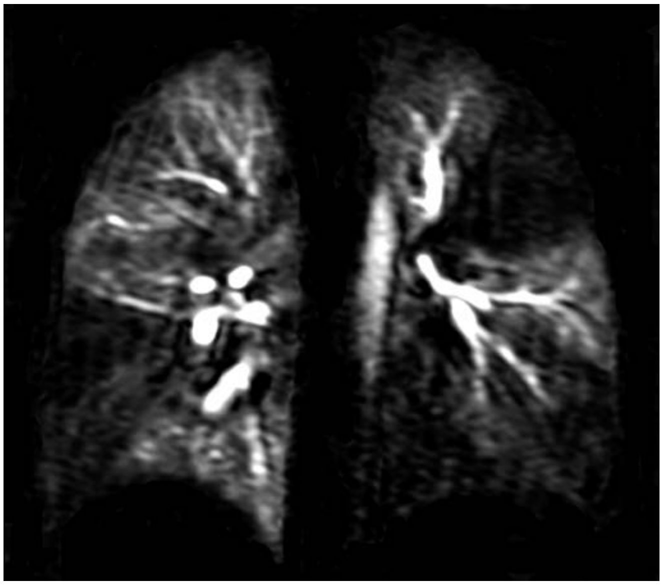

**Figure 49.9. Contrast-enhanced lung perfusion MRI.** A coronal image obtained from time-resolved MRA shows maximal contrast enhancement in the normal lung areas and multiple lung perfusion defects. The signal outside the lung is suppressed by means of subtraction.

showed that lung nodules of a diameter larger than 3 to 4 mm can be detected with MRI with use of 1.5-T systems.[63] Contrast-enhanced time-resolved magnetic resonance angiography (MRA) offers not only anatomic details of pulmonary vessels but also hemodynamics of the pulmonary circulation. Because contrast bolus timing is not needed and less motion artifact occurs because of high temporal resolution (e.g., <1 second for the entire lung), time-resolved MRA often replaces static high-resolution MRA in pediatric patients.[64] Lung perfusion MRI can be obtained with either the contrast-enhanced or non–contrast-enhanced technique (Fig. 49.9). Real-time dynamic chest MRI with the patient breathing freely may be used to demonstrate normal and abnormal respiratory dynamics.[65] Regional ventilation may be assessed with oxygen-enhanced MRI or hyperpolarized gas (${}^{3}$helium or ${}^{129}$xenon) MRI. Diffusion-weighted imaging using hyperpolarized gas enables calculation of the size of peripheral air spaces. Hyperpolarized xenon MRI has an additional capability of assessing diffusing capacity in the lung. Newer free-breathing proton MRI techniques without any contrast agents allow both lung perfusion and lung tissue density determination in a single data acquisition.[66]

## NUCLEAR MEDICINE STUDIES

In some clinical settings, nuclear medicine techniques have an important advantage over anatomic imaging methods because they

**TABLE 49.2** Recommended Administered Activities Based on the North American Consensus Guidelines for Administered Radiopharmaceutical Activities in Children and Adolescents

| Radiopharmaceutical Agent | Recommended Administered Activity | Minimum Administered Activity | Maximum Administered Activity |
|---|---|---|---|
| $^{99m}$Tc macroaggregated albumin | If $^{99m}$Tc is used for ventilation, 2.59 MBq/kg (0.07 mCi/kg)<br>If no $^{99m}$Tc ventilation study is performed, 1.11 MBq/kg (0.03 mCi/kg) | 14.8 MBq (0.4 mCi) | |
| $^{99m}$Tc methylene diphosphonate | 9.3 MBq/kg (0.25 mCi/kg) | 37 MBq (1.0 mCi) | |
| $^{123}$I metaiodobenzylguanidine | 5.2 MBq/kg (0.14 mCi/kg) | 37 MBq (1.0 mCi) | 370 MBq (10.0 mCi) |
| 18F deoxyglucose | 3.7–5.2 MBq/kg (0.10–0.14 mCi/kg) | 37 MBq (1.0 mCi) | |

*This research was originally published in JNM. Gelfand MJ, Parisi MT, Treves ST, Pediatric radiopharmaceutical administered doses: 2010 North American consensus guidelines.* J Nucl Med. *2011;52:318–322. Copyright by the Society of Nuclear Medicine and Molecular Imaging, Inc.*

evaluate physiologic processes. Several radionuclide techniques are commonly used to evaluate pediatric diseases of the respiratory system or chest wall, as listed in Table 49.2. Most nuclear medicine studies are performed with an intravenous injection of a radiopharmaceutical agent. Many nuclear medicine procedures carry inherently higher radiation exposure to the patient than plain film radiographic procedures, but the radiation exposure is comparable to or less than that of CT examinations. It is important to use the lowest possible injected tracer dosage that allows good-quality images to be recorded. Although accepted standard adult radiopharmaceutical dosages often are established, dosage determination in children is best calculated on the basis of weight, which in turn is derived from the adult reference administered activity.[67] Current recommendations are presented in Table 49.2.

The acquisition time for nuclear medicine images often is quite long compared with radiographic techniques, and gentle immobilization and distraction is necessary in small children. Sedation occasionally is required during lengthy imaging sessions. Currently available nuclear medicine studies that are used to assess thoracic disorders in pediatric patients include the lung perfusion and ventilation study, salivagram, neuroendocrine imaging study, bone scan, and positron emission tomography. Only those studies that are specific to the chest are discussed here.

## Lung Perfusion and Ventilation Study

Lung perfusion imaging, although largely supplanted by CT techniques for the diagnosis of pulmonary embolus, remains an important technique for the evaluation of lung physiology and pathology. The incidence of pulmonary embolism in the pediatric population is lower than in the adult population, but occasionally perfusion imaging is used with patients who have significant risk factors to evaluate for an embolus when a contraindication to the administration of radiographic contrast material exists. Nuclear ventilation and perfusion imaging is much more commonly used to evaluate relative function in diseases in which knowledge of physiology helps guide clinical care. Both relative ventilation and perfusion can be quantitated, which permits treatment planning and follow-up evaluation in a variety of clinical entities such as lung malformations resulting from congenital lobar emphysema and congenital pulmonary airway malformations (Fig. 49.10). The quantitative analysis of relative lung perfusion and ventilation also is useful in preoperative cases before pneumonectomy to evaluate for the estimated postsurgical lung capacity.[68]

Patients with congenital heart disease frequently undergo perfusion imaging to quantitate relative perfusion between the right and left lungs at baseline and after catheter intervention, as well as long term (e-Fig. 49.11). A recent study evaluated the utility of lung perfusion scans in patients with primary pulmonary vein stenosis. The findings showed a good correlation of lung scan and cardiac catheterization angiography.[69]

The perfusion study is performed with technetium-99m ($^{99m}$Tc) macroaggregated albumin (MAA). The dosage in pediatrics is based on patient weight (see Table 49.2). In cases of congenital heart disease when differential lung perfusion is evaluated, a specially prepared radiopharmaceutical agent with a low concentration of particles of MAA is recommended. The tracer is always injected with the patient supine so a hydrostatic gradient is not present from lung apex to base. Imaging can be performed with the patient either upright or supine, but supine imaging typically is performed in children. If imaging is being performed to evaluate pulmonary physiology, typically only anterior and posterior planar views are acquired. The differential lung perfusion is then calculated by drawing a region of interest around each lung and calculating the geometric mean (i.e., the square root of the product of anterior and posterior views) of counts in each lung. If the perfusion scan is being performed to evaluate for a pulmonary embolism, additional anatomic information is recorded, with a standard of eight planar images (i.e., anterior, posterior, left and right lateral, right anterior oblique, left anterior oblique, right posterior oblique, and left posterior oblique views). Alternatively, single-photon emission computed tomography (SPECT) imaging of the lungs can be performed. When evaluating for a possible pulmonary embolus, a correlation should be made with a chest radiograph obtained within 24 hours of the study.

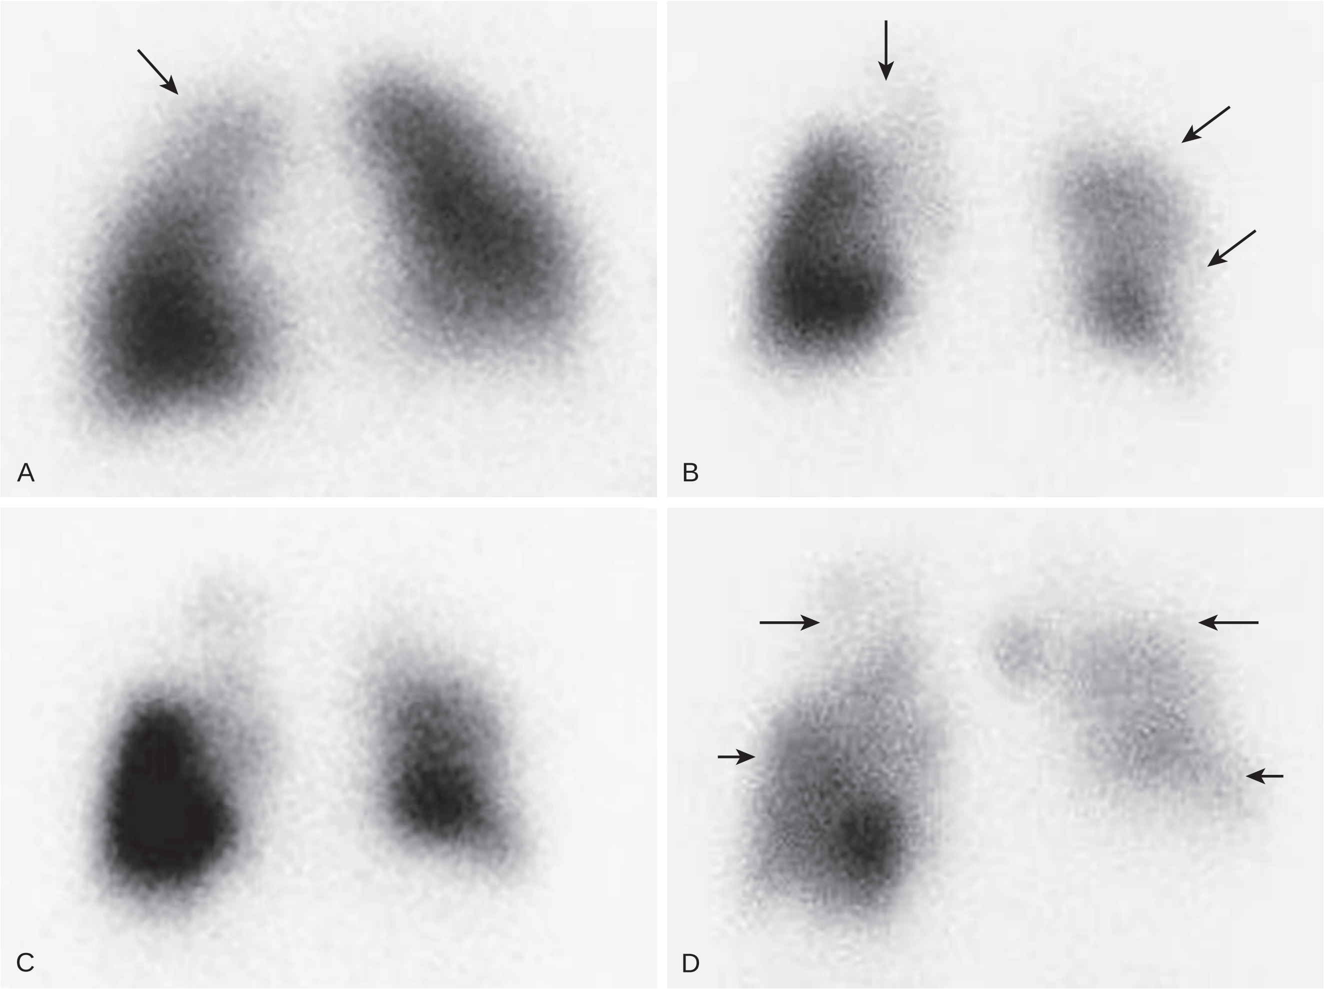
The ventilation study can be performed either with a radioactive gas (xenon-133) that demonstrates air flow or a radio aerosol ($^{99m}$Tc diethylenetriaminepentaacetic acid [DTPA]) that localizes in alveoli without significant large airway deposition. 133Xe gas has a principal photon energy of 81 keV, which is lower than $^{99m}$Tc. The DTPA aerosol study uses the same $^{99m}$Tc label as MAA perfusion imaging, but much less aerosol tracer activity localizes in the lungs than is present with the intravenous MAA injection. Thus both xenon and aerosol ventilation imaging must be performed before the perfusion agent is administered.

133Xe gas is administered by inhalation. The recommended dose is 10 to 20 mCi. The dynamic nature of the xenon study limits the projections that can be obtained, and thus imaging typically is acquired in the posterior view with a single-head camera. If a dual-head camera is used, simultaneous anterior and posterior imaging can be acquired. The presence of the anterior detector over the child's face and thorax can cause anxiety, and thus in young children only the posterior image typically is acquired.

$^{99m}$Tc DTPA aerosol is administered via a shielded nebulizer; the child inhales long enough to accumulate sufficient aerosol in the lung for imaging. The aerosol remains in the lungs long enough for imaging to be performed in multiple projections, matching those acquired with perfusion imaging. When SPECT perfusion imaging is performed, SPECT aerosol images also can be acquired for comparison.

## Salivagram

Radionuclide evaluation for salivary aspiration (i.e., a salivagram) offers a safe and easily performed test with minimal radiation exposure to the patient. The sensitivity of the salivagram has been



**e-Figure 49.11. Nuclear medicine perfusion imaging of an 8-year-old boy with diagnosis of pulmonary vein stenosis of all four pulmonary veins.** (A) Posterior view of the lung scan showing the relative decreased perfusion of the left upper lung *(arrow).* (B) Follow-up lung scan showing worsening perfusion to the right lung, in addition to the decreased perfusion of the left upper lung. (C) Follow-up study after repair of the stenosis of the right inferior pulmonary vein, now showing better perfusion to the right lower lung. (D) The patient presents again with increasing symptoms and lung scan shows worsening perfusion to the right lung and left upper lung suggestive of restenosis of the pulmonary veins *(arrows)*.

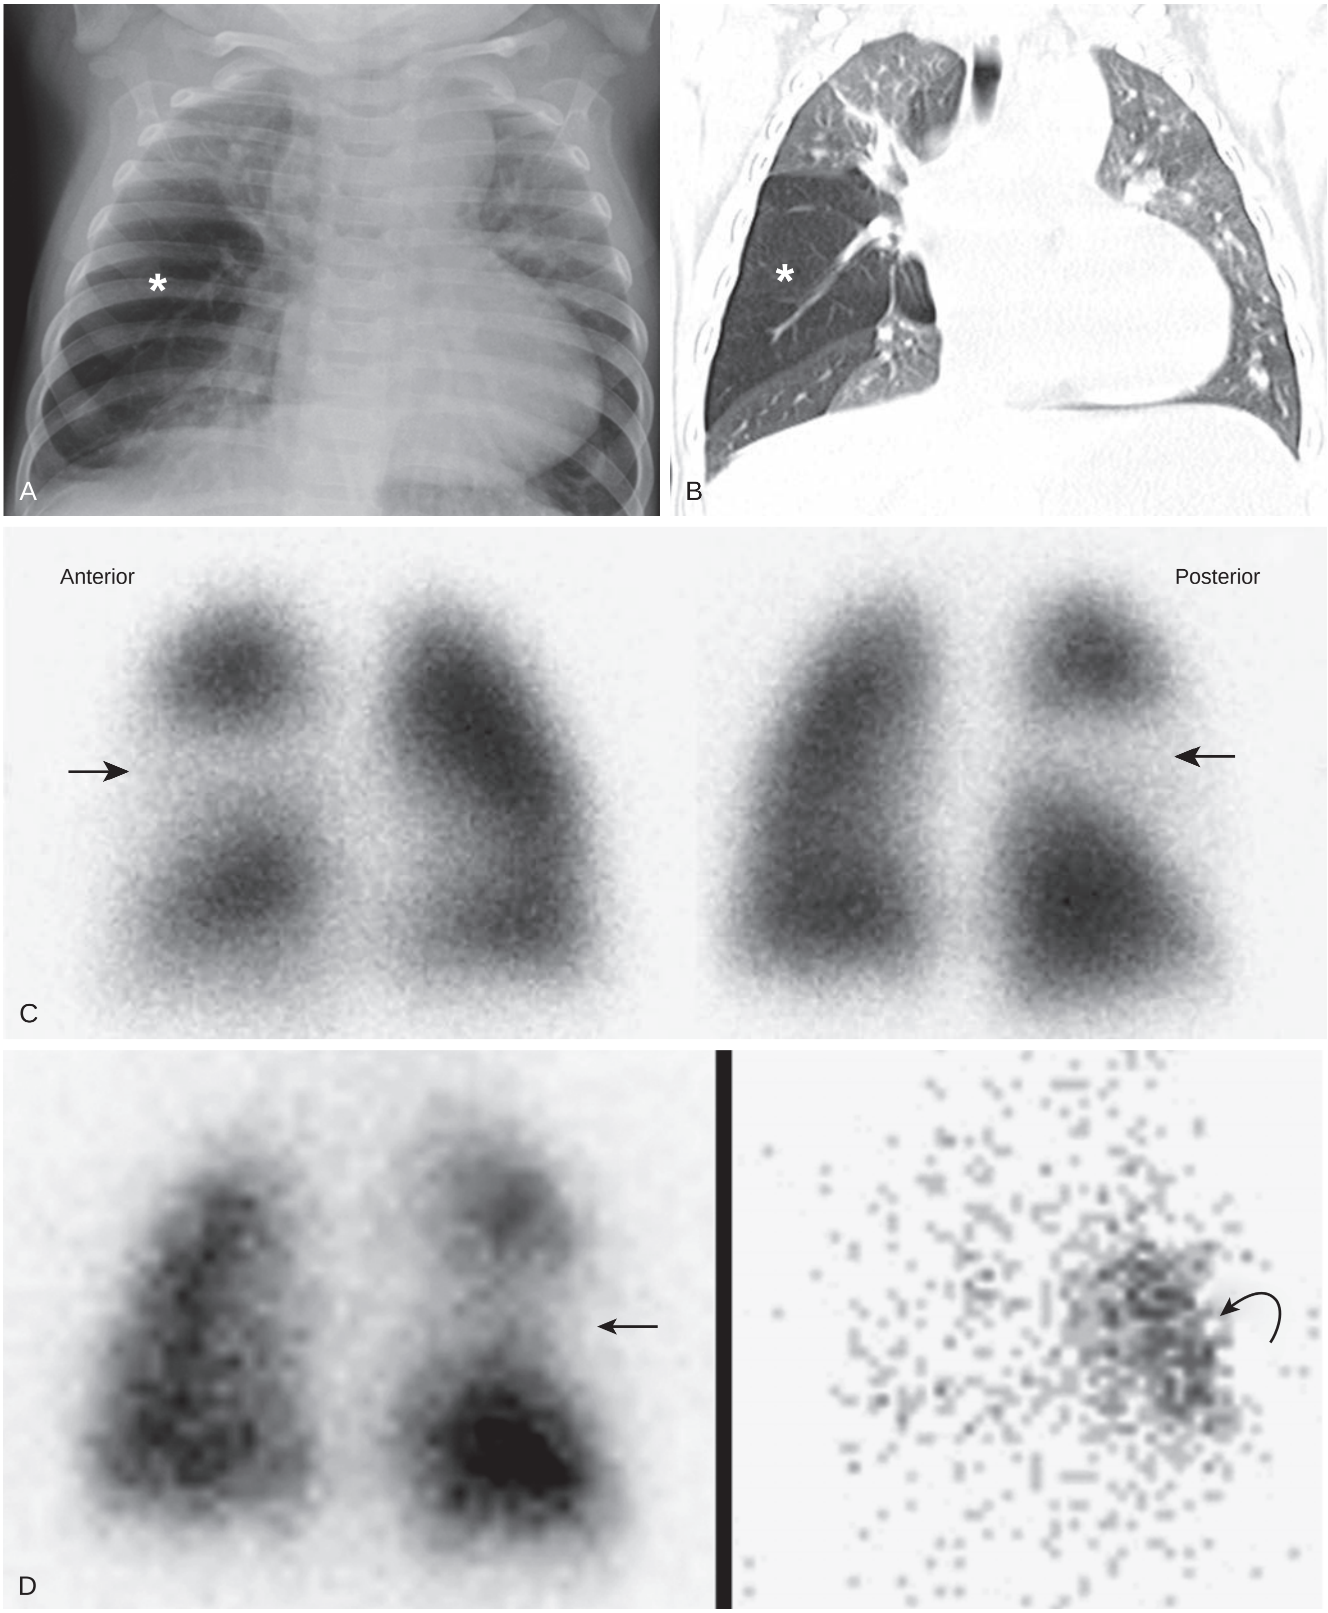


**Figure 49.10. Multimodality imaging of a 7-month-old girl with congenital lobar emphysema.** (A) Frontal chest radiograph shows hyperlucency *(asterisk)* in the right mid to lower lung zone. (B) Coronal lung window CT demonstrates hyperinflation and oligemia of the right middle lobe *(asterisk),* consistent with congenital lobar emphysema. (C) Perfusion lung scan shows no perfusion to the right middle lobe *(arrow)* on the anterior view *(Anterior)* and posterior view *(Posterior).* (D) Posterior image from a ventilation scan on the left showing initial decreased ventilation to the right middle lung *(straight arrow)* with air trapping in the same area on the later images *(curved arrow).*

reported to range between 26% and 73%.[70-72] The salivagram can be performed with the administration of a small drop (approximately 100 µL) of $^{99m}$Tc sulfur colloid (300 µCi [11.1 MBq]) that is placed in the oral cavity while the patient is lying in a supine position in the imaging bed. After administration of the radiopharmaceutical agent, the patient is allowed to swallow normally and posterior planar imaging of the mouth, chest, and upper abdomen is obtained dynamically for 60 minutes. Imaging is acquired using a low-energy, high-resolution or ultra–high-resolution collimator, with consecutive dynamic images recorded every 30 seconds for a total of 120 frames. A positive salivagram for aspiration shows the radiopharmaceutical agent entering the bronchi (Fig. 49.12).

## Positron Emission Tomography

Positron emission tomography (PET) is useful in evaluating many primary and metastatic intrathoracic tumors in pediatric patients (Fig. 49.13). Pediatric tumors commonly evaluated with PET include Hodgkin lymphoma, non-Hodgkin lymphoma, rhabdomyosarcoma, osteosarcoma, Ewing sarcoma, neuroblastoma, and other less common malignancies.

The recommended dosage of fluorine-18–labeled deoxyglucose (FDG) is 150 µCi/kg (5.55 MBq) (minimum 500 µCi [18.5 MBq] and maximum 10 mCi [370 MBq]). Imaging is performed about 60 minutes after the injection to allow adequate accumulation of the tracer in the tumor. Images of the torso or of the entire body can be obtained according to the indication of the study. Several elements of patient preparation for the study are important. Because FDG is taken up competitively with glucose, the patient must fast (i.e., no solid food and nothing to drink except water) for at least 4 hours before the PET scan. The patient must not receive any form of glucose, including intravenous fluids containing glucose, for at least 4 hours before administration. The blood glucose level is measured routinely at the time of tracer administration and should be between 50 and 200 mg/dL. Patients who are diabetic and/or dependent on insulin should take their diabetic medication and/or insulin 2 hours before the examination with a small amount of juice and dry toast or plain crackers. The patient should avoid any strenuous exercise 24 hours before the study because such exercise might lead to an increase in muscle uptake that hinders the interpretation of the study.

Another important aspect of pediatric PET studies is the high incidence of metabolically active brown fat activation compared with the adult population. The presence of brown fat increases

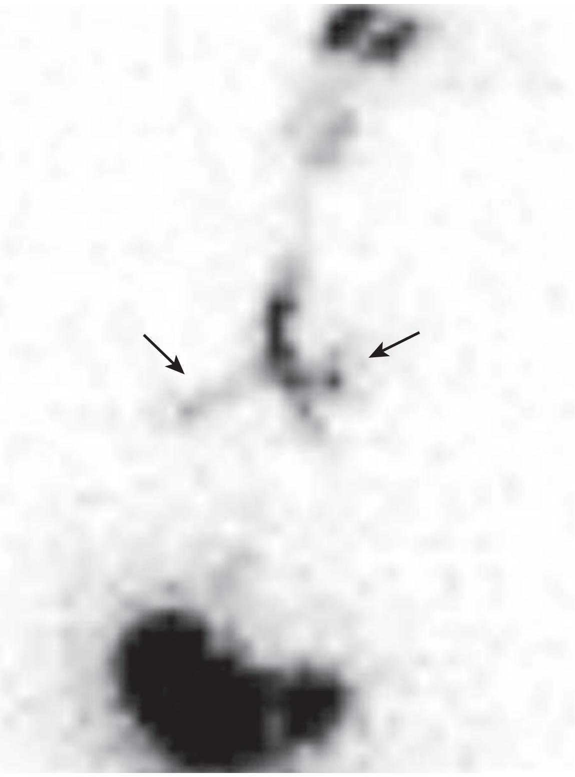

**Figure 49.12. Salivagram.** A posterior view of the neck, chest, and upper abdomen shows bilateral aspiration into the proximal bronchi *(arrows).*

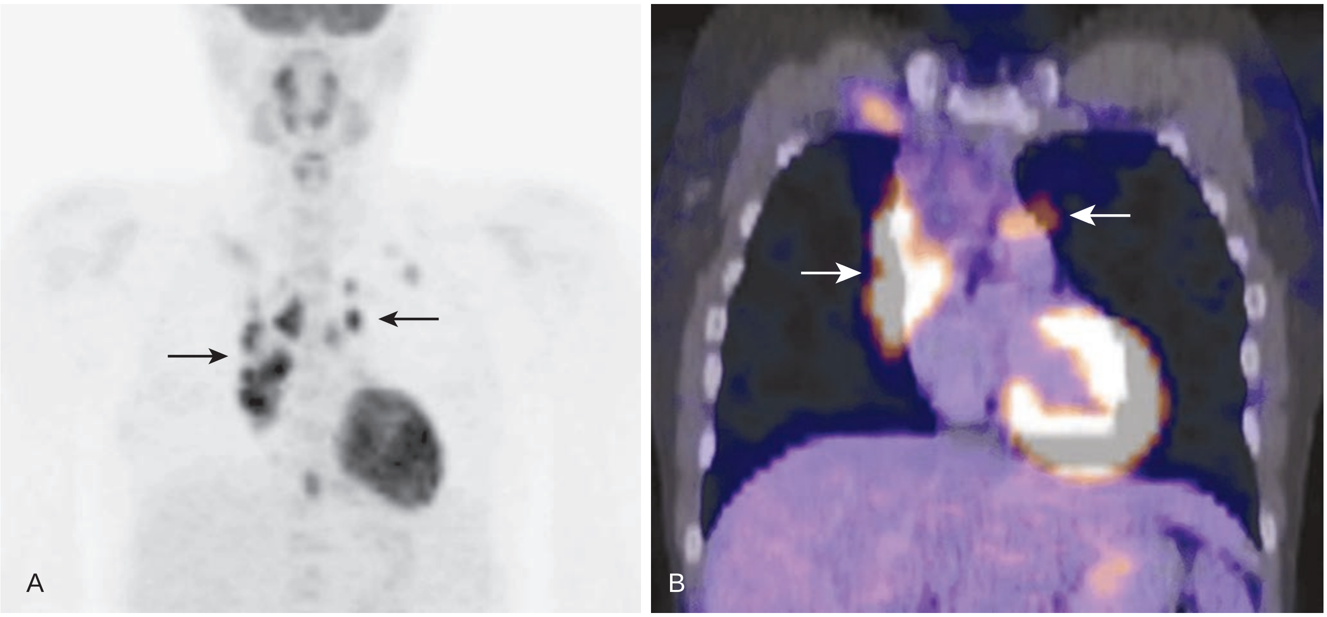

**Figure 49.13. PET imaging in a 19-year-old with newly diagnosed Hodgkin disease.** (A) Coronal PET image shows multiple sites of abnormal uptake in the anterior mediastinum *(arrows).* (B) Fusion of PET and CT images shows the abnormal areas of uptake corresponding to enlarged lymph nodes on CT *(arrows).*

the number of equivocal studies.[73] Keeping patients at an ambient temperature of 24°C before and during the FDG uptake phase decreases the incidence of brown fat activation significantly.[74]

In the evaluation of tumors, PET provides an advantage over anatomic imaging because it detects metabolically active viable tissue. Use of PET in the evaluation of Hodgkin lymphoma has been shown to increase the detection of metastases when compared with CT alone.[75]

## KEY POINTS

- Up-to-date knowledge regarding imaging techniques is essential to achieve optimum diagnostic performance and to choose an appropriate imaging method for evaluation of the pediatric respiratory system.
- Imaging parameters should be tailored to each individual pediatric patient for optimal results.
- Risks related to diagnostic imaging, such as radiation exposure, the use of a contrast agent, and sedation, should be minimized.

# Prenatal Imaging and Intervention

Dorothy Bulas

With the advances in ultrasound (US) and magnetic resonance imaging (MRI), thoracic lesions are now commonly detected before birth. The most common congenital thoracic lesions include congenital diaphragmatic hernia (CDH); congenital bronchopulmonary malformations, which represent a group of lung anomalies, including congenital pulmonary airway malformation (CPAM), bronchopulmonary sequestration (BPS), and congenital lobar overinflation (CLO); and congenital hydrothorax. Additionally, congenital high airway obstruction (CHAOS), which is caused by obstruction or absence of the trachea, may also present in utero. Pulmonary hypoplasia, agenesis, and aplasia are less common and discussed in Chapter 53.[1-4]

In a fetus, the clinical importance of these lesions lies primarily in the mass effect on surrounding structures. This may result in compression of the airway, blood vessels, lymphatics, and lung parenchyma with development of pleural effusions, polyhydramnios, hydrops, and pulmonary hypoplasia. The outcome depends on the timing of secondary effects and the severity of pulmonary hypoplasia. With improvements in fetal imaging, fetal intervention has also advanced. Masses that resulted in hydrops in the past were typically lethal. Now these masses may be amenable to fetal intervention, including maternal steroids, intrauterine cyst aspiration, fetal thoracentesis, thoracoamniotic shunts, laser therapy, sclerotherapy, and in utero fetoscopic or open fetal surgery.[5-9]

In maternal-fetal surgery, the greatest responsibility is to the mother, who is an innocent bystander in the maldevelopment occurring in utero. She must be aware of the risks and benefits for herself and the fetus and has the potential to undergo an operation that has no direct benefit to her. A limiting factor of invasive fetal therapy is the risk of preterm labor, although fetoscopic surgery carries a lower risk.[7] Women who have undergone open fetal surgery have been able to have children subsequently, although delivery of subsequent pregnancies requires cesarean section.

## COMMON CONGENITAL THORACIC LESIONS IN THE FETUS

### Congenital Diaphragmatic Hernia

***Etiology.*** The diaphragm develops in the fourth week of gestation with fusion of its four embryonic components. By 8 weeks, the pleural–peritoneal cavity separates. There is caudal migration with final diaphragmatic positioning by 12 weeks. The most common CDH occurs secondary to failure of fusion of the left pleuroperitoneal membrane to the remaining primitive diaphragm (Bochdalek hernia). The bowel returns to the abdomen by the 10th week of gestation and may begin to herniate into the chest if a diaphragmatic defect is present.

CDH occurs in 1:3000 to 1:4000 live births. They can be classified by location: posterolateral Bochdalek hernia (70%–75%), anterior Morgagni hernia (23%–28%), and central hernia (2%–7%). They occur on the left in 88%, the right in 10%, and bilaterally in 2% of cases.[10-12]

Herniation can occur in the second trimester and may affect early lung development on the contralateral as well as ipsilateral sides. CDH is typically sporadic; however, a 15% to 45% incidence of associated anomalies is seen. Rare familial cases and syndromes have been described.[11] The presence of additional major malformations significantly increases the mortality rate. Careful evaluation for additional anomalies, fetal echocardiography, and karyotyping are important for appropriate counseling and delivery planning.

***Imaging.*** The diagnosis of CDH in fetuses may be missed by US, particularly when the stomach is not herniated into the chest.[12,13] In these cases, mediastinal shift may be the first finding to suggest the diagnosis. Coronal and sagittal US images help delineate the defect, whereas axial images are important to assess the amount of mediastinal deviation. Contralateral lung volume should be measured. Ipsilateral lung tissue should be looked for but typically is too compressed to be visualized. The stomach and gallbladder are identified, and the location above or below the diaphragm is noted. Polyhydramnios may develop due to esophageal and/or gastric kinking.

Herniation of the liver into the chest is associated with a poorer outcome. Evaluation may be difficult by US because the liver, bowel, and lung have similar echogenicity. An abnormal course of the umbilical, hepatic, and portal veins may help confirm liver herniation.[14] With left CDH, the left lobe of the liver typically herniates into the anterior chest. If the stomach is adjacent to the anterior chest wall, liver herniation is unlikely. The more posterior the stomach is in the chest, the more liver is herniated superiorly. At times, small bowel loops may mimic lung cysts, making it difficult to differentiate hernia from CPAM. Color Doppler of the superior mesenteric artery may be helpful in confirming herniation of bowel loops by following the vessel into the chest. Associated anomalies, particularly cardiac, should be searched for with dedicated fetal echocardiography.

Fetal MRI protocols should include T2-weighted images in all three planes and T1-weighted breath hold gradient recalled echo images in the coronal and sagittal plane to assess for liver and meconium positions (Figs. 50.1 and 50.2). Meconium-filled bowel loops are low signal on T2-weighted images and high signal on T1-weighted images. The liver is high signal on T1-weighted images and intermediate signal on T2-weighted images, making it easier to quantitate amount of liver herniation than with US (e-Fig. 50.3). MRI is particularly helpful in the evaluation of right and bilateral CDH.[15,16] In these cases, with the stomach often located below the diaphragm, it may be difficult to differentiate a CPAM from a CDH by US. MRI easily distinguishes abdominal contents within the chest from cystic pulmonary lesions and provides specific information on hernia content and amount of residual ipsilateral and contralateral lung.

One goal of fetal imaging is predicting severity, important in guiding therapeutic options and delivery planning. Survival rates range from 40% to 90% with an overall survival reported to be 70% to 80%.[17] Currently, no single finding or measurement is an absolute indicator of postnatal outcome. Indications of poor prognosis include large mediastinal shift, low observed to expected lung volumes, and percentage of liver herniation.[18] When liver herniation is present, the survival rate has been reported to be approximately 50%, whereas fetuses without herniation may have up to 90% survival.[15,19,20] Additional findings such as intrathoracic location of the stomach, asymmetric size of cardiac ventricles, and polyhydramnios also may indicate a worse prognosis. Syndromes associated with CDH, including Fryns syndrome, have a poorer prognosis (e-Fig. 50.4).[11] The presence of additional anomalies affects outcome as well. Bilateral CDHs are typically fatal.

## Abstract:

With the advances in high-resolution ultrasonography and magnetic resonance imaging (MRI), thoracic lesions are now commonly detected before birth. The most common congenital thoracic lesions include congenital diaphragmatic hernia (CDH); congenital bronchopulmonary malformations, which represent a group of lung anomalies, including congenital pulmonary airway malformation (CPAM), bronchopulmonary sequestration (BPS), and congenital lobar overinflation (CLO); and congenital hydrothorax. Additionally, congenital high airway obstruction (CHAOS), which is caused by obstruction or absence of the trachea, may also present in utero.

In a fetus, the clinical importance of these lesions lies primarily in the mass effect on surrounding structures. This may result in compression of the airway, blood vessels, lymphatics, and lung parenchyma with development of pleural effusions, polyhydramnios, hydrops, and pulmonary hypoplasia. The outcome depends on the timing of secondary effects and the severity of pulmonary hypoplasia. With improvements in fetal imaging, fetal intervention has also advanced. While in the past lungs masses that developed hydrops were often lethal. Now these masses may be amenable to fetal intervention including maternal steroids, intrauterine cyst aspiration, fetal thoracentesis, thoracoamniotic shunts, laser therapy, sclerotherapy, and in utero fetoscopic or open fetal surgery.

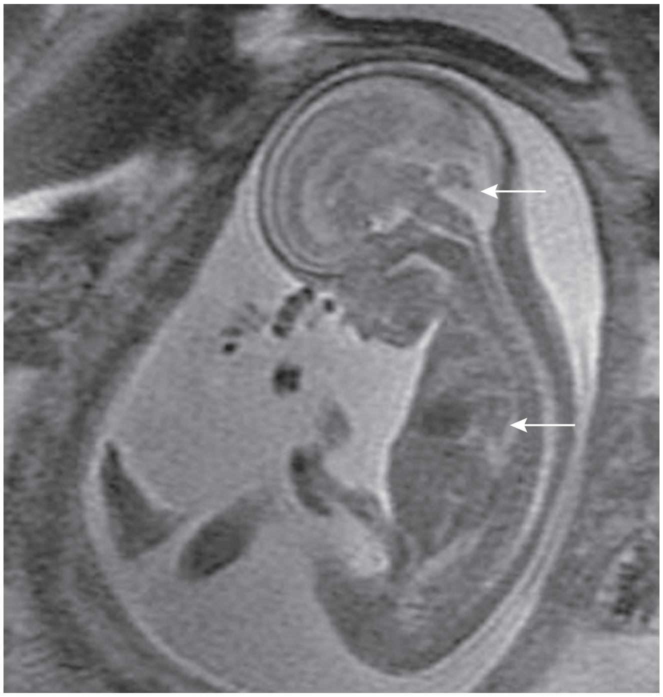
**e-Figure 50.3. Congenital diaphragmatic hernia with covering membrane.** (A) Coronal single-shot fast spin echo T2-weighted MRI shows stomach, bowel, and a portion of the left lobe of the liver herniated into the left hemithorax. Residual left lung parenchyma is noted superior to the stomach. (B) Coronal gradient recalled echo T1-weighted MRI confirms that high signal meconium-filled colon and intermediate high signal liver are herniated into the left hemithorax.



**e-Figure 50.4. Fryns syndrome.** A single-shot fast spin echo T2-weighted right parasagittal MRI of a fetus at 24 weeks of gestational age shows bowel loops *(inferior arrow)* herniated into the hemithorax. Inferior vermian hypoplasia *(superior arrow)* and nuchal thickening are present. This infant was diagnosed with Fryns syndrome at delivery.

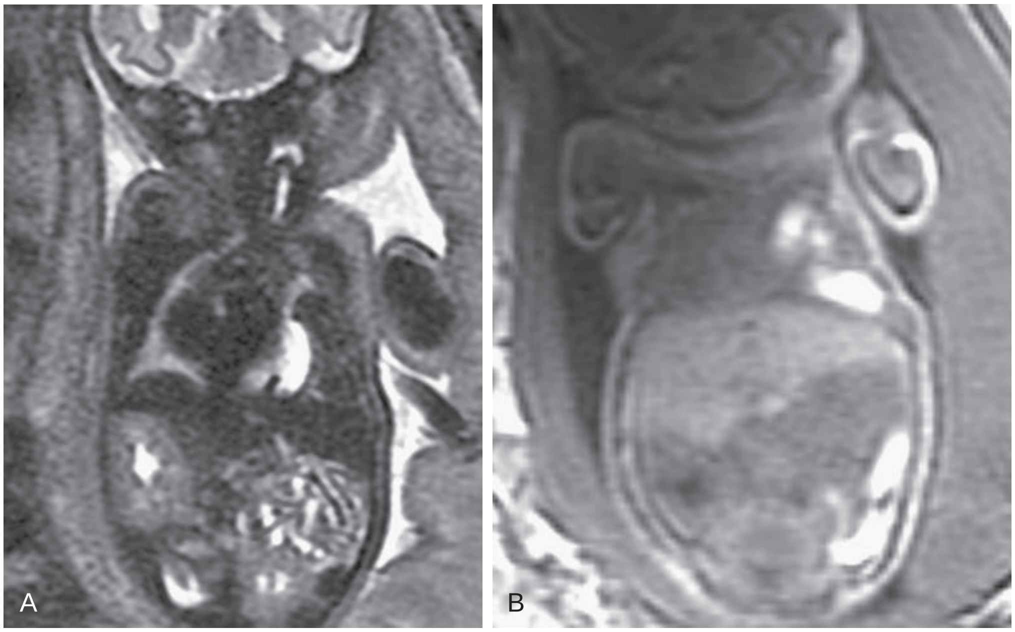


**Figure 50.1. Left congenital diaphragmatic hernia.** (A) Coronal single-shot fast spin echo T2-weighted MRI at 32 weeks of gestation demonstrates deviation of the heart to the right. High-signal fluid-filled stomach and low-signal meconium are herniated into the left chest. The liver appears infradiaphragmatic. (B) Coronal gradient recalled echo T1-weighted image shows high signal meconium-filled colon herniated into the left hemithorax. The intermediate signal liver is infradiaphragmatic.

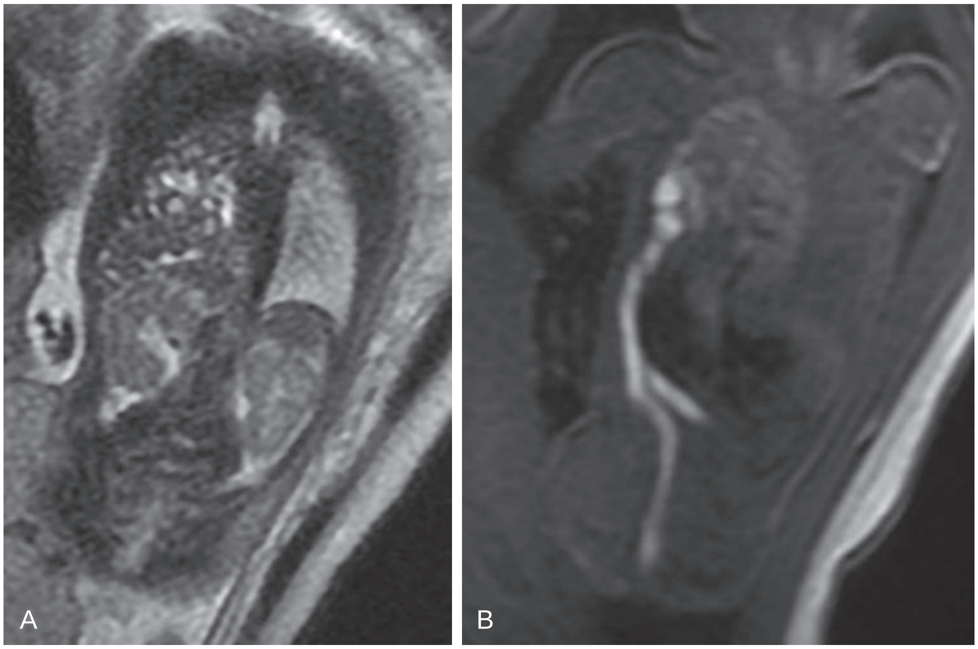

**Figure 50.2. Right congenital diaphragmatic hernia.** (A) Coronal single-shot fast spin echo T2-weighted MRI at 32 weeks of gestation demonstrates loops of fluid filled bowel filling the right hemithorax. (B) Coronal gradient recalled echo T1-weighted MRI demonstrates the right lobe of the liver, as well as loops of colon filled with high signal meconium herniated into the right hemithorax.

Various US and MRI measurement have been proposed to estimate severity of lung hypoplasia and outcome. By US, measurement of the lung-to-head ratio (LHR) and observed to expected LHR are used to estimate residual lung and predict outcome. Lower ratios correlate with higher mortality, with an LHR of less than 0.6 and an observed to expected LHR of less than 25% suggesting a low survival rate. However, measurements can be difficult to reproduce and do not take liver position into account.[20-28]

Various volumetric measurements can be obtained with MRI and used as indicators of outcome. MRI measurements allow assessment of both lungs and can be more reliably obtained than US[29-35] MRI measurements include total lung volume, observed to expected total lung volume (o/e TLV), percent predicted lung volume (PPLV), fetal lung volume to fetal body volume ratio (FLV/FBV), percent liver herniation (%LH), and herniated liver to fetal thoracic volume ratio (LiTR).[36-40]

Total lung MRI volumes have been used to quantify degree of lung hypoplasia. A better prognosis is expected in fetuses with a total lung volume of 25 $cm^3$ or more, compared with fetuses with a lung volume of 18 $cm^3$ or less. Various methods of measuring lung volume ratios all show a correlation of lower numbers with poor outcome.[24-27,37] Similarly a large herniated liver volume predicts higher mortality.[38-40]

Infants struggle with various degrees of pulmonary hypertension after delivery. Pulmonary hypertension may be predicted using the modified McGoon index. From prenatal US or MRI measurements, the right and left pulmonary artery diameters are added, and then divided by the aortic diameter. If the value is less than 0.8, the risk of developing pulmonary hypertension is high; if the value is greater than 1.0, the risk is low.[41,42]

Variables including measurement technique, gestational age at time of the study, right vs left hernia, associated anomalies, and development of pulmonary hypertension limit accuracy for perfect outcome prediction using US or MRI. Developing reliable, reproducible measurements, however, is critical as invasive fetal therapeutic options become more available.[42-44]

***Treatment and Follow-up.*** The severity of pulmonary hypoplasia and pulmonary hypertension affects outcome.

Postnatally, extracorporeal membrane oxygenation (ECMO) is a method of supporting neonatal oxygenation until pulmonary hypertension resolves. Outcome is variable, however, with the most severe cases not surviving despite weeks on ECMO or ex utero intrapartum treatment (EXIT)–to–ECMO strategies. Thus surgeons have turned to in utero surgery as a potential way to improve outcomes of those with the most severe hernias. To help lungs have more space to grow in utero, open fetal surgical diaphragmatic repair was initially attempted. Outcomes were no better than those with postnatal support with complications including umbilical vein kinks and high risk for preterm delivery.[45]

Fetal intervention has evolved with less invasive fetoscopic techniques.[43,46,47] It was noted that fetuses with laryngeal or tracheal atresia have larger than normal lungs. Animal experimentation that revealed that when the trachea was occluded and fetal lung fluid egress blocked, lung growth was stimulated. In utero tracheal occlusion, initially by application of an external tracheal clip and now by fetal bronchoscopic insertion of an occlusive balloon, has been performed with resultant lung growth.[48] At delivery, the EXIT procedure is performed to remove the tracheal occlusion device before separation from the placenta. Temporary tracheal occlusion via fetoscopy is now being attempted in some centers, with a suggestion of early favorable results. Until this study is completed, the standard of care includes supportive care after delivery as close to term as possible with high-frequency ventilation and ECMO, if needed, with some centers advocating an EXIT-to-ECMO approach for high-risk fetuses.[49]

## Congenital Pulmonary Airway Malformation

***Etiology.*** CPAM, previously known as congenital cystic adenomatoid malformation, is the most common congenital lung abnormality, representing 30% to 47% of lung masses diagnosed in utero. CPAM is a hamartomatous lesion characterized by abnormal growth of terminal bronchioles containing cystic and solid tissue. It is currently thought that maldevelopment of the airways results in obstructive dysplastic changes.[50-52] Typically unilobular (85%–95%), CPAMs may be multilobular and bilateral. They contain multiple microcysts or macrocysts lined by respiratory epithelium. Usually, an abnormal communication with the tracheobronchial tree exists, with blood supplied from pulmonary arteries.

Stocker's classification of CPAM includes five different types.[53] This is based on cyst size and underlying histologic resemblance to the bronchial tree and airspaces. Adzick described a classification based on fetal imaging appearance and gross anatomy: (1) macrocystic CPAM (multiple large cysts >5 mm with slow growth and favorable prognosis); and (2) microcystic CPAM (cysts <5 mm with solid appearance, which have the highest risk for developing hydrops).[54]

***Imaging.*** Fetal ultrasonographic appearance of CPAM depends on histology. With macrocystic CPAM, multiple nonconnecting cysts are seen. Often a single lobe is affected, although multiple lobes and bilateral CPAM have been reported. Microcystic CPAMs are homogeneously echogenic and usually more echogenic than the adjacent lung.[55] If the echogenicity of the CPAM is similar to adjacent lung (more common in the third trimester), mass affect may be the only finding to suggest the diagnosis.[56] Vascularity is usually from distorted pulmonary arteries in contradistinction to BPS, in which the vascular supply is from the aorta. Hybrid lesions with mixed features of CPAM (macrocysts) and BPS (aortic supply) are common. CLO can also present as a homogeneous echogenic mass fed by pulmonary arteries branching more normally through the lobe.

MRI is useful in delineating the lung mass and amount of residual normal lung. CPAM usually has high T2-weighted signal with macrocysts and or microcysts (Figs. 50.5 and 50.6).[57] They may be difficult to differentiate from the surrounding normal lung, particularly in the later weeks of gestation when normal lung signal increases. When bilateral, differentiation from CHAOS must be made. In these cases, MRI is useful in showing fetal tracheal obstruction. In cases of CLO, high signal lung that respects the anatomic boundaries of a normal lobe may be seen.

Prognosis of CPAM is typically favorable with spontaneous decrease in size in up to 90% of cases.[58-60] Although some masses may appear to resolve completely prenatally and can have a normal appearing chest radiograph after delivery, computed tomography (CT) often identifies a residual mass. Theories as to the reason for the resolution include decompression into the bronchial tree, outgrowth of blood supply, or vascular pedicle torsion.

***Treatment and Follow-up.*** Rapidly growing CPAM, either solid or with a large dominant cyst, have a higher incidence of hydrops and are associated with a poorer outcome. Hydrops results from severe mediastinal shift causing venous and lymphatic obstruction and ultimately fetal cardiac failure. If no hydrops exists, the outcome is excellent, with greater than 95% survival. If hydrops develops, the fetus may die without intervention.[5,61] The greatest period of growth of a CPAM is between 20 to 26 weeks of gestation.[61] Lesions that are largely solid appearing and rapidly increasing in size are at most risk for causing hydrops.

The CPAM volume ratio (CVR) can be used to predict which fetuses are at risk to progress to hydrops. The lung mass volume is determined using the ellipse formula (length × width × anteroposterior diameter × 0.52), which is then divided by the head circumference. If the CVR is greater than 1.6, the risk is 75% for developing hydrops. Fetuses with CVR less than 1.6 without a dominant cyst have less than a 3% risk of developing hydrops and those with macrocystic lesions have a 14% risk.[61]

In uncontrolled studies, maternal steroid administration reversed hydrops and improved outcome.[62-68] Although it is possible that fetal thoracic growth and/or CPAM regression rather than steroids account for the resolution of hydrops, the current recommendation are to treat large microcystic CPAM with two doses of 12 mg intramuscularly 24 hours apart. Steroids have been used for macrocystic disease as well, but with less promising results.

If hydrops develops after 32 weeks of gestation, delivery is recommended. In the past, fetuses with solid lesions that developed hydrops in the second trimester underwent in utero resection.[69,70] With the current steroid protocol, there has been a decrease in the number of solid/microcystic masses that require in utero

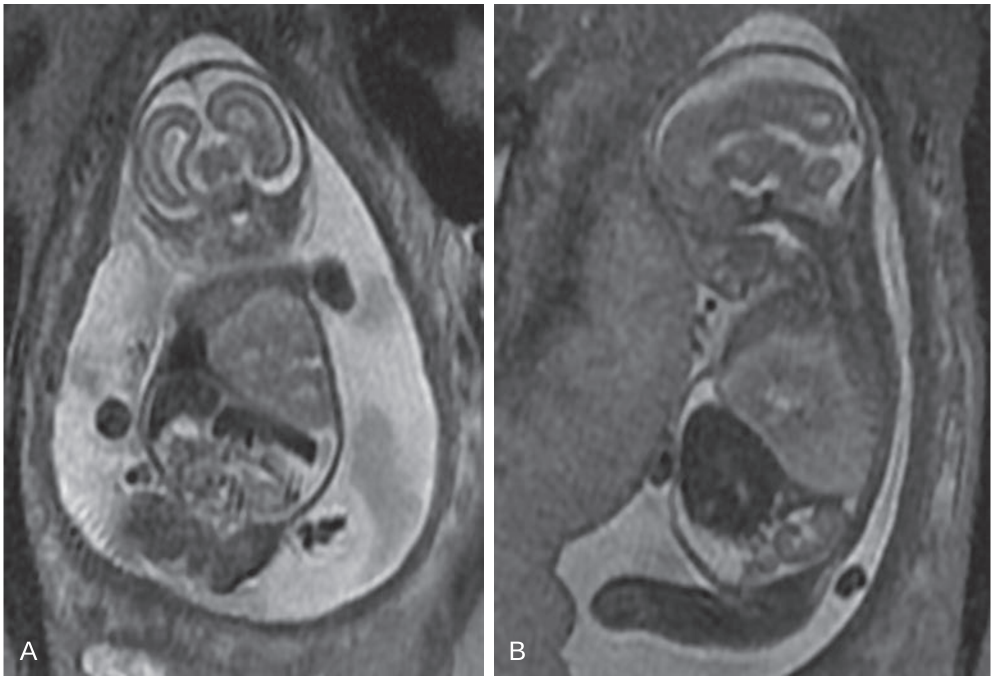

**Figure 50.5. Microcystic congenital pulmonary airway malformation with ascites.** Coronal (A) and sagittal (B) single shot fast spin echo T2-weighted MRI demonstrates a large left lower lobe heterogeneous mass deviating the mediastinum to the left and diaphragm inferiorly. Ascites is present.

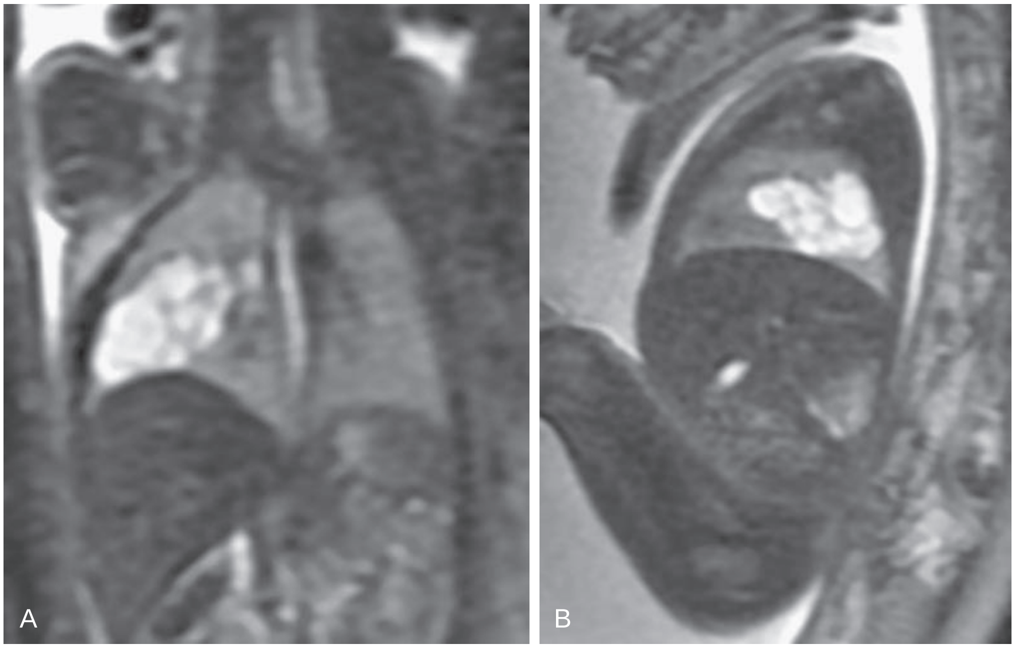

**Figure 50.6. Macrocystic congenital pulmonary airway malformation.** Coronal (A) and sagittal (B) single-shot fast spin echo T2-weighted MRI demonstrates a multicystic high signal mass involving the posterior right lower lobe. No significant mass affect is seen.

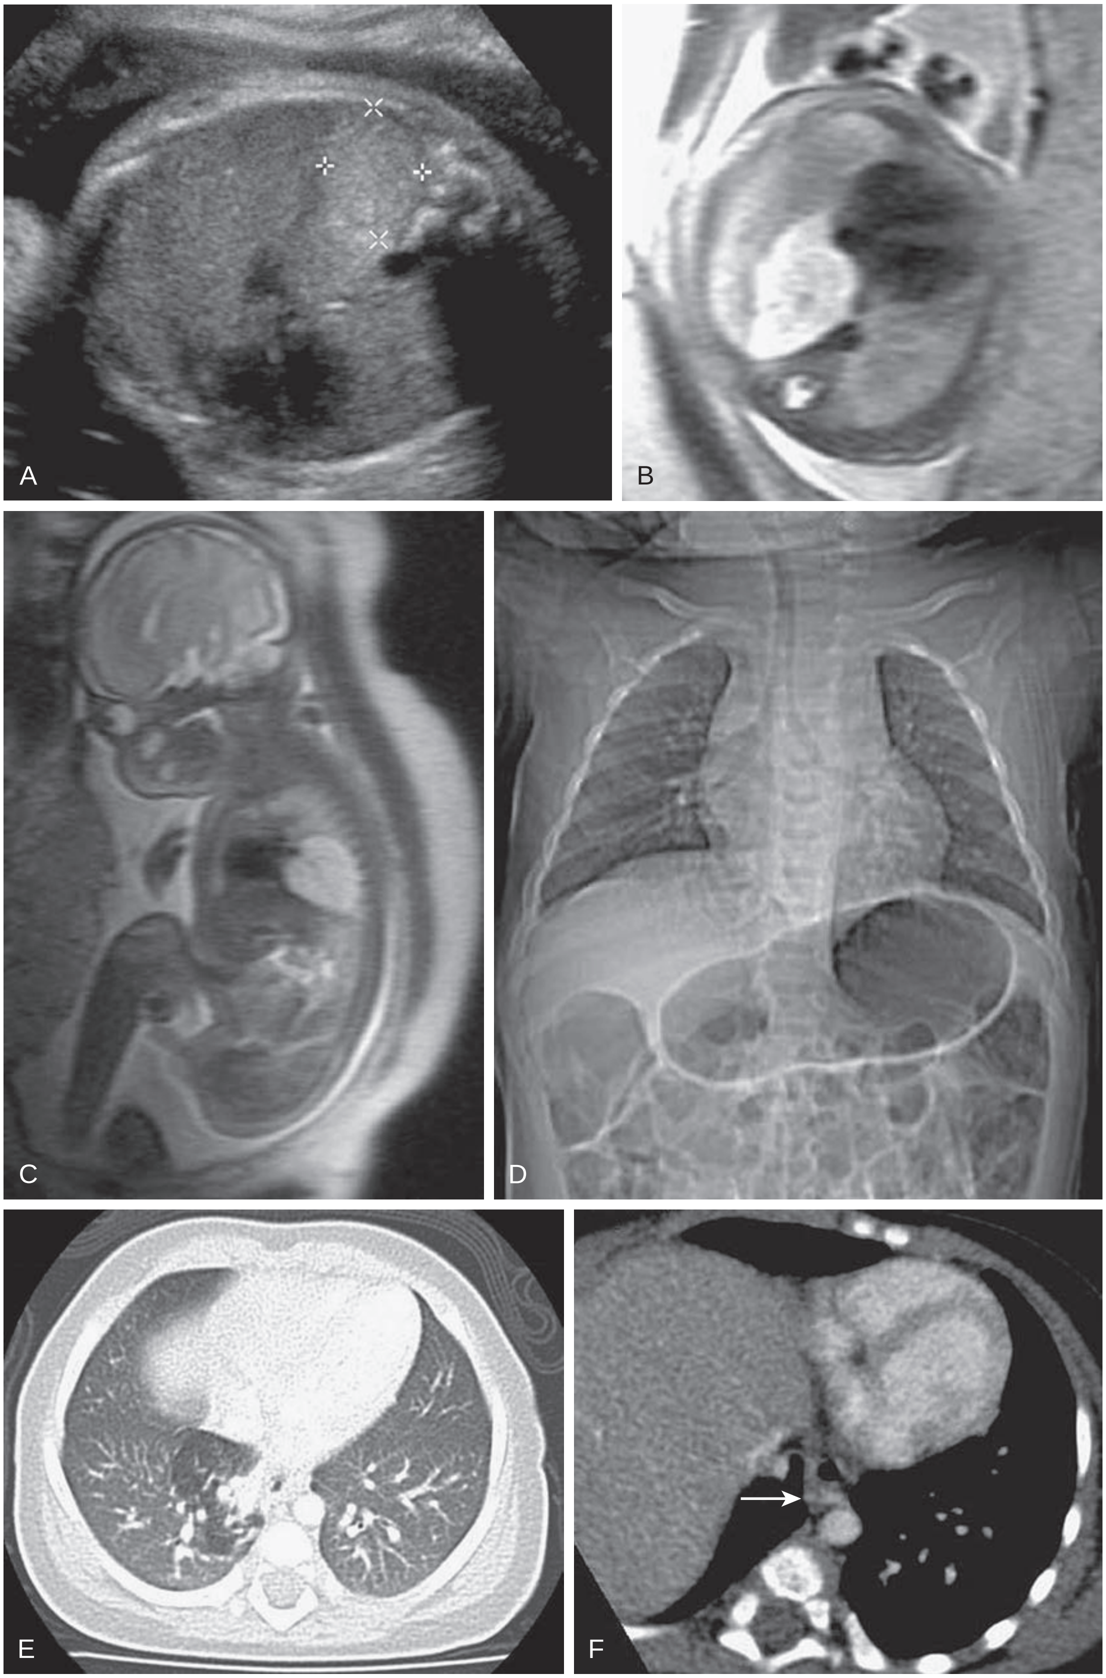
resection. In macrocystic lesions where hydrops is less likely to resolve with steroids, aspiration, thoracoamniotic shunting, and laser therapy have been attempted.[71]

After delivery, if the infant is symptomatic, prompt resection is required. The need for resection if the infant is asymptomatic continues to be debated.[72-74] Even if the chest radiograph appears normal, CT scans typically show a residual CPAM (e-Fig. 50.7).[75,76] Residual cysts may develop air trapping or a pneumothorax. Recurrent infections may occur. Rhabdomyosarcoma and bronchoalveolar carcinoma developing from CPAM has been reported.[77-81] Thus surgical resection is currently advocated in asymptomatic patients despite the lack of large long-term outcome studies.



**e-Figure 50.7. Hybrid congenital pulmonary airway malformation-sequestration.** (A) Axial sonogram shows an echogenic mass in the right lower hemithorax *(calipers).* (B and C) Single-shot fast spin echo T2-weighted MRI in the coronal (B) and sagittal (C) planes confirms the presence of a high signal mass in the right lower lobe. At delivery, the infant had no respiratory symptoms. (D) CT scout image of the chest at 3 weeks of gestational age shows no evidence of a residual lung mass. (E) Axial CT scan demonstrates a hyperlucent lesion in the medial right lower lobe. (F) Mediastinal reformatted image shows a feeding vessel *(arrow)* coursing from the aorta. At surgery, a congenital pulmonary airway malformation with a systemic feeding vessel was resected.

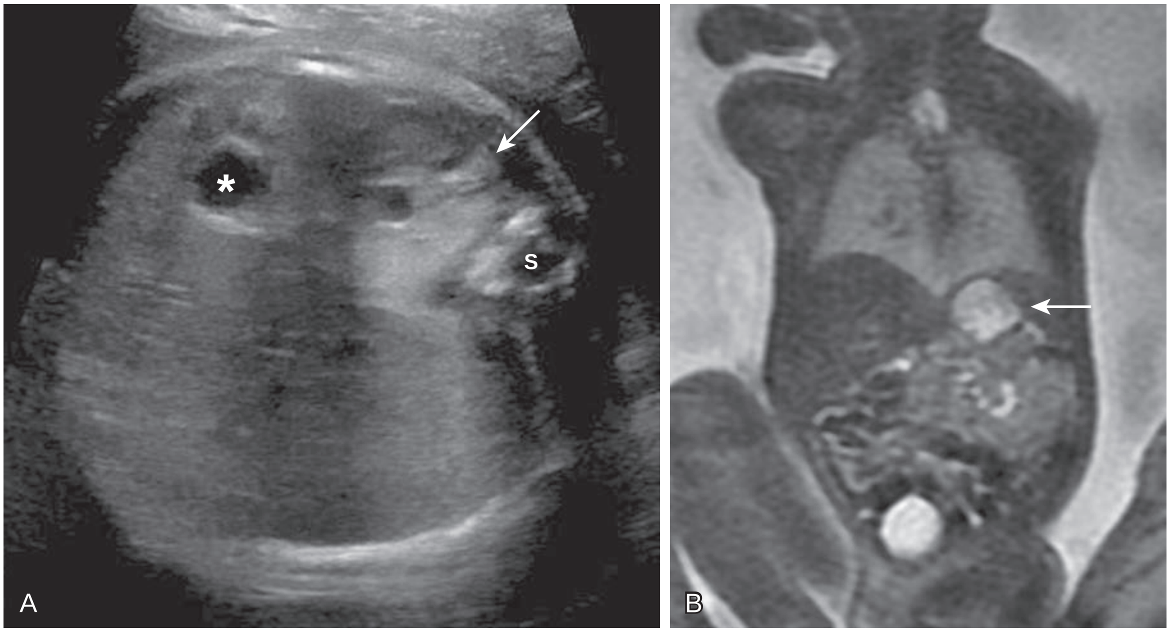


**Figure 50.8. Infradiaphragmatic sequestration.** (A) Axial sonogram of a fetus at 26 weeks of gestational age demonstrates a mixed cystic and solid mass *(arrow)* adjacent to the spine *(S)* and posterior to the stomach *(asterisk).* (B) A coronal single-shot fast spin echo T2-weighted MRI demonstrates a high signal mass below the diaphragm *(arrow).* The systemic feeding vessel was difficult to document prenatally.

## Bronchopulmonary Sequestration

***Etiology.*** BPS is abnormal pulmonary tissue with no connection with the normal tracheobronchial tree and systemic arterial blood supply from the aorta.[82] Typically located in the left posteroinferior thorax, BPSs have been found infradiaphragmatically and within the diaphragm and may mimic a suprarenal neuroblastoma (Fig. 50.8).[83]

There are two types of BPS: extralobar and intralobar. Extralobar sequestration has a separate pleural covering and has systemic venous drainage via the azygos system or inferior vena cava. Intralobar sequestration has no separate pleura with venous drainage via the pulmonary veins. Both types receive arterial blood supply from the systemic circulation, usually the aorta.

Extralobar sequestration has a higher association with anomalies, including CDH, eventration, and foregut anomalies. Hybrid lesions are relatively common with CPAM masses associated with systemic arterial supply (see e-Fig. 50.7).[84] Rarely, sequestrations can present with effusions or hydrops (Fig. 50.9).

***Imaging.*** The prenatal US appearance of BPS is typically a solid triangular hyperechoic mass in the lower hemithorax adjacent to the diaphragm.[85] Hybrid lesions may have a cystic component.[86] The masses are typically small and decrease in size in later gestation in 75% of cases.[87]

Systemic vascular supply should be searched for, typically branching from the aorta below the diaphragm. Color and power Doppler are helpful in identifying the vessel but may be difficult to demonstrate.

On MRI, BPS has homogeneous intermediate high signal on T2-weighted images. Vascular supply may be suggested by a low signal line coursing to the mass but also may be difficult to identify prenatally. As the lesions regress they may appear of lower signal intensity to lung on T2-weighted images.

Torsion of extralobar sequestration has been described as a source of hydrothorax/effusion.[88]

Masses that appeared to resolve in utero are typically still found on postnatal CT.[89] The apparent resolution is likely due to decompression into the normal lung, lesion outgrowing blood supply, or torsion around the vascular pedicle resulting in infarction.[90] As these lesions regress, they become more difficult to visualize on US.

***Treatment and Follow-up.*** Prognosis is typically favorable with only rare reports of associated pleural effusions or hydrops.[91,92] If hydrops develops after 32 weeks of gestation, early delivery is recommended. Before 32 weeks, in utero surgical resection may be considered.[93] Percutaneous laser ablation of the feeding vessel is a less invasive procedure and has been reported to decrease tumor size.[94,95]

In one series, cases complicated by pleural effusion or hydrops treated by laser ablation of the feeding vessel resulted in decrease in BPS size, increase in mass of normal lung parenchyma, and disappearance of pulmonary effusions. After delivery, these patients were all asymptomatic and none of them required surgical intervention.[96]

A macrocyst within BPS suggests a hybrid lesion (macrocystic CPAM and BPS). In these cases, a maternal course of antenatal steroids and cyst drainage are options, as with CPAM.

If the BPS is solid with a large pleural effusion, thoracentesis to prevent pulmonary hypoplasia is possible, but rapid reaccumulation of fluid limits its usefulness. Placement of a thoracoamniotic shunt has been attempted in these cases.[97]

Postnatal CT with contrast enhancement or MRI is useful in identifying the feeding systemic vessel. Symptoms depend on the size of the mass. Because BPS may become infected, elective surgery is often recommended even if the infant is asymptomatic.[98]

## Congenital Lobar Overinflation

***Etiology.*** CLO, also known as congenital lobar hyperinflation or emphysema, is characterized by hyperinflation of a lung segment or lobe with normal pulmonary vascular supply. Microscopically, the alveoli are dilated but not maldeveloped.[2,3,50,52] The alveolar walls are intact, thus the preference of using the term *overinflation* rather than *emphysema*. Two subgroups of CLO seem to exist. The first group presents with respiratory distress postnatally with overinflation secondary to airway cartilage anomalies, absent bronchial cartilage, or extrinsic compression of the airway by a

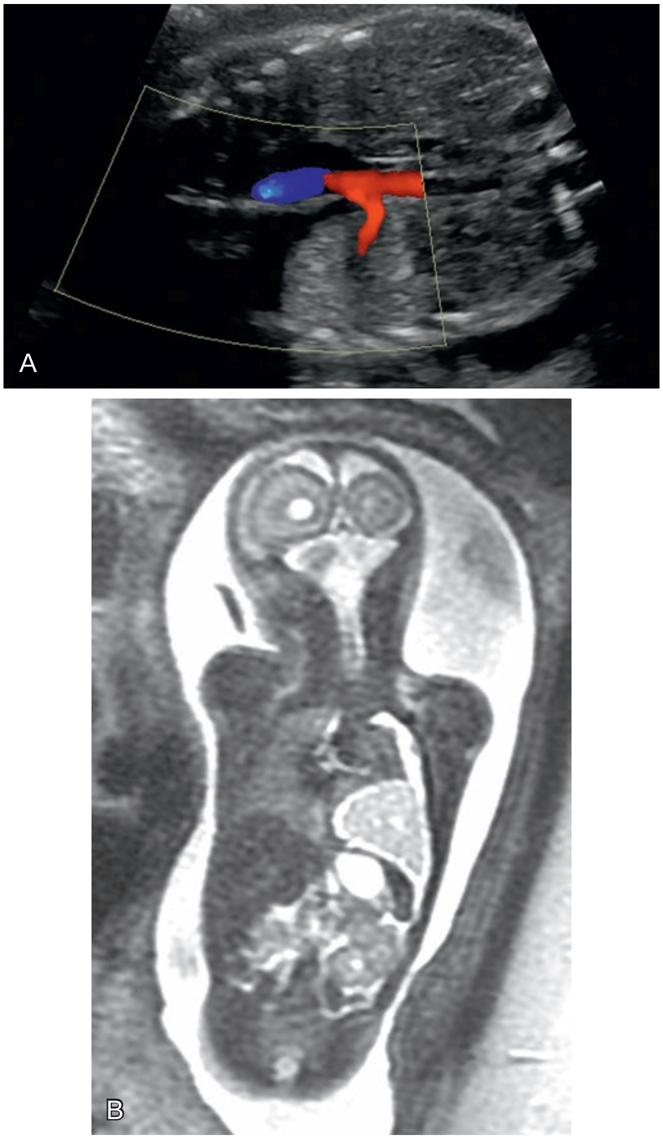

**Figure 50.9. Bronchopulmonary sequestration with pleural effusion at 24 weeks of gestation.** (A) Coronal sonogram of the fetal chest demonstrates a systemic vessel coursing from the aorta into an echogenic left lower lobe mass. (B) Coronal single-shot fast spin echo T2-weighted MRI demonstrates a high signal left lower lobe mass with moderate pleural effusion. The feeding vessel was not as well seen by MRI.

bronchogenic cyst or an enlarged pulmonary artery.[98] The partially obstructed airway results in air trapping. This group most commonly affects the left upper lobe, then the right upper and middle lobes.[99] The second group of CLO is now recognized more frequently prenatally. These cases of segmental or lobar hyperinflation are often associated with bronchial atresia, most common in the lower lobes.[100-102]

***Imaging.*** CLO is often recognized with US in the second trimester as a homogeneously hyperechoic mass. No macrocysts are present. The hyperechogenicity is thought to be secondary to accumulation of fluid within the alveoli.[100] By the third trimester, the mass often becomes isoechoic and difficult to differentiate from adjacent normal lung. Mediastinal deviation may be the only clue that a CLO is present.

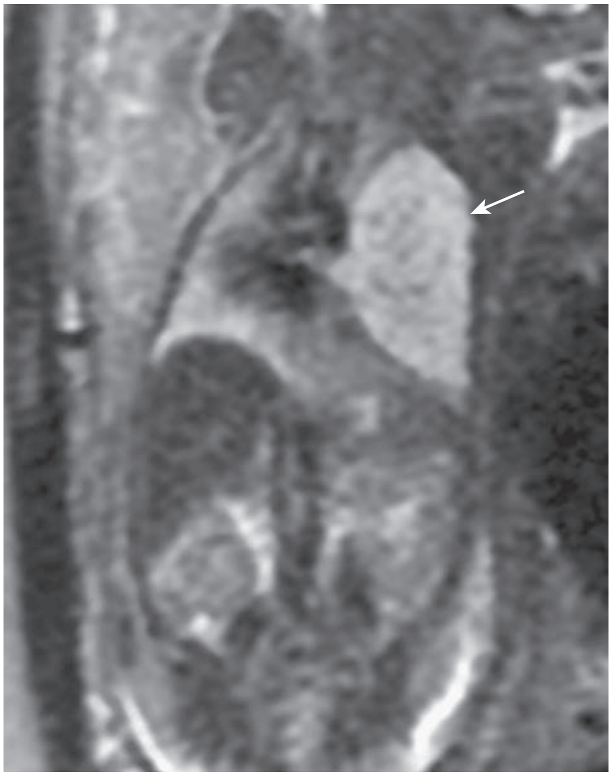

**Figure 50.10. Congenital lobar overinflation.** Coronal single-shot fast spin echo T2-weighted MRI of a fetus at 25 weeks of gestational age demonstrates a high signal homogeneous left upper lobe *(arrow).* Pulmonary vessels can be seen coursing through the parenchyma.

With MRI, the mass is of high signal compared with adjacent lung on T2-weighted images. Mass effect on the adjacent intermediate signal normal lung may be noted. The diaphragm often is flattened.

Differentiation of CLO from microcystic CPAM or sequestration may be difficult prenatally both by US and MRI. One useful differentiation is the assessment of vascularity with Doppler; normal pulmonary vessels course through CLO, with no systemic feeders (Fig. 50.10). Rarely, the mediastinal shift is severe enough to result in polyhydramnios, hydrops, and pulmonary hypoplasia.[103-105]

***Treatment and Follow-up.*** Prognosis is typically favorable. As with other fetal lung masses, follow-up US prenatally is useful to exclude the rare development of hydrops and polyhydramnios. Diagnosis may be confirmed by following delivery with radiography and CT.[104,105] Postnatal surgery is performed if the child is symptomatic.

## Congenital Hydrothorax

***Etiology.*** Fetal pleural fluid may develop without an associated mass and is considered abnormal at any gestational age.[106,107] The fluid collection may be unilateral or bilateral. The incidence is 1:15,000 births. Chylothorax is the most common cause of congenital hydrothorax and may be caused by thoracic duct anomalies. Lesions associated with pleural effusions include masses (CDH, CPAM, BPS), lymphangiectasia, cardiac anomalies, Turner syndrome, trisomy 21, lymphatic malformation, and TORCH (toxoplasmosis, other [congenital syphilis and viruses], rubella, cytomegalovirus, and herpes simplex virus) infection. Thorough evaluation is required to identify associated anomalies. Overall mortality is reported to be as high as 50%. Outcome is best if the

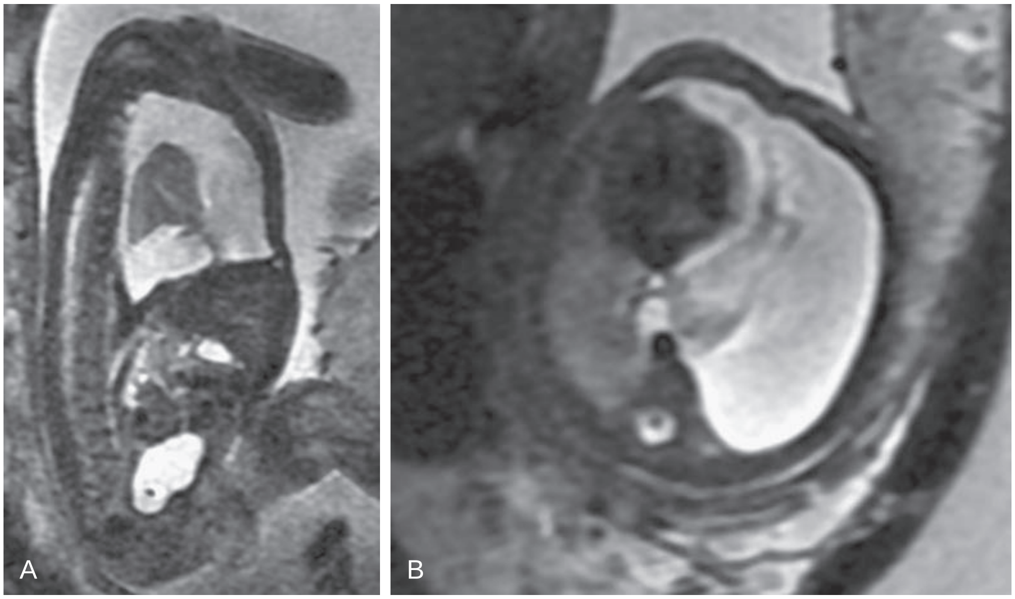

**Figure 50.11. Pleural effusion.** (A) Sagittal single-shot fast spin echo T2-weighted MRI shows a large pleural effusion with compression of the underlying lung parenchyma. (B) Axial single-shot fast spin echo T2-weighted MRI of the chest demonstrates the severity of the mediastinal shift and compression of both ipsilateral and contralateral lung.

effusion is unilateral. Primary chylothorax may resolve spontaneously (22%). If effusions progress to hydrops, mortality increases owing to the development of pulmonary hypoplasia.

***Imaging.*** US demonstrates anechoic fluid in the pleural space. MRI shows high signal fluid surrounding lung parenchyma. MRI may be useful in identifying a cause for the hydrothorax such as an underlying CPAM or BPS (Fig. 50.11).

***Treatment and Follow-up.*** If the effusion is small, conservative observation is appropriate. If the effusion is large, and the infant is less than 32 weeks of gestational age, fetal thoracentesis and thoracoamniotic shunting are potential prenatal treatment options, although reaccumulation of fluid is frequent.

## Congenital High Airway Obstruction

***Etiology.*** CHAOS is caused by obstruction or absence of the trachea. This rare entity may be the result of laryngotracheal atresia, tracheal stenosis, or tracheal web. Aberrant pulmonary budding off the foregut is present and in most cases there is a connection with the esophagus. Other anomalies can be associated with this entity, including Fraser syndrome and DiGeorge syndrome.

***Imaging.*** With US, both lungs are seen to be symmetrically enlarged and echogenic as a result of fluid trapping. The heart is compressed, and the diaphragms are flattened. Hydrops may develop. Increase or decrease in amniotic fluid may occur.[108-110] MRI shows abnormally large high signal lungs on T2-weighted images. Diaphragmatic eversion is present (Fig. 50.12). Identification of a fluid-filled trachea and bronchi confirms the diagnosis. Differential diagnosis includes bilateral CPAM.

***Treatment and Follow-Up.*** EXIT delivery with airway control is the current management of choice in a fetus with CHAOS. The prognosis is typically poor.[111,112]

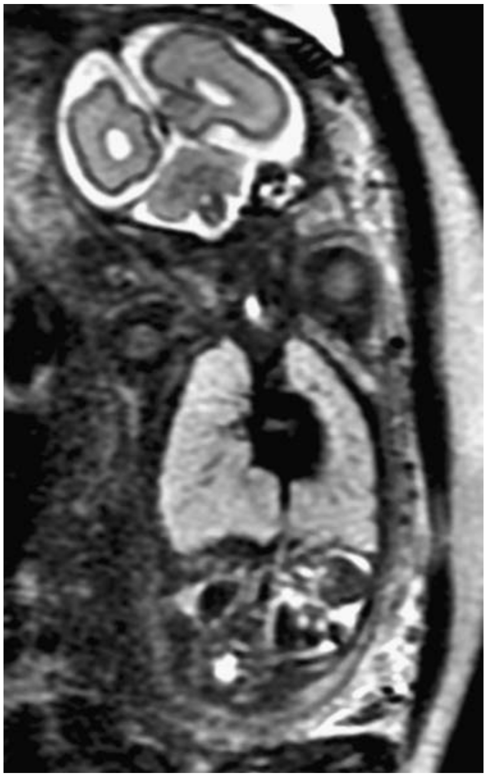

**Figure 50.12. Congenital high airway obstruction secondary to tracheal stenosis.** Coronal T2-weighted MRI of a 27-week-old fetus demonstrates abnormally enlarged high signal lungs. The diaphragms are flattened. Mild ascites is present.

## KEY POINTS

- The most common fetal chest abnormalities include CDH, congenital bronchopulmonary malformations, and congenital hydrothorax.
- Accurate prenatal diagnosis aids in counseling and planning potential fetal therapy, mode of delivery, and postnatal care.
- In a fetus with CDH, low lung-to-head circumference ratio and liver herniation into the chest suggest a worse outcome.
- Prognosis of congenital bronchopulmonary malformations is typically excellent. However, if hydrops develops prenatally, the outcome is poor without intervention.
- Chylothorax is the most common cause of congenital hydrothorax.

# Upper Airway Disease

Bernard F. Laya and Edward Y. Lee

The upper airway, by definition, lies above the thoracic inlet. The anomalies and abnormalities involving the upper airway in children are common and varied. They include a combination of congenital and acquired morphologic, neuromuscular, bony, and cartilaginous abnormalities.[1] The anatomic considerations that predispose children to acute respiratory distress, even with only partial obstruction, are as follows: (1) The nasopharynx is narrower than in adults, (2) the pediatric larynx is more anteriorly and superiorly located, (3) the conus elasticus is susceptible to edema, (4) the vocal cords are more angled anteriorly, (5) the epiglottis is broader and longer, and (6) the tongue is larger.[2]

Affected children usually present with acute respiratory distress associated with stridor, apnea, or even acute pulmonary edema.[3,4] Some children may present with more chronic clinical symptoms characterized by recurrent chest infections or obstructive sleep apnea, which can lead to growth retardation, chronic respiratory failure, cor pulmonale, and even death.[3]

Although a thorough history and physical examination may narrow differential diagnostic considerations of upper airway disease in the pediatric population, imaging evaluation plays an important role in establishing the diagnosis, localizing the anatomic area of abnormality, and defining the extent of disease.[5] Frontal and lateral radiographs of the airway and fluoroscopy have been mainstays in upper airway evaluation. Advances in cross-sectional imaging techniques approaching near-endoscopic detail have been developed to more accurately demonstrate airway anatomy.[3] For practical purposes, the discussion of pathology in this chapter is divided into the supraglottic, glottic, and subglottic regions.

## SUPRAGLOTTIC ABNORMALITIES

### Laryngomalacia

***Etiology.*** Laryngomalacia is abnormal laxity of the pharyngeal tissues that causes the epiglottis, arytenoids, and aryepiglottic folds to involute and partially obstruct breathing during inspiration. The underlying cause of laryngomalacia is attributed to the immaturity of the laryngeal cartilages and muscles, which allows the larynx and the supralaryngeal structures to collapse.[3-6] The unstable epiglottis and redundant arytenoid cartilage mucosa tend to be sucked into the glottis during inspiratory airflow causing obstruction.[7] Laryngomalacia accounts for more than 75% of cases of congenital stridor and is the most common cause of symptomatic partial upper airway obstruction in infants.[8,9] The stridor typically improves when the infant is agitated or active and becomes worse when the infant is at rest.

***Imaging.*** The diagnosis of laryngomalacia can be established with use of airway fluoroscopy, although laryngoscopy is the diagnostic procedure of choice.[10] The characteristic imaging finding in patients with laryngomalacia consists of downward and posterior bending of the epiglottis and anterior buckling of the aryepiglottic folds, which narrow and eventually obliterate the upper airway (Fig. 51.1).[9] Although airway fluoroscopy appears to be reliable because of its high specificity, it has low sensitivity, and thus negative findings of a fluoroscopic study require further diagnostic evaluation in the setting of a high clinical suspicion.[11]

***Treatment and Follow-up.*** In most infants with laryngomalacia, stridor resolves during the first year of life. However, potentially serious complications, including airway obstruction and sudden death, may occur. In severe or life-threatening cases, various surgical treatment options are available including supraglottoplasty, an incision in the aryepiglottic folds, epiglottopexy, and tracheostomy.[7,12]

### Epiglottitis

***Etiology.*** Acute bacterial epiglottitis is a potentially serious cause of upper airway obstruction in children. It is characterized by inflammation and swelling of the epiglottis and the aryepiglottic folds but also can affect the false cords and the subglottic region.[13] Epiglottitis usually is attributed to *Haemophilus influenzae*, although other bacteria including *Streptococcus*, *Staphylococcus*, *Moraxella*, and *Pseudomonas* also have been implicated.[14] Because *H. influenzae* is now preventable by immunization, the incidence of epiglottitis has substantially diminished, although vaccine failures do occur.[15,16] Epiglottitis typically occurs in children between 3 and 6 years of age, but it also can occur in adults.[17] Epiglottitis usually has a sudden onset with no history of a preceding upper respiratory tract infection. Affected children typically appear toxic with acute stridor, dysphagia, fever, restlessness, drooling, and increased respiratory distress in the recumbent position. Epiglottitis is a life-threatening disease that requires potential emergent intubation.

***Imaging.*** Epiglottitis usually is diagnosed with radiography, and endoscopy is obtained for confirmation. A lateral radiograph reveals swelling and marked enlargement of the epiglottis that resembles the shape of a thumb (Fig. 51.2). Associated thickening of the aryepiglottic folds also occurs. Inflammation extends into the glottis and subglottic regions, causing a steeple or funnel configuration of the airway on frontal views. Because of the potentially rapid progression of the condition, which can lead to sudden and complete obstruction of the upper airway, radiographs should be obtained expeditiously with minimal manipulation of the neck. When undergoing imaging, patients should remain upright in their position of maximal comfort. Conditions that mimic bacterial epiglottitis in children include caustic ingestion, angioneurotic edema, chemical or thermal injury, abscess, and epithelial cyst, among others. The omega epiglottis with prominent lateral folds is a normal variant and should not be misinterpreted as epiglottitis. In such cases, the aryepiglottic folds remain thin.[18]

***Treatment and Follow-up.*** Antibiotic therapy is a mainstay of treatment, and steroids are administered to some patients. Direct laryngoscopy with intubation is performed to secure the airway in severely affected patients.[14]

## GLOTTIC ABNORMALITIES

### Laryngeal Atresia

***Etiology.*** Laryngeal atresia, a rare congenital malformation, is usually fatal. The malformation is caused by nondevelopment of the sixth branchial arch during embryogenesis, resulting in failure of the larynx and the trachea to recanalize. Typical presentation of affected patients with laryngeal atresia at birth is severe

## Abstract:

The upper airway, by definition, lies above the thoracic inlet. The anomalies and abnormalities involving the upper airway in children are common and varied. They include a combination of congenital and acquired morphologic, neuromuscular, bony, and cartilaginous abnormalities. The anatomic considerations that predispose children to acute respiratory distress, even with only partial obstruction, are as follows: (1) The nasopharynx is narrower than in adults, (2) the pediatric larynx is more anteriorly and superiorly located, (3) the conus elasticus is susceptible to edema, (4) the vocal cords are more angled anteriorly, (5) the epiglottis is broader and longer, and (6) the tongue is larger.

Affected children usually present with acute respiratory distress associated with stridor, apnea, or even acute pulmonary edema. Some children may present with more chronic clinical symptoms characterized by recurrent chest infections or obstructive sleep apnea, which can lead to growth retardation, chronic respiratory failure, cor pulmonale, and even death.

Although a thorough history and physical examination may narrow differential diagnostic considerations of upper airway disease in the pediatric population, imaging evaluation plays an important role in establishing the diagnosis, localizing the anatomic area of abnormality, and defining the extent of disease. In this chapter, the imaging modalities utilized in the evaluation of upper airway are discussed. Various congenital as well as acquired upper airway diseases in children are presented with emphasis on their typical imaging characteristics.

Imaging of the Upper Airways
Stridor in Children

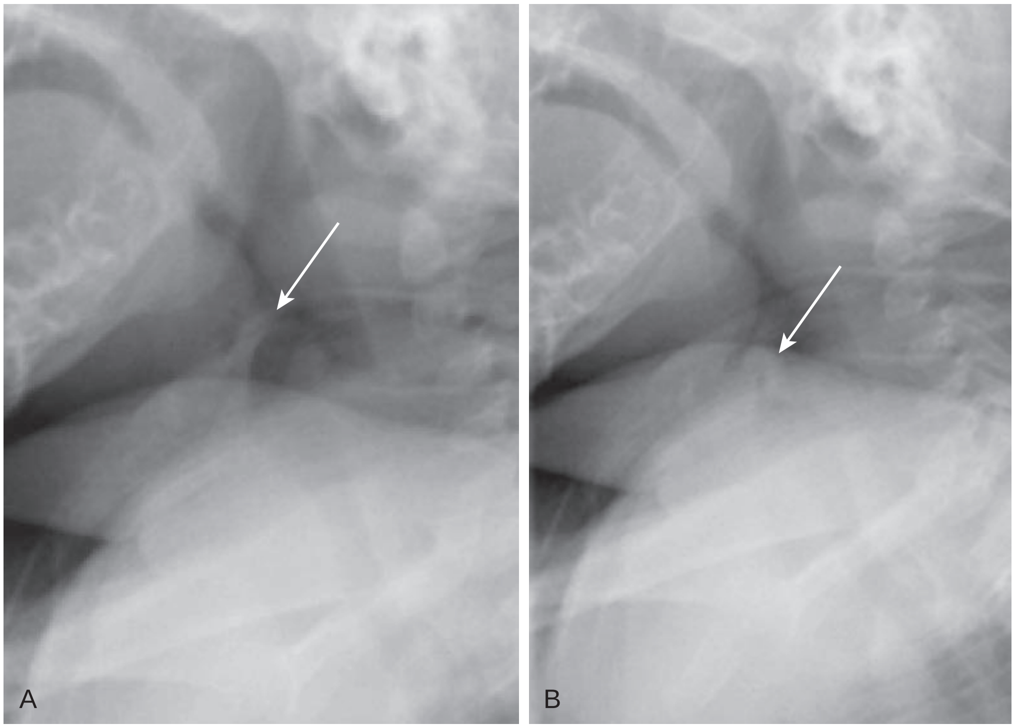

**Figure 51.1. Laryngomalacia in a 3-month-old boy with stridor.** (A) Still lateral image from an airway fluoroscopic study demonstrates the normal position of the epiglottis *(arrow).* (B) Still image from an airway fluoroscopic study during inspiration shows laxity of the epiglottis with posterior, downward movement obstructing the airway *(arrow)* consistent with laryngomalacia.

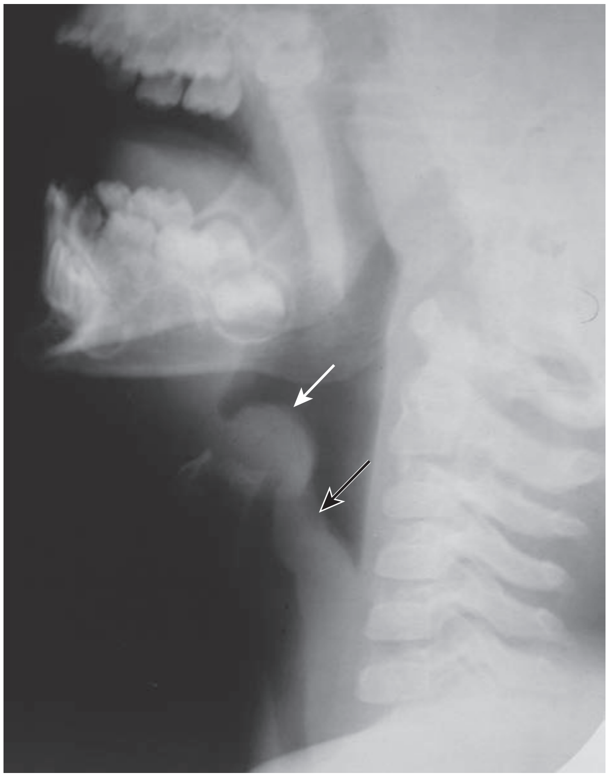

**Figure 51.2. Epiglottitis in a 5-year-old boy with respiratory distress and drooling.** A lateral soft tissue neck radiograph shows a markedly thickened epiglottis *(white arrow),* which is referred to as the "thumb" sign. The aryepiglottic folds *(black arrow)* also are thickened.

respiratory distress despite strong respiratory effort. Associated anomalies include a tracheoesophageal fistula, esophageal atresia, urinary tract abnormalities, limb defects, and low-set ears.[19] Laryngeal atresia is the most common reason for congenital high airway obstruction syndrome (CHAOS), a rare entity causing fluid entrapment within the enlarged trachea and lungs along with flattening of the diaphragm (see also Chapter 50).[20]

***Imaging.*** Laryngeal atresia can be diagnosed with use of prenatal ultrasound by identifying the signs of congenital high airway obstruction syndrome, such as enlarged hyperechogenic lungs, a flattened or inverted diaphragm, a dilated and fluid-filled trachea, fetal hydrops, and polyhydramnios.[20,21] Fetal magnetic resonance imaging (MRI), which correlates highly with prenatal ultrasound, can detect laryngeal atresia with the advantage of having the capability to identify the level of obstruction in most cases (e-Fig. 51.3).[20,22]

***Treatment and Follow-up.*** The treatment of laryngeal atresia focuses on prompt airway intervention at delivery after an accurate prenatal diagnosis, which may allow survival of infants with this otherwise fatal condition. An emergent tracheostomy is required immediately after birth to secure an airway. Ex utero intrapartum treatment (EXIT) procedure has also been used for this condition to facilitate safe delivery and allow some time to secure the airway.[20] Repair of laryngeal atresia requires laryngotracheal reconstruction.

## Laryngeal Web

***Etiology.*** A congenital laryngeal web is an uncommon condition caused by faulty embryogenesis of the laryngotracheal groove. This web is a band of varying thickness, usually located anteriorly at the level of the cords, which obliterates the anterior commissure. A congenital laryngeal web occasionally occurs just below the true cords. Affected infants present with a weak or absent cry, varying

degrees of stridor, and respiratory distress; they often have concomitant abnormalities such as subglottic stenosis.[3]

***Imaging.*** A definitive diagnosis of laryngeal web can be provided by direct laryngoscopy, but imaging evaluation plays a role in diagnosis. Plain radiography and fluoroscopy can demonstrate that the abnormality is in the glottis region, but no definitive radiographic findings exist.[6] Computed tomography (CT) with multiplanar imaging and three-dimensional reconstructions can provide precise information with respect to the exact location of the web, its thickness, and extent (Fig. 51.4). Furthermore, CT is able to visualize the structures beyond the area of obstruction, which is a limitation of laryngoscopy.[23]

***Treatment and Follow-up.*** The primary goals of treatment for a congenital laryngeal web are to provide a patent airway and achieve sufficient voice quality. Treatment depends on the thickness and extent of the abnormality. Surgical procedures include laryngotracheal reconstruction, laryngofissure and placement of a stent or keel, and endoscopic lysis with application of mitomycin C.[24,25]

## Laryngocele

***Etiology.*** A laryngocele is a rare lesion characterized by abnormal dilation of the laryngeal saccule, which is a narrow blind pouch arising from the anterior end of the laryngeal ventricle.[20,26,27] Laryngoceles may extend internal or external to the larynx.[21,28]

Most childhood laryngoceles are congenital; acquired laryngocele may develop in older children or adults who experience increased intralaryngeal pressure.

***Imaging.*** CT and MRI have replaced older plain film and fluoroscopic techniques.[20,21,28] A laryngocele typically is a well-defined cystic structure of air or near-water density value in a characteristic location, with a smooth surface, lack of mucosal abnormality, and variable extent of airway narrowing (Fig. 51.5).[22,29,30]

***Treatment and Follow-up.*** Microlaryngoscopic surgery with the use of $CO_2$ laser has become the treatment of choice for internal laryngoceles (those that lie within the larynx). An external approach remains the main surgical treatment of combined or external laryngoceles (those that protrude through the thyrohyoid membrane).[30]

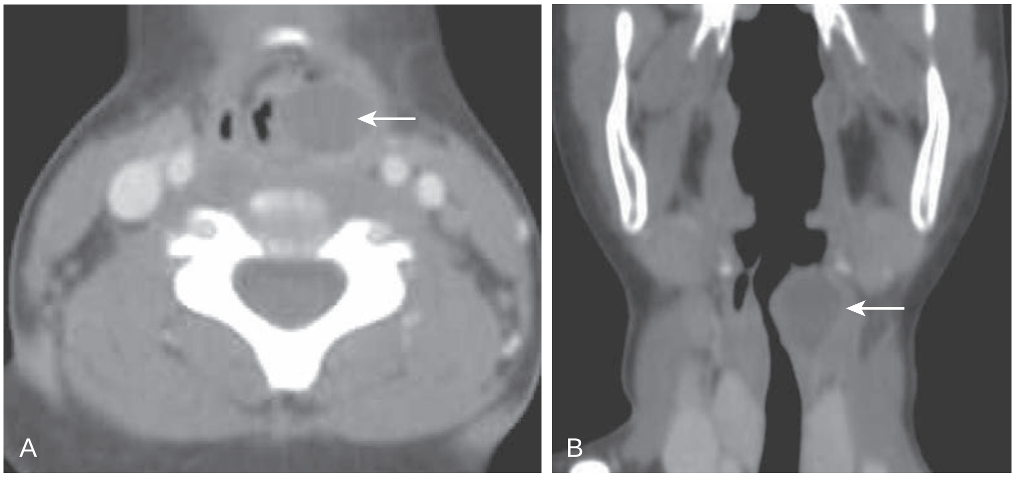

**Figure 51.5. Laryngocele in a 5-year-old boy with chronic stridor.** Axial CT scan (A) with coronal reconstruction (B) of the upper airway reveals a well-demarcated fluid-filled rounded structure *(arrow)* adjacent to the left laryngeal ventricle compatible with a laryngocele. Also noted is a marked narrowing of the upper airway.

## Recurrent Respiratory Papillomatosis

***Etiology.*** Recurrent respiratory papillomatosis (RRP) is the most common benign neoplasm to affect the larynx in children.[31] It is the proliferation of benign squamous papillomas in the aerodigestive tract, usually involving the larynx. The etiology of RRP is infection of the upper airway with human papillomavirus types 6 and 11.[7,32] Vertical transmission occurring during delivery through an infected birth canal is presumed to be the major mode of transmission in children.[33] Maternal vaccination has greatly reduced the incidence of this potentially devastating disease.

Change in voice (e.g., hoarseness, weak cry, and aphonia) and stridor are the most common symptoms in patients with RRP. Less common presenting symptoms include chronic cough, recurrent pneumonia, failure to thrive, dyspnea, dysphagia, and acute respiratory distress, especially in infants with a superimposed upper respiratory tract infection.[34] The age of symptom onset typically ranges from neonates to 6 years. RRP can mimic other diseases including croup, tracheomalacia, or asthma.[35] This diagnosis should be considered in children when other common pediatric airway diseases either do not follow the expected natural history or do not respond to treatment.[36]

***Imaging.*** On plain radiographs, RRP typically appears as irregular filling defect in the glottis (Fig. 51.6). It also can extend into the subglottic region and seed peripherally in the respiratory tract, resulting in pulmonary nodules or nonspecific lung parenchymal changes.[3] A confirmatory diagnosis of RRP is made by direct laryngoscopy and biopsy for tissue diagnosis.[36]

***Treatment and Follow-up.*** Carbon dioxide laser surgery, antiviral therapy, and other adjuvant regimens have been tried, but none of them have proved to be completely successful in treating RRP. Recurrences are very common.[34,37]

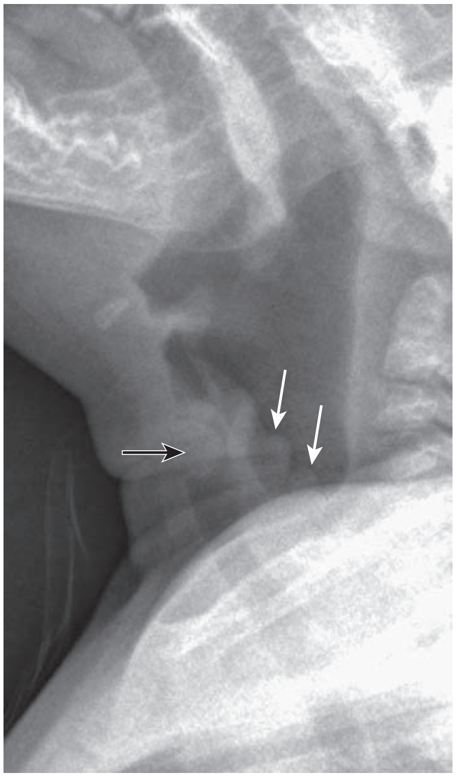

**Figure 51.6. Recurrent respiratory papillomatosis in a 4-year-old boy.** A lateral soft tissue radiograph demonstrates a rounded soft tissue mass in the laryngeal region *(black arrow).* Nodular soft tissue densities also are noted along the aryepiglottic folds *(white arrows). (Courtesy of Elizabeth H. Ey, MD, Dayton, OH.)*

## SUBGLOTTIC ABNORMALITIES

### Subglottic Stenosis

***Etiology.*** Subglottic stenosis is a narrowing of the subglottic airway that can be either congenital or acquired. In pediatric patients, congenital subglottic stenosis is due to faulty recanalization of the fetal laryngeal lumen, whereas the acquired type usually is the result of prolonged endotracheal intubation.[3,7] Because of improved management of neonates who require ventilatory support, the incidence of neonatal subglottic stenosis has diminished substantially.[38] Stridor is the most common clinical presentation. However, an infant or child with a mild degree of congenital or acquired subglottic stenosis may remain asymptomatic until an upper respiratory tract infection results in aggravation of the subglottic airway narrowing.[6]

***Imaging.*** Endoscopy is the reference standard for diagnosis, but imaging plays an important role in the evaluation of subglottic stenosis. Plain radiography and fluoroscopy, which show fixed narrowing of the subglottic airway, usually enable diagnosis.

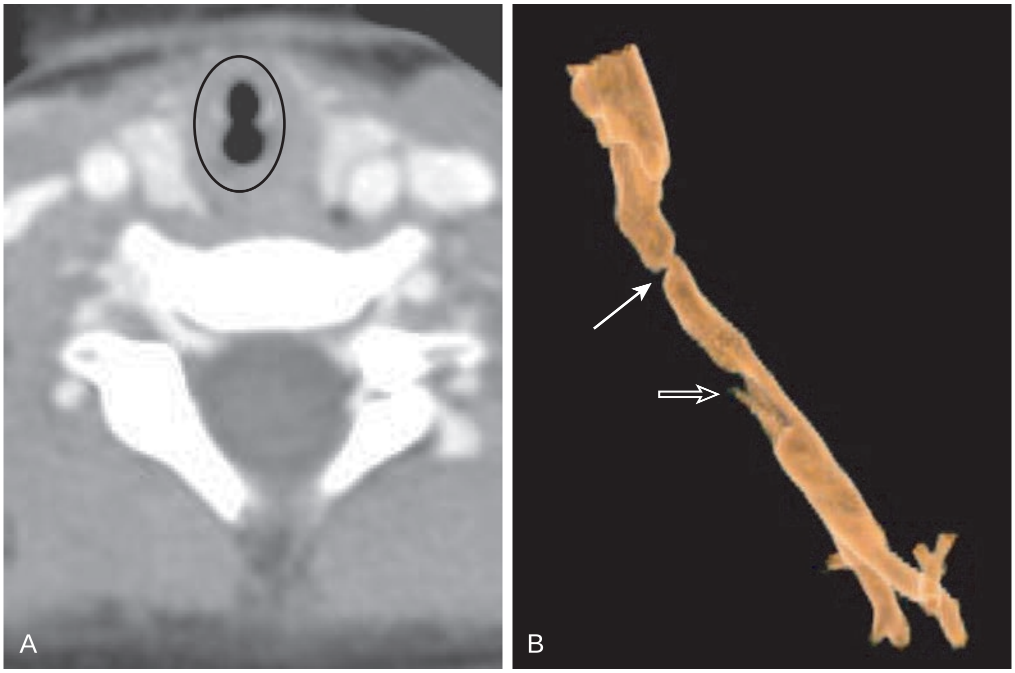

**Figure 51.7. Subglottic stenosis in a 2-year-old girl, a former premature infant who had undergone chronic intubation.** (A) Axial neck CT demonstrates severe transverse narrowing of the subglottic trachea *(circled).* (B) An external surface volume-rendered reconstruction shows severe subglottic stenosis *(solid arrow)* and a defect from the tracheostomy tube *(open arrow).*

However, CT with virtual bronchoscopy and MRI can be useful in assessing the exact site and length of stenosis and the airway distal to the area of narrowing (Fig. 51.7).[6,39]

***Treatment and Follow-up.*** The two major treatment options currently available for subglottic stenosis are endoscopic dilation and surgical reconstruction.[7,40]

## Croup

***Etiology.*** Viral croup or laryngotracheobronchitis is the most common cause of upper airway obstruction in children from 6 months to 3 years of age. Parainfluenza and influenza virus are the two most common etiologic agents for viral croup. They induce a reactive inflammatory response, which results in subglottic edema and subsequent upper airway narrowing. Clinically, viral croup is characterized by a low-grade fever and varying degrees of inspiratory stridor, barking cough, and hoarseness.[2,6,41]

***Imaging.*** Although the diagnosis of viral croup is mainly clinical, airway studies may be obtained for diagnostic confirmation and exclusion of other causes of acute stridor, such as epiglottitis. On a frontal radiograph, the lateral walls of the subglottic larynx normally are convex or shouldered. Mucosal edema in viral croup narrows this space, which results in a loss of lateral convexity, creating a "steeple" shape below the vocal cords (Fig. 51.8). The narrowing can extend 5 to 10 mm below the vocal cords. The steeple sign is not specific for croup and may be seen in some children with epiglottitis. Furthermore, it can be absent in children affected with viral croup. On lateral radiographs, the hypopharynx often is overdistended, and the subglottic region is hazy or indistinct as a result of narrowing of the airway by mucosal edema. The epiglottis, aryepiglottic folds, and prevertebral spaces are normal in persons with viral croup.[2-6]

***Treatment and Follow-up.*** In most pediatric patients with viral croup, the disease is mild and self-limited. Depending on the severity of disease, steroids and nebulized epinephrine have been administered to treat patients.[41,42]

## Bacterial Tracheitis

***Etiology.*** Bacterial tracheitis is a potentially life-threatening cause of upper airway obstruction. Bacterial tracheitis also has been referred as membranous croup, pseudomembranous croup, bacterial croup, purulent tracheobronchitis, and membranous laryngotracheobronchitis. The common etiologic bacteria include *Staphylococcus*, *Moraxella*, *Streptococcus*, and *Haemophilus* species.[43,44] The bacterial infection causes an inflammatory response that produces thick adherent mucopurulent exudates, ulceration, and sloughing of the laryngeal, tracheal, and bronchial mucosa. Affected children usually are preschool- to school-age children and are sicker than those affected with viral croup. Clinically there is typically a recent history of viral respiratory illness, rhinorrhea, cough, fever, and sore throat. With the advent of bacterial tracheitis there is often progression to high fever, a toxic appearance, and severe upper airway obstruction with hoarseness, cough, stridor, and tachypnea.[43-45] A definitive diagnosis of bacterial tracheitis is made on the basis of the history and physical examination, combined with findings from laboratory and bronchoscopic evaluation.[45]

***Imaging.*** Typical radiographic findings of bacterial tracheitis on the frontal radiograph of the cervical airway is narrowing of the subglottic airway. On lateral radiographs of the upper airway, diffuse haziness and marked irregularity of the anterior wall of the trachea may be seen, which is referred to as the "candle-dripping sign" (Fig. 51.9).[43,46] Opaque linear streaks or filling defects, membranes, or plaquelike irregularities can be seen within the airway. Chest radiographic abnormalities are common in children with bacterial tracheitis, with at least 50% showing concomitant findings of pneumonia.[46]

***Treatment and Follow-up.*** When managing symptomatic children with bacterial tracheitis, a patent airway should be established to treat acute respiratory failure.[33] Antibiotic therapy usually is initiated, and laryngoscopy may be required for endoscopic removal of the obstructing purulent secretions and membranes.

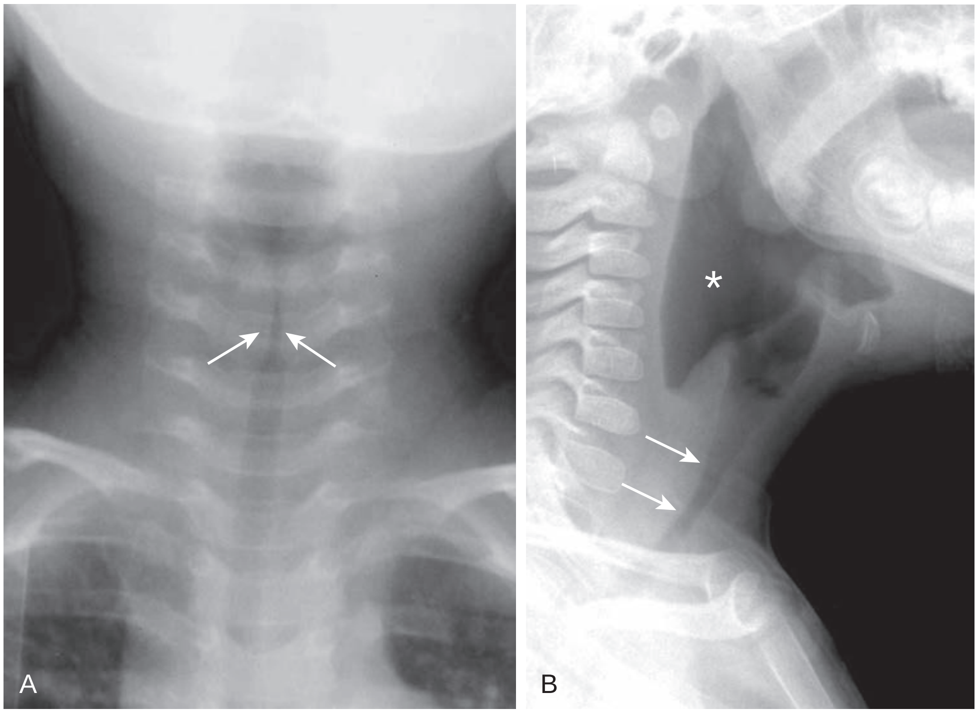

**Figure 51.8. Croup.** (A) Frontal soft tissue neck radiograph demonstrates a "steeple" appearance of the subglottic trachea *(arrows).* (B) Lateral soft tissue neck radiograph in another patient shows a dilated hypopharynx *(asterisk),* as well as haziness and narrowing of the subglottic region *(arrows).*

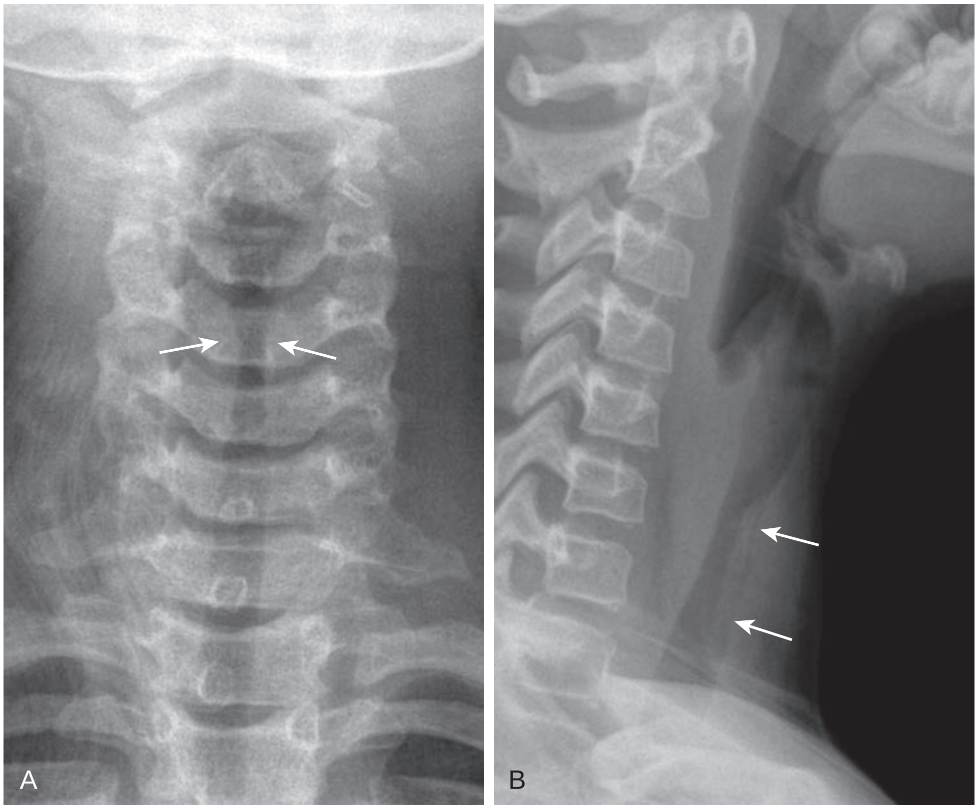

**Figure 51.9. Bacterial tracheitis in a 9-year-old girl with a high fever, cough, and stridor.** (A) Frontal soft tissue neck radiograph shows subglottic tracheal narrowing *(arrows).* (B) Lateral soft tissue neck radiograph shows irregular linear membranous debris within the trachea *(arrows).*

## Retropharyngeal Cellulitis/Abscess

***Etiology.*** Retropharyngeal cellulitis/abscess is a serious and occasionally life-threatening pyogenic infection with the potential to encroach on the upper airway. It occurs as a consequence of infections of the nasopharynx, paranasal sinuses, or middle ear. Suppurative lymph nodes in the retropharyngeal space are the usual cause, but infection can also extend from diskitis, osteomyelitis, mediastinitis, or a penetrating foreign body.[2] Usual etiologic agents are *Streptococcus*, *Staphylococcus*, and *Haemophilus*, although anaerobes and even *Mycobacterium tuberculosis* have been implicated.[47] The infection occurs predominantly in early childhood; typical clinical symptoms are fever, neck stiffness, and dysphagia, with occasional presentation with signs of upper airway obstruction.[1,6,43] Diagnosis is based on clinical suspicion with supportive imaging studies.

***Imaging.*** On a lateral neck radiograph, the normal prevertebral space in infants and children is wide because the vertebrae are not fully ossified. As a general guide, the thickness of the prevertebral soft tissue space from C1 to C4 is equal to half of the adjacent vertebral body width. In the older child, the vertebral bodies become larger and the prevertebral space becomes smaller. However, if the thickness of the prevertebral space is greater than the adjacent vertebral body width below C3, it usually is abnormal.[4] Attention to imaging technique is important; a poorly obtained neck radiograph that is taken obliquely, on expiration, or with the neck flexed can accentuate the retropharyngeal space and mimic pathology. Typical plain film radiographic findings of retropharyngeal cellulitis/abscess include fixed retropharyngeal soft tissue widening, anterior displacement of the airway, and often reversal of the cervical lordotic curvature.[3,6] Retropharyngeal cellulitis or abscess are not distinguishable on a plain radiograph unless retropharyngeal air is seen.[6] CT is the preferred imaging modality to confirm the diagnosis and demonstrate the size, extent, and location of the pus collection from a retropharyngeal abscess.[3,48,49] Lesions with a low-density center surrounded by an enhancing thick rim are more characteristic of a retropharyngeal abscess rather than cellulitis (e-Fig. 51.10).

***Treatment and Follow-up.*** Although retropharyngeal abscesses traditionally have been treated with surgical drainage of the pus collection, some cases may be managed with antibiotics alone.[38,39,48-51]

# OTHER CAUSES OF UPPER AIRWAY ABNORMALITIES

## Obstructive Sleep Apnea

***Etiology.*** Obstructive sleep apnea syndrome (OSA) is a disorder of breathing during sleep characterized by prolonged partial or complete upper airway obstruction that disrupts normal ventilation and sleep patterns. Typical symptoms of OSA include snoring, disturbed sleep, and daytime neurobehavioral problems. Common complications from OSA are neurocognitive impairment, behavioral problems, failure to thrive, and cor pulmonale in severe cases. Risk factors for developing OSA include adenotonsillar hypertrophy, obesity, craniofacial anomalies, and neuromuscular disorders.[52] Nocturnal polysomnography (sleep study) is the only diagnostic technique shown to quantify the ventilatory and sleep abnormalities associated with sleep-disordered breathing.

***Imaging.*** For imaging assessment of OSA, a lateral soft tissue neck radiograph can be obtained to evaluate adenoid size.[3] The adenoidal-nasopharyngeal ratio derived from the lateral soft tissue neck radiograph is a clinically useful index of pharyngeal patency.[6,53,54] Also, the lingual or palatine tonsils are considered enlarged if they narrow the nasopharynx.[2] Videofluoroscopic evaluation of the airway while the child is asleep can be performed to investigate inspiratory collapse of the nasopharynx and oropharynx as a result of proximal airway obstruction acting in concert with sleep-related hypotonia of the pharyngeal musculature.[55] More recently, cine MRI has been advocated as the more accurate diagnostic imaging technique because it shows the volumetric dimension of the adenoids and palatine tonsils (Fig. 51.11). Furthermore, it also can demonstrate dynamic motion of the upper airway, thereby allowing evaluation of the relationship between the size of the adenoid and palatine tonsils and the degree of airway motion.[56]

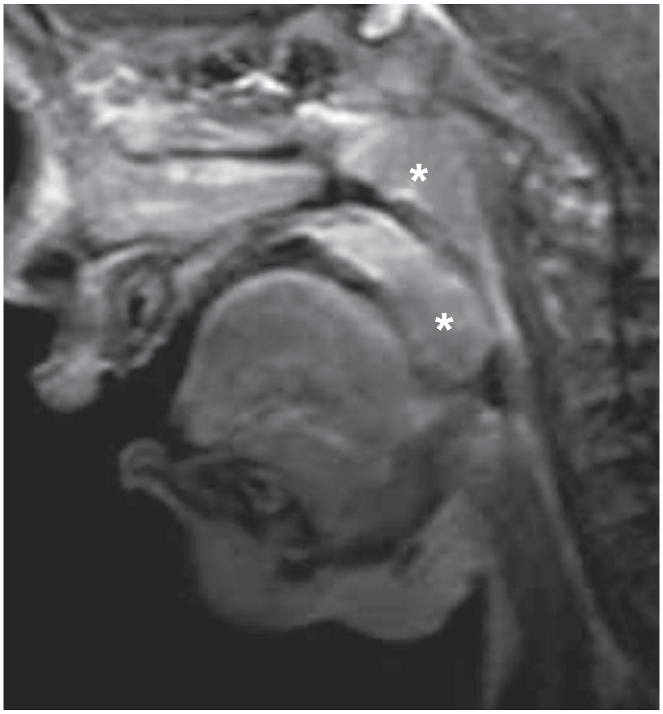

**Figure 51.11. Obstructive sleep apnea in a 2-year-old girl with snoring.** Sagittal MRI sequence of the upper airway shows markedly enlarged adenoids *(upper asterisk)* and palatine tonsils *(lower asterisk)* causing narrowing of the nasopharyngeal airway.

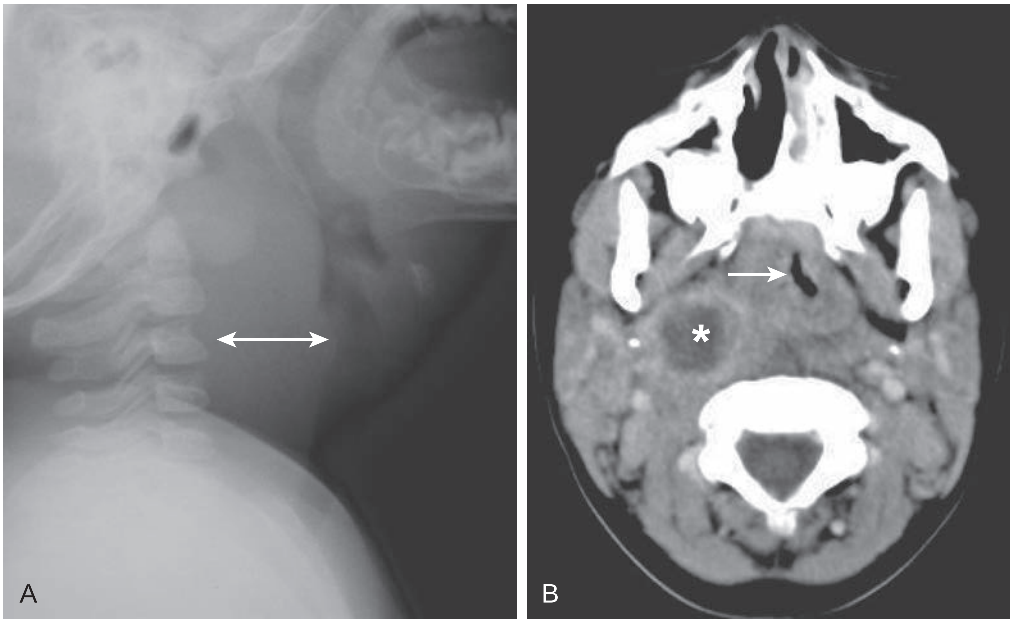
***Treatment and Follow-up.*** Treatment of mild cases of OSA include lifestyle changes such as weight loss. For moderate to severe OSA, the most commonly used treatments include a continuous positive airway pressure or automatic positive airway pressure device that can maintain the patency of the patient's airway during sleep by providing the pressurized air flow into the upper airway. Additionally, several surgical treatments currently are available in patients with anatomic causes of upper airway obstruction, including septoplasty, turbinate surgery, tonsillectomy, and uvulopalatopharyngoplasty.

## Foreign Body

***Etiology.*** Most patients who present with foreign bodies in the upper airway are children between 6 months and 3 years of age. The most commonly aspirated foreign bodies in the upper airway are usually bulky, irregularly shaped, or sharp objects (Fig. 51.12).[2]

Nasal foreign bodies tend to be located on the floor of the nasal passage, just below the inferior turbinate, or in the upper nasal fossa anterior to the middle turbinate (Fig. 51.13).[57] Affected pediatric patients often present with unilateral, foul-smelling nasal discharge. Only 3% of aspirated foreign bodies are lodged in the larynx, but it is a common cause of death in children younger than 2 years old.[2] Patients with a foreign body lodged in the supraglottic region present with cough, dyspnea, salivation, and voice changes; when in the larynx, there is stridor, cough, voice changes, and severe



**e-Figure 51.10. Retropharyngeal abscess in a 3-year-old girl.** (A) Lateral soft tissue neck radiograph shows markedly widened retropharyngeal soft tissue *(double arrow).* (B) Axial CT scan through the upper airway demonstrates a rounded area of hypoattenuation with enhancing border compatible with abscess *(asterisk)* and associated soft tissue swelling effacing the airway *(arrow).*

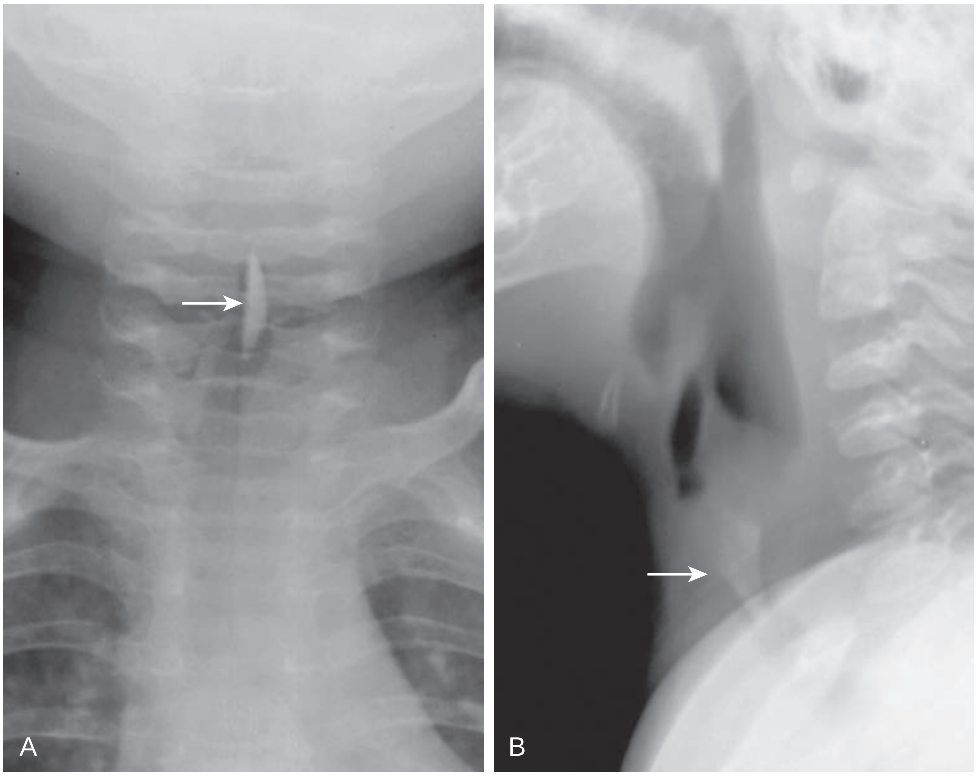


**Figure 51.12. Laryngeal foreign body in a 5-month-old boy who presented with stridor.** Frontal (A) and lateral (B) radiographs of the upper airway reveals an elongated density in the laryngeal region *(arrow)* proven to be a piece of bone.

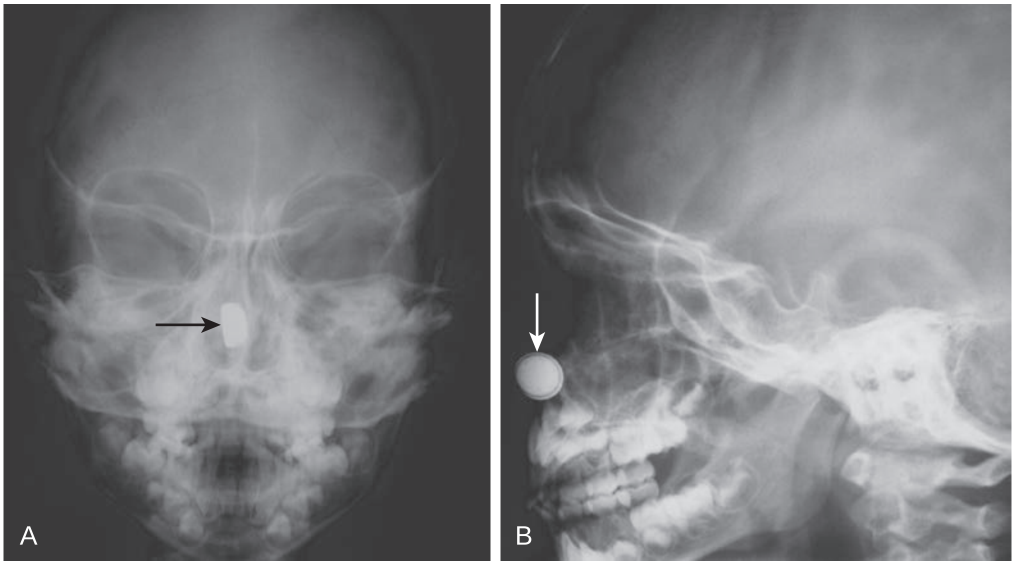

**Figure 51.13. A nasal foreign body in a boy who presented with nasal congestion and foul-smelling discharge for 1 week.** Frontal (A) and lateral (B) radiographs of the nasal airway show a metallic foreign body (battery; *arrow*) in the right nasal cavity. Battery foreign bodies must be removed emergently.

breathing difficulty; when in the extrathoracic trachea, inspiratory stridor and expiratory rhonchi are observed.[58]

***Imaging.*** Radiography can be helpful in localizing radiopaque foreign bodies such as coins, buttons, and batteries, but because most foreign bodies are radiolucent, management should not be based solely on imaging.[59] Plain radiography is sufficient to demonstrate radiopaque upper airway and esophageal foreign bodies. On frontal radiographs, coins in the esophagus are seen en face, whereas coins in the trachea are seen in tangent because of a posterior gap in the tracheal cartilage rings. Indirect signs of airway obstruction include overdistention of the hypopharynx and prevertebral soft tissue swelling. Food and other nonradiopaque foreign bodies in the upper airway often are identified only with endoscopy.[6]

***Treatment and Follow-up.*** Most nasal foreign bodies can be removed by a skilled physician, although attempts at removal may push the nasal foreign body into the pharynx, creating an airway hazard. Pharyngeal and laryngeal foreign bodies are medical emergencies because airway obstruction usually occurs at the time of aspiration and results in immediate respiratory distress. Flexible or rigid endoscopy usually is required to confirm the diagnosis, remove the foreign body, and avoid complications, including airway obstruction, laryngeal edema, and pushing the foreign body into the subglottic space or trachea.[59]

## Traumatic Injuries

***Etiology.*** Pediatric laryngotracheal injuries are infrequent because of the softer cartilage and the protection provided by the prominent mandible.[60,61] Airway compromise is suggested if dysphonia, dysphagia, or dyspnea is present.[62] The most important clinical signs of laryngeal injury include hoarseness and subcutaneous emphysema.[61] Injuries may be subtle and present with minimal initial symptoms that, if undiagnosed, may rapidly progress to loss of the airway. Thus a high index of suspicion is needed to promptly and accurately diagnose and manage pediatric laryngotracheal injuries. Fiberoptic laryngoscopy is mandatory when injury to the larynx and trachea is suspected.[61,62]

***Imaging.*** In any pediatric patient with possible upper airway injury, plain radiographs of the neck and chest may aid in the diagnosis. Radiographs also can be useful to assess the cervical spine. Findings of laryngotracheal injuries in pediatric patients vary considerably according to the mechanism of injury, but radiographic evidence of soft tissue air and wounds opening into the airway are common findings. CT is also useful and can play a primary role in localizing the injury and determining its extent (Fig. 51.14).[60-64]

***Treatment and Follow-up.*** Most laryngotracheal injuries in children can be managed conservatively. However, extensive injuries, including displaced fractures of the cartilage, injuries to the recurrent nerves, and laryngotracheal separation, require surgical intervention.[63]

## Neoplasms

### Subglottic Hemangioma

***Etiology.*** Subglottic hemangioma, a congenital vascular tumor, is the most common primary neoplasm affecting the subglottic trachea. Although the tumor is present at birth, patients with subglottic hemangioma usually become symptomatic between 1 and 6 months of age because of their rapid initial growth. Affected infants usually present with intermittent or acute onset of acute respiratory difficulty that varies in severity and includes stridor and crouplike symptoms. Fifty percent of patients also have concomitant cutaneous hemangiomas. During its initial proliferative phase, the mass grows rapidly during the first 18 months of life, followed by a gradual involution that may last until age 10 years. Generally, a subglottic hemangioma is a self-limiting condition, and the respiratory distress tends to diminish and may disappear. However, the behavior of the individual lesion is unpredictable, and the symptoms are variable in severity.[65]

***Imaging.*** Plain radiographs of infants and children with subglottic hemangiomas typically show an irregular, small, soft tissue mass below the true vocal cords (e-Fig. 51.15A). These lesions have a characteristic radiographic appearance of a soft tissue shadow bulging into the airway lumen, often with asymmetric subglottic narrowing. However, symmetric narrowing of the trachea can be caused by a hemangioma if it is located central to the plane of projection. CT or MRI can show the mass at the subglottic region with intense enhancement after the administration of contrast material (e-Fig. 51.15B).[65]

***Treatment and Follow-up.*** Propranolol has recently emerged as the primary treatment for hemangioma.[66] However, laryngotracheoplasty and direct surgical excision are alternative therapies in patients with severe airway compromise who are refractory to propranolol therapy.[67]

### Malignant Neoplasms

Neoplasms of the head and neck may present with upper airway obstruction. Lymphoma and rhabdomyosarcoma are the most

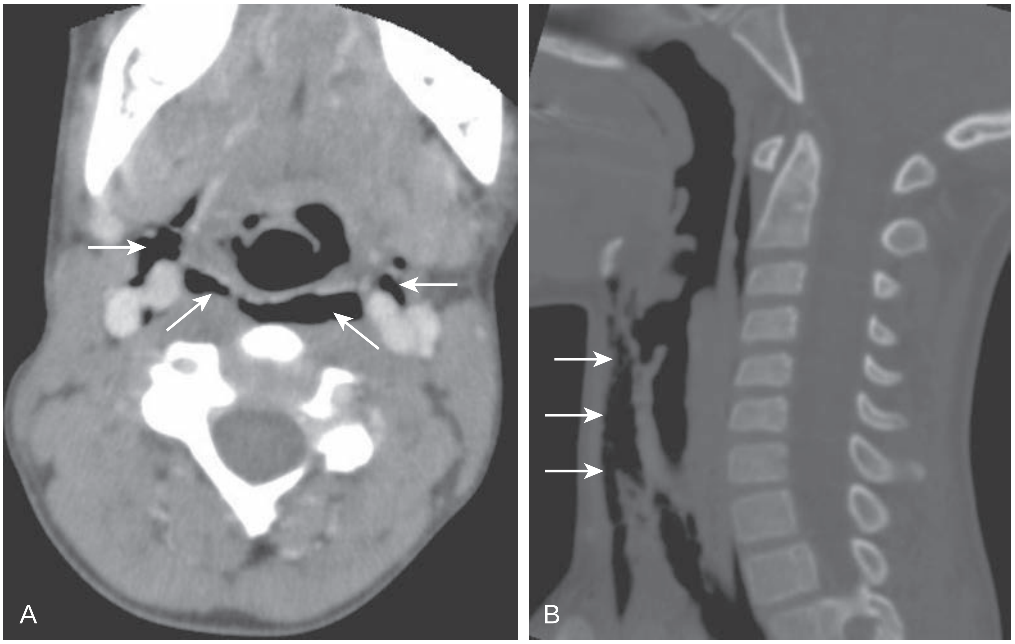

**Figure 51.14. Laryngeal trauma in a 10-year-old boy who tripped and struck his anterior neck across a log.** Axial (A) and sagittal reconstruction (B) CT scans of the neck show air dissecting along the parapharyngeal region *(arrows)* compatible with laryngeal trauma. *(Courtesy of Elizabeth H. Ey, MD, Dayton, OH.)*

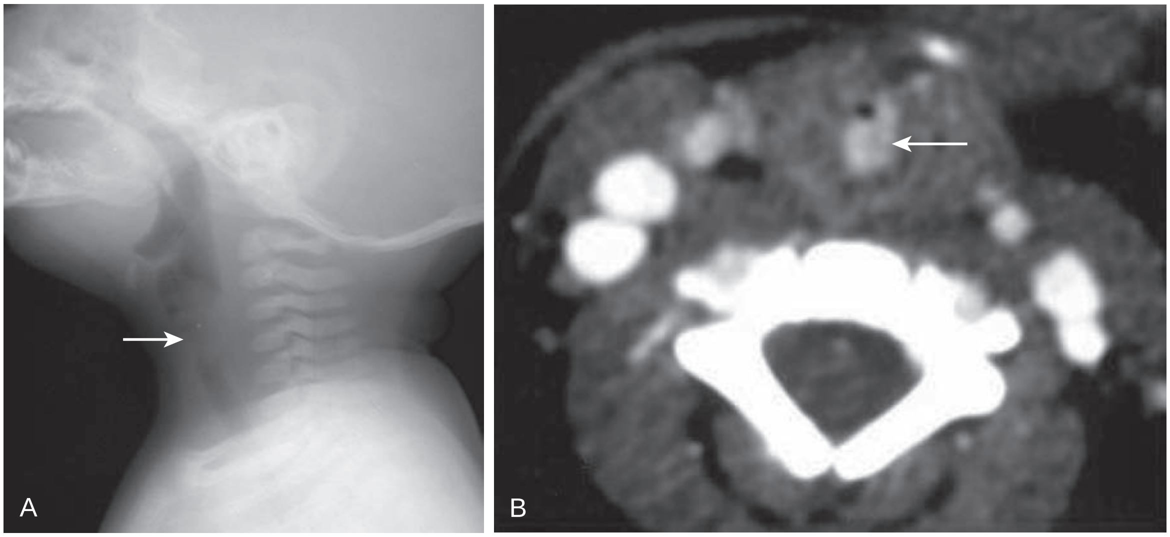

**e-Figure 51.15. Subglottic hemangioma in a 6-month-old boy with stridor.** (A) Lateral neck radiograph demonstrates haziness and soft tissue densities in the subglottic tracheal region *(arrow).* (B) Axial CT scan at the subglottic region shows the hemangioma *(arrow),* an intensely enhancing soft tissue mass causing marked narrowing of the subglottic trachea.

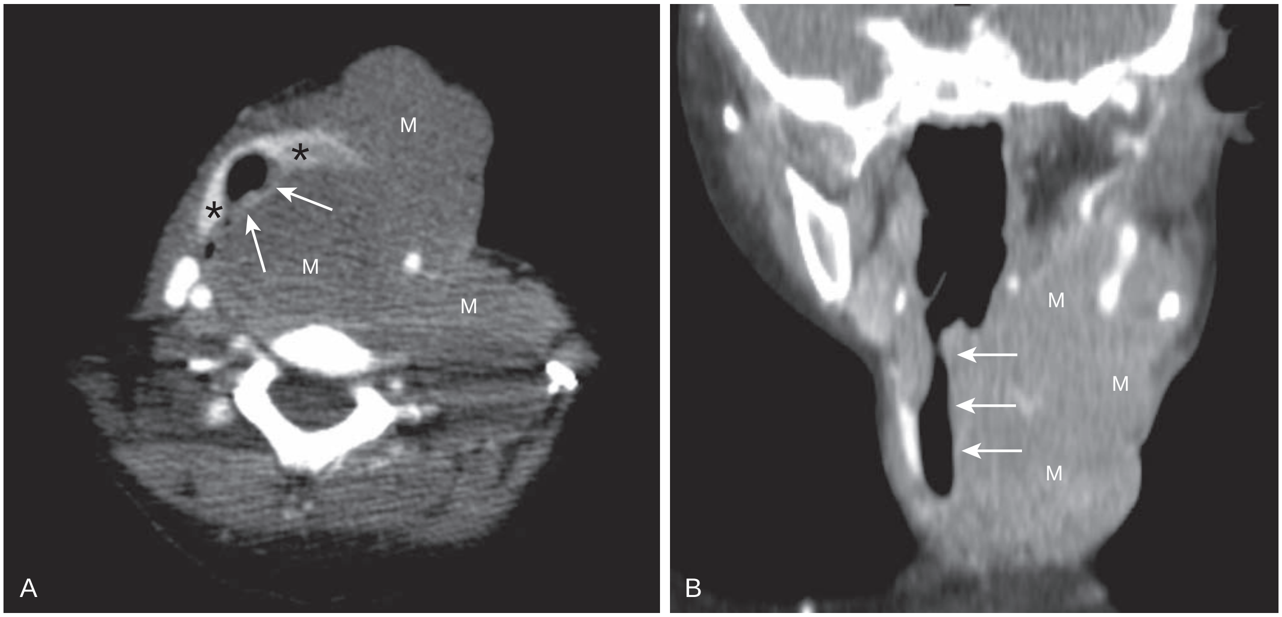

**Figure 51.17. Embryonal rhabdomyosarcoma in a 2-year-old girl with noisy breathing.** Frontal (A) and coronal (B) CT images of the neck reveal a large soft tissue mass *(M)* in the left neck region significantly effacing the upper airway *(arrows)* anteriorly and to the right. The lobes of the thyroid gland *(asterisks)* are also effaced anteriorly.

common malignancies in this region in children.[68–70] CT and MRI are the predominant imaging modalities for evaluating the location, extent, and vascularity of these tumors, as well as the degree of airway compromise (e-Fig. 51.16 and Fig. 51.17). Both CT and MRI with intravenous contrast can be used for diagnosis, staging, and follow-up.[71] These lesions are discussed in detail in Chapter 16.

Other malignant neoplasms involving the head and neck that have the potential to affect the airway include nasopharyngeal carcinoma, thyroid cancers, and salivary gland tumors, although these entities are uncommon in children.

## KEY POINTS

- Upper airway disease is a common problem in infants and children because of the narrow diameter of the airway early in life.
- Upper airway diseases in children can be categorized as acute or chronic, but the etiology is diverse and includes congenital, infectious/inflammatory, foreign body, posttraumatic, and neoplastic causes.
- Radiographs maintain an integral role in the initial evaluation of a patient with upper airway disease, but attention to proper positioning and technique is important to avoid pitfalls.
- Cross-sectional imaging (CT and MRI) is capable of multiplanar reconstruction, which allows a detailed evaluation of airway anatomy and disease in both static and dynamic states.
- Endoscopy is still the gold standard in evaluating upper airway diseases, but CT three-dimensional–virtual endoscopy has the ability to produce a realistic representation of the inner walls of the airway, simulating a real endoscopic examination, with the advantage of depicting the anatomy below a high-grade stenosis, a limitation of endoscopy.

# Lower Large Airway Disease

Edward Y. Lee

## OVERVIEW

Disorders of the lower large airways occur frequently in the pediatric population and have the potential to be life threatening.[1-3] Because these disorders are often associated with nonspecific clinical symptoms, the diagnosis frequently is missed or delayed, particularly in infants and young children. After careful investigation of the clinical history and physical examination, imaging evaluation is the next management step. Imaging plays an important role in the diagnosis of congenital and acquired lower large airway disorders. By becoming familiar with the characteristic imaging findings of lower large airway disorders, radiologists can play an important role in ensuring prompt diagnosis, guiding appropriate management, and providing follow-up evaluation of these often acute and complex conditions in pediatric patients.

This chapter reviews the etiology, imaging findings, and management of the frequently encountered congenital and acquired lower large airway disorders in the pediatric population. Large airway disorders due to primary benign neoplasms and extrinsic compression due to mediastinal vascular anomalies are not included in this chapter because they are discussed in other chapters (see Chapters 51 and 76, respectively) in this book.

## SPECTRUM OF LOWER LARGE AIRWAY DISEASE

### Congenital Anomalies

### Tracheobronchial Branching Anomalies

**Tracheal Agenesis**

***Etiology.*** Tracheal agenesis is characterized by either partial or complete tracheal underdevelopment.[4-7] Three main types of tracheal agenesis exist. Type 1 consists of absent upper trachea and connection of the lower trachea to the esophagus; type 2 consists of a common bronchus connecting bilateral main bronchi to the esophagus; and type 3 consists of independent bilateral main bronchi arising from the esophagus (Fig. 52.1A). Of these three types, type 2 is the most common. Affected pediatric patients typically present with severe respiratory distress and absence of an audible cry, and the airway cannot be intubated below the larynx immediately after birth.[4-7] The diagnosis of tracheal agenesis should be considered in any infant who demonstrates improved lung ventilation after placement of the endotracheal tube in the esophagus after an initial unsuccessful intubation attempt. Once tracheal agenesis is diagnosed, radiologists should carefully investigate for other congenital anomalies that frequently are associated with this condition, such as congenital heart disease, duodenal atresia, and radial ray anomalies.[4-7]

***Imaging.*** Chest radiographic imaging findings of tracheal agenesis often are nonspecific, such as unaerated lungs or decreased lung volume. However, the diagnosis of tracheal agenesis should be considered when absence of the normal tracheal air lucency, abnormal carinal position, and placement of the endotracheal tube in the esophagus are seen on chest radiographs immediately after birth (Fig. 52.1B and C). Computed tomography (CT) and/or bronchoesophagoscopy confirm the diagnosis,[4-8] which can show both the partial or complete tracheal underdevelopment and anomalous bronchi connected to the esophagus (Fig. 52.1D).

***Treatment and Follow-up.*** Because of difficulties related to both early diagnosis and treatment, tracheal agenesis usually is a fatal condition.[4-7] The initial management of tracheal agenesis is aimed at early diagnosis at birth and immediate maintenance of airway patency, usually via the esophagus in the presence of a bronchoesophageal fistula. Patients with short-segment tracheal agenesis may be amenable to direct tracheal anastomosis.[5,7]

**Tracheal Bronchus**

***Etiology.*** Tracheal bronchus is a congenital bronchial branching anomaly in which an ectopic (more frequently) or supernumerary bronchial branch arises from the lateral tracheal wall just above the carina.[9-15] This condition also is known as bronchus suis because it is a normal finding in pigs. The incidence of tracheal bronchus in the pediatric population is between 0.1% and 5%.[16] Tracheal bronchus most frequently occurs on the right side. Most pediatric patients with tracheal bronchus are asymptomatic, and it is usually an incidental finding detected on imaging studies obtained for the workup of other medical conditions. However, patients with tracheal bronchus also may present with symptoms of persistent or recurrent upper lobe pneumonia, atelectasis, or air trapping.[11] Additionally, tracheal bronchus may unexpectedly be discovered after intubation as a result of upper lobe atelectasis related to inadvertent occlusion of the ectopic upper lobe bronchial orifice by a low-lying endotracheal tube.[14]

***Imaging.*** On chest radiographs, secondary imaging findings of tracheal bronchus such as upper lobe atelectasis or pneumonia can be detected, but the anomalous upper lobe bronchus cannot be reliably visualized. In the past, tracheal bronchus was evaluated with tracheobronchography. However, CT with two-dimensional (2D) and three-dimensional (3D) reconstructions is the imaging technique of choice for evaluating anomalous tracheal bronchus and associated lung abnormalities[17-19] (Fig. 52.2). Bronchoscopy can confirm the diagnosis of tracheal bronchus when necessary.

***Treatment and Follow-up.*** Patients with incidentally detected tracheal bronchus generally do not require treatment. However, symptomatic children with recurrent upper lobe infection due to tracheal bronchus may require surgical resection, especially if permanent lung damage has developed or they are considered at risk for the development of permanent lung damage.[1]

**Esophageal Bronchus or Lung**

***Etiology.*** Esophageal bronchus or lung is a rare congenital anomaly.[11,20] The term *esophageal bronchus* refers to the condition in which a lobar bronchus, typically the medial basal segment of the right lower lobe, arises directly from the esophagus. The term *esophageal lung* is used when the main bronchus arises directly from the esophagus. It is associated with a wide spectrum of clinical presentations ranging from asymptomatic to recurrent severe pulmonary infections or even death depending on the size and location of the anomaly. In general, symptomatic pediatric patients with esophageal bronchus or lung typically present with feeding difficulties and recurrent respiratory tract infections. Other associated congenital anomalies include congenital heart disease, duodenal atresia, duodenal stenosis, distal tracheoesophageal fistula, and esophageal atresia.

***Imaging.*** Affected pediatric patients typically present as a result of aspiration during feeding, with radiographic findings of air

## Abstract:

Disorders affecting the lower large airways occur frequently in the pediatric population and have the potential to be life threatening. After initial investigation of the clinical history and physical examination, imaging evaluation is the next management step. Imaging plays an important role in the diagnosis of congenital and acquired lower large airway disorders in infants and children. By becoming familiar with the characteristic imaging findings of lower large airway disorders, radiologists can play an important role in ensuring prompt diagnosis, guiding appropriate management, and providing follow-up evaluation of these often acute and complex conditions in pediatric patients. This chapter reviews the etiology, imaging findings, and current management of the congenital and acquired lower large airway disorders in infants and children in daily clinical practice.

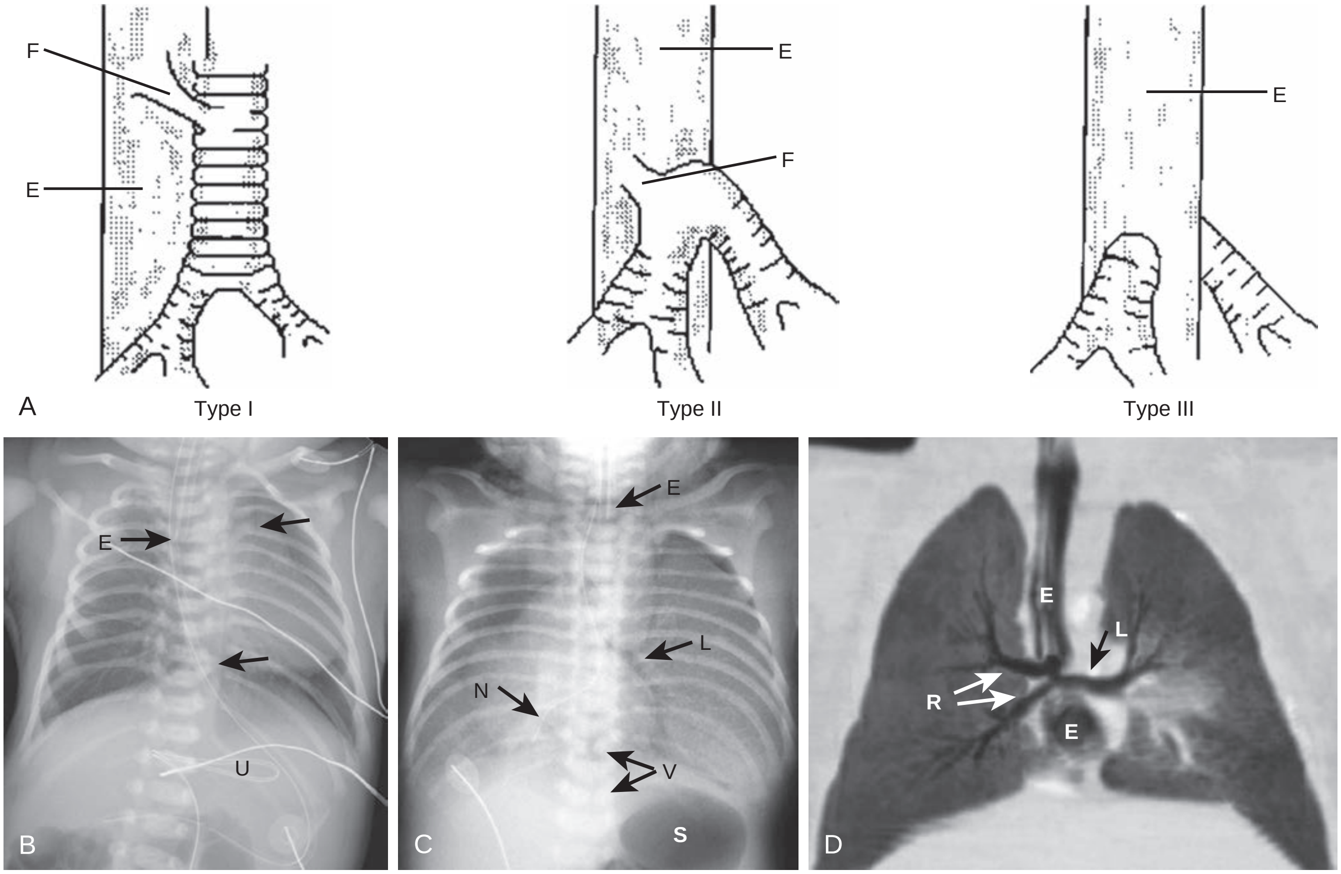

**Figure 52.1. Tracheal agenesis.** (A) Schematic of three types. In type I, part of the proximal trachea is absent with a short distal trachea communicating to the esophagus via a tracheoesophageal fistula. In type II, the most common type, the trachea is completely absent with a carina connecting the two main bronchi. A bronchoesophageal fistula is usually, but not always, present. In type III, the trachea and carina are absent with the bronchial orifices separately arising directly from the esophagus. (B) Newborn with type II tracheal agenesis. Chest radiograph shows lungs that are relatively normal in aeration, although haziness is present, which may represent retained fetal fluid. The endotracheal tube *(E)* is slightly low but otherwise is unremarkable. The nasogastric tube also is present and is in the stomach. Segmentation abnormalities of the spine and upper left ribs are noted *(arrows).* The umbilical venous catheter *(U)* is malpositioned. (C) Newborn with type III tracheal agenesis. Chest radiograph obtained during resuscitation shows poorly aerated lungs with pneumomediastinum and a left pneumothorax. The endotracheal tube *(E)* is at the thoracic inlet level. The nasogastric tube *(N)* is in the right bronchial tree, which appears to originate lower than normal. Note the low position of the left main bronchus *(L).* "Butterfly" vertebrae *(V)* are seen. (D) Newborn with type III trachea agenesis. Coronal maximum intensity projection reformatted CT image shows two right bronchi *(R)* and the left bronchus *(L)* arising near the midline from the esophagus *(E).* The trachea is absent with the possible exception of a small segment connecting the bronchi. A nasogastric tube is present in the esophagus *(E). E,* Esophagus; *F,* fistula; *S,* stomach. (A, *From Effmann EI, Spackman TJ, Berdon WE, et al. Tracheal agenesis.* AJR Am J Roentgenol. *1975;125:767.* B–D, *From Strouse PJ, Newman B, Hernandez RJ, et al. CT of tracheal agenesis.* Pediatr Radiol. *2006;36:920–926.)*

space opacification in the medial lower lobe in the case of esophageal bronchus and air space opacification that involves the entire lung in the case of esophageal lung.[1,11] An esophagram can provide a definitive diagnosis by allowing visualization of a direct communication between a bronchus and the esophagus (Fig. 52.3). CT may be helpful for evaluating associated lung parenchymal abnormalities and guiding surgery.

***Treatment and Follow-up.*** Surgical lobectomy or pneumonectomy is the current management of choice for symptomatic patients with esophageal bronchus or lung, respectively.[20]

## Congenital Tracheal Stenosis

***Etiology.*** Congenital tracheal stenosis is a rare condition characterized by intrinsic narrowing of the tracheal lumen, usually as a result of underlying complete cartilaginous rings.[2,3,21,22] Such cartilaginous rings with an absent or deficient posterior membranous portion render the tracheal lumen smaller and less pliable. Affected pediatric patients typically present in the first year of life with expiratory stridor, wheezing, and respiratory distress.[2,3,21,22] Congenital tracheal stenosis traditionally is classified into three types: (1) focal (50%), (2) generalized (30%), and (3) funnel shaped (20%).[23] Other congenital anomalies often associated with congenital tracheal stenosis are tracheoesophageal fistula, pulmonary agenesis or hypoplasia, pulmonary artery sling type 2, and bronchial stenosis.[2,3,11,24]

***Imaging.*** Although neck and chest radiographs or fluoroscopy may lead to the suspicion of congenital tracheal stenosis when a narrowed trachea is encountered in pediatric patients with respiratory symptoms, CT is the current imaging modality of choice for

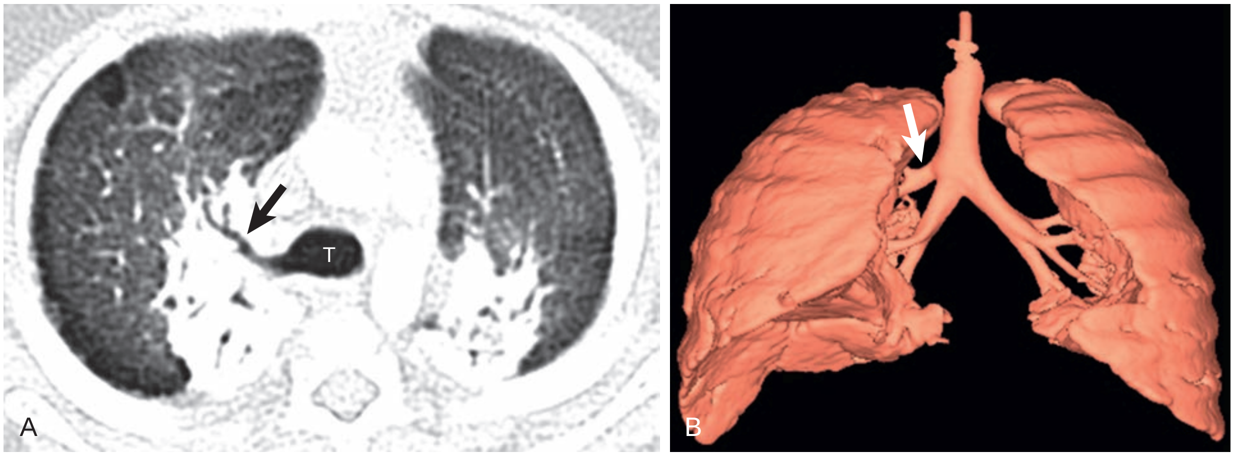

**Figure 52.2. Tracheal bronchus in an 8-month-old girl with recurrent right upper lobe atelectasis.** (A) Axial lung window CT image shows an anomalous right upper lobe bronchus *(arrow)* directly arising from the trachea *(T).* Atelectasis is present adjacent to the tracheal bronchus. (B) Frontal 3D volume-rendered CT image of the central airways and lungs shows an anomalous right upper lobe bronchus *(arrow)* directly arising from the trachea. The location, size, and course of this anomalous tracheal bronchus are better demonstrated than on an axial CT image.

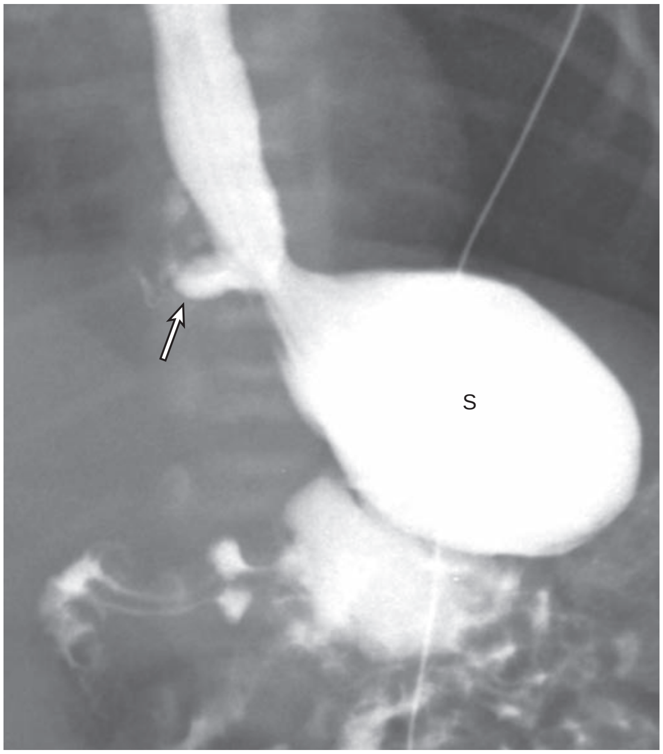

**Figure 52.3. Esophageal bronchus in a 4-day-old infant girl who presented with acute respiratory distress during feeding.** Esophagram shows a barium-filled medial right lower lobe bronchus *(arrow)* directly arising from the distal esophagus. *S,* Stomach.

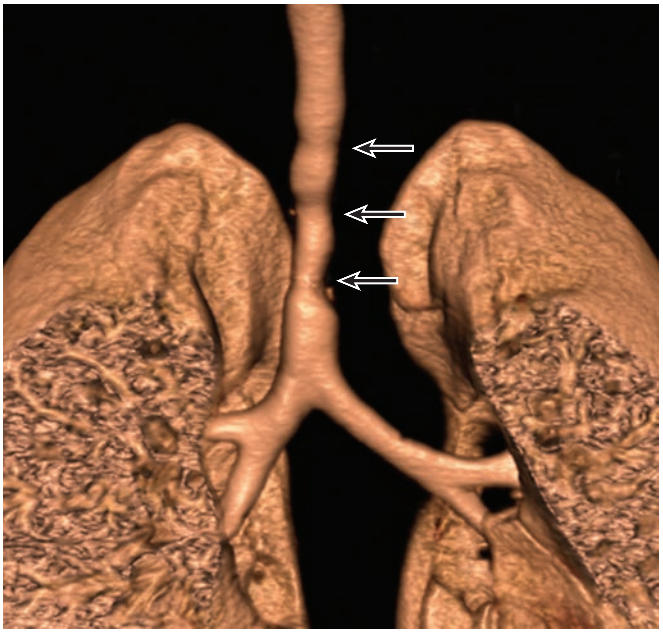

**Figure 52.4. Congenital tracheal stenosis in a 3-month-old boy with expiratory stridor and respiratory distress.** Frontal 3D volume-rendered CT image of the large airways and lungs shows several areas of mild to moderate mid to distal tracheal narrowing *(arrows).*

diagnosis and characterization.[2,4,24] With CT, the diagnosis of congenital tracheal stenosis is based on the identification of decreased caliber with a rounded configuration of the trachea without evidence of tracheal wall thickening. The size of the subglottic region (which does not contain tracheal cartilage) can serve as an internal reference standard. The use of 2D/3D reconstructed CT imaging is particularly helpful for increasing detection of subtle stenoses, improving measurement of craniocaudal extent of disease, and enhancing evaluation of its anatomic relationship with other mediastinal structures for preoperative assessment (Fig. 52.4).[2,4,24-26] This appearance contrasts with the normal appearance in which the C-shaped rings do not extend to the posterior membranous wall.[25] In addition, virtual bronchoscopy can evaluate the airways distal to high-grade tracheal stenoses, beyond which a conventional bronchoscope cannot pass.[2,4,24,25] CT also may aid in the detection of other associated anomalies that often have an abnormal lung component.

***Treatment and Follow-up.*** A short tracheal stenosis may be treated by end-to-end anastomosis, whereas a longer lesion is now typically repaired with sliding tracheoplasty.[22] Other available options for short-segment tracheal stenosis include stent placement or balloon dilation, although these methods are used more commonly to treat acquired tracheal stenosis.

### Tracheobronchomegaly

***Etiology.*** Tracheobronchomegaly, also known as Mounier–Kuhn syndrome, is a rare disorder characterized by dilation of the trachea and main bronchi.[27-29] Although the exact etiology of this condition currently is unknown, a defect in the elastic and muscular tissues of the large airways is presumed to be a potential underlying cause. The increased compliance of the large airway walls as a result of the atrophy of longitudinal elastic fibers with thinning of the muscularis mucosa often results in the development of broad, diverticulum-like protrusions of redundant musculomembranous tissue between the cartilaginous rings. It may occur either as a familial condition or in association with a connective tissue disorder such as Ehlers–Danlos syndrome.[30] It typically occurs in pediatric patients who have received prolonged ventilatory support or who have a chronic pulmonary infection such as cystic fibrosis. Although the clinical manifestations of tracheobronchomegaly are nonspecific, affected patients may present with a harsh cough, copious purulent sputum, occasional hemoptysis, and progressive dyspnea.

***Imaging.*** Chest radiographs alone may be adequate to detect the enlargement of trachea and bronchi in severe cases, but CT is the imaging modality of choice for diagnosing tracheobronchomegaly, potential tracheal diverticulum, and associated lung abnormalities (Fig. 52.5).[1] Because of the increased incidence of tracheobronchomalacia (TBM) in patients with tracheobronchomegaly, a dynamic CT study consisting of both inspiratory and expiratory phase imaging may be beneficial for detecting concomitant TBM.

***Treatment and Follow-up.*** Asymptomatic pediatric patients with tracheobronchomegaly require no specific treatment. For symptomatic patients, treatment usually is conservative, including chest physiotherapy for assistance with clearing of secretions and antibiotics for treatment of pulmonary infections.[31,32]

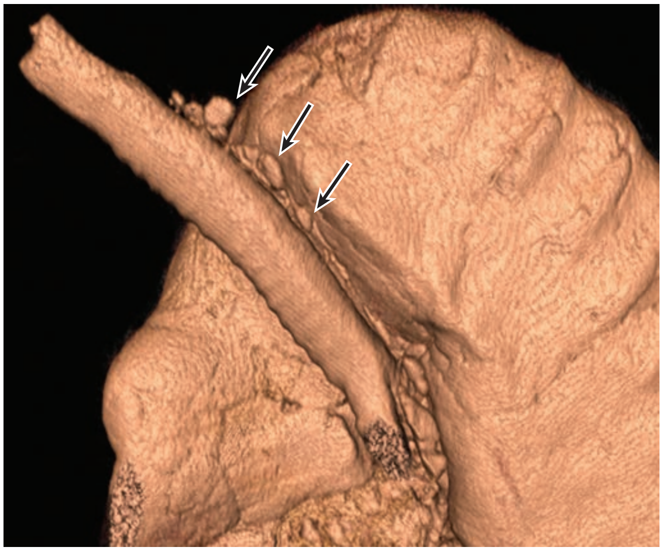

**Figure 52.5. Tracheomegaly with tracheal diverticuli in an adolescent girl with cystic fibrosis.** 3D volume-rendered CT lateral view of the large airway shows multiple diverticuli *(arrows)* arising from the posterior aspect of the enlarged trachea.

## Acquired Abnormalities

### Foreign Body Aspiration

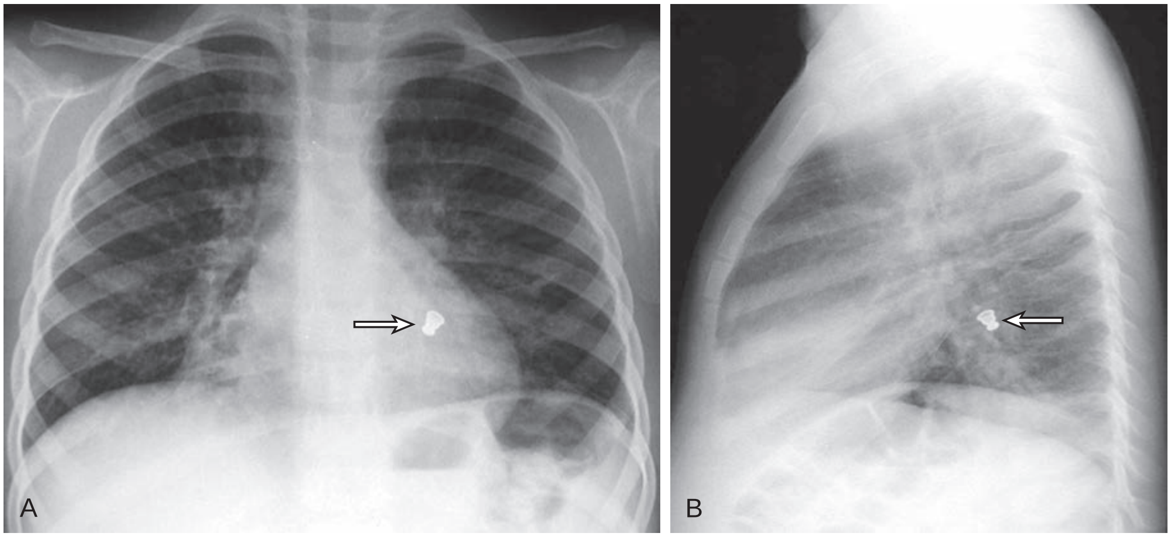
***Etiology.*** Foreign body aspiration into the tracheobronchial airway is a frequent cause of acute respiratory distress in pediatric patients, especially those between 6 months and 3 years of age.[1-3,33,34] Although some pediatric patients may present with a clinical history of possible aspiration followed by cough, wheezing, respiratory distress, or decreased breath sounds, most affected pediatric patients present with a history that is either lacking or misleading.[1-3,33,34] Therefore a high clinical suspicion and thorough investigation are required for any infants and young children with respiratory symptoms suspicious for possible foreign body aspiration.

Only approximately 10% of aspirated foreign bodies within the tracheobronchial airway are radiopaque.[35] The remaining 90% of nonradiopaque foreign bodies are particularly difficult to diagnose early in pediatric patients. Nearly 70% of aspirated foreign bodies lodge in the bronchi, with the right side (52%) affected more frequently than the left side (18%).[33] The remaining 30% of aspirated foreign bodies lodge in the trachea (13%) and less common locations (17%).[33] In the early phase of foreign body aspiration, affected patients typically present with cough, wheezing, respiratory distress, or decreased breath sounds. During the late phase of missed foreign body aspiration, affected patients often present with episodic wheezing and/or recurrent pneumonias.

***Imaging.*** Radiographic findings of foreign body aspiration depend on the size, location, duration, and nature of the aspirated foreign body (e-Fig. 52.6). Radiopaque foreign bodies usually are detected easily with radiographic studies, which should include frontal and lateral films encompassing the upper airway from the nasopharynx to the upper abdomen. When the foreign body is not radiopaque, careful inspection of the tracheobronchial airway with high-kilovoltage films or fluoroscopy may show a faintly visible opacity interrupting the air column within the large airways. If the foreign object is located in the trachea, the chest radiograph may be normal or may show bilateral hypoinflation or hyperinflation depending on the degree of obstruction. Many intratracheal foreign bodies escape detection without the use of CT.

Rather than lodging in the trachea, most foreign bodies lodge in the main bronchi. In approximately 20% of cases, the foreign body migrates into a segmental bronchial branch.[33] The chest radiograph may show a variety of findings, the most common of which is a unilateral hyperlucent lung. If the bronchial obstruction becomes more complete, postobstructive atelectasis, pneumonia, or bronchiectasis may develop. A chest radiograph obtained at full inspiration can appear normal in approximately 20% to 30% of patients with bronchial foreign bodies; close inspection may show relatively increased volume on the normal side with a slight mediastinal shift toward the partially obstructed side. If a foreign body is suspected clinically, an expiratory chest radiograph is useful to demonstrate ipsilateral air trapping. Lateral decubitus films may be diagnostic if satisfactory inspiration-expiration chest radiographs cannot be obtained. When air trapping is present in a dependent lung on the decubitus view, the affected lobe or segment remains hyperlucent rather than deflating, as would normally occur (Fig. 52.7). Fluoroscopic examination of the chest also is valuable for detecting air trapping. It can show inspiratory mediastinal shift toward the affected side and restricted diaphragmatic excursion on the affected side.

The sensitivity and specificity of chest radiographs for foreign body detection were only 74% and 45%, respectively, in a series of 93 patients examined by Silva et al.[36] and 68% and 67%, respectively, in a series of 83 patients examined by Svedstrom et al.[38] Because of this relatively poor accuracy, Silva and colleagues have suggested that chest radiographs should not be relied on for diagnosis, but rather that all patients with suspected foreign body aspiration should undergo bronchoscopy.[36] This approach results



**e-Figure 52.6. Radiopaque foreign body aspiration in a 4-year-old boy who presented with acute onset of coughing and respiratory distress.** (A) Frontal chest radiograph shows a radiopaque foreign body *(arrow)* located in the left lower lobe, retrocardiac region. (B) Lateral chest radiograph confirms the location of the foreign body *(arrow)* in a left lower lobe bronchus. Bronchoscopy showed a metallic bottle cap lodged in the left lower lobe bronchus. *(From Lee EY, Restrepo R, Dillman JR, et al. Imaging evaluation of pediatric trachea and bronchi: systematic review and updates.* Semin Roentgenol. *2012;47(2):183.)*

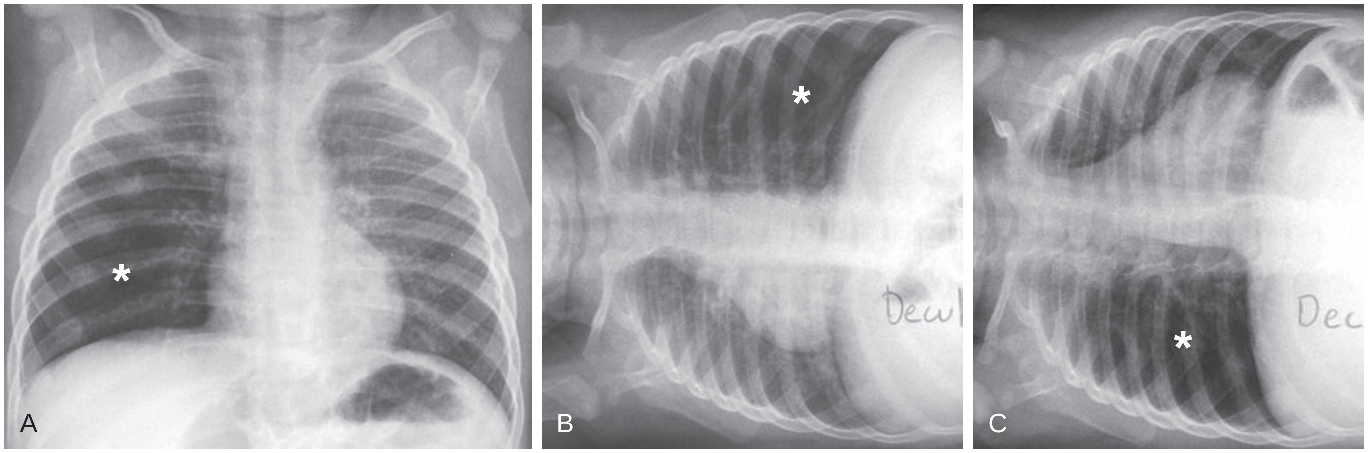


**Figure 52.7. Nonradiopaque foreign body aspiration in a 5-year-old girl who presented with persistent coughing and respiratory distress while eating popcorn.** (A) Frontal chest radiograph obtained at end-inspiration shows mild hyperinflation *(asterisk)* of the right lower lobe. (B) Frontal chest radiograph obtained at end-inspiration in the left lateral decubitus position demonstrates normal volume loss in the left lung and mild hyperinflation *(asterisk)* of the right lower lobe. (C) Frontal chest radiograph obtained at end-inspiration in the right lateral decubitus position shows persistent hyperinflation *(asterisk)* of the right lower lobe.

in a false-negative bronchoscopy rate of at least 20% in most series, however.[36]

CT is the most sensitive diagnostic imaging technique, but in general it should be reserved for patients for whom chest radiography is either normal or nonspecific. With use of CT, the diagnosis of a foreign body can be established with nearly 100% accuracy.[2,38] Either the foreign body is visualized or a focal pulmonary abnormality such as postobstructive air trapping, atelectasis, or consolidation is seen. If none of these findings is present, it is extremely unlikely that a foreign body is present. However, CT is less likely to visualize the foreign body directly if the lung is consolidated unless the foreign body is calcified or opaque.

Preliminary studies of low-dose multidetector computed tomography (MDCT) virtual bronchoscopy suggest that it may be able to (1) identify the precise location of a foreign body before bronchoscopy and (2) exclude a foreign body in children with a low level of suspicion and normal or nonspecific findings on chest radiography.[26,37-41] Because CT is less expensive and less invasive than bronchoscopy, it may be a viable alternative for selected patients.

***Treatment and Follow-up.*** Once an aspirated foreign body is diagnosed on imaging studies, bronchoscopy and removal of the aspirated foreign body should be performed. Although imaging findings may be nonspecific or normal, symptomatic pediatric patients with high clinical suspicion and a convincing history of possible foreign body aspiration require bronchoscopy for a complete assessment.

## Infection/Inflammation

### Tuberculosis

***Etiology.*** Tuberculosis (TB) is caused by *Mycobacterium tuberculosis*. Although advances in diagnosis and treatment have been made in the past 2 decades, TB continues to be a major cause of morbidity and mortality, particularly in infants, elderly persons, and immunocompromised patients.[42,43] In developed countries, TB most commonly is transmitted to infants and children by an adult family member infected with active TB. Although most pediatric patients with primary TB are asymptomatic, some may present with nonspecific symptoms such as a mild cough, a low-grade fever, weight loss, fatigue, and malaise. Respiratory distress may be the primary symptom in pediatric patients with large airway involvement from TB infection. The diagnosis usually can be made by skin testing, whereas sputum and gastric aspirates are confirmatory in anergic patients.

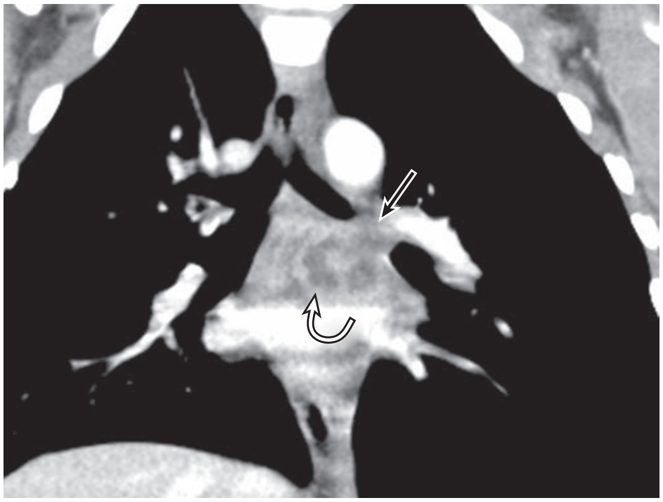

**Figure 52.8. Left main bronchial obstruction due to subcarinal lymphadenopathy from tuberculosis infection in a 4-year-old girl.** Coronal contrast-enhanced CT image shows left main stem bronchial obstruction *(straight arrow)* as a result of the necrotic subcarinal lymphadenopathy *(curved arrow).*

***Imaging.*** Large airway involvement of TB infection mainly results from either extrinsic compression of airways by enlarged mediastinal and/or hilar infectious lymph nodes, or direct infection of the airway wall through peribronchial lymphatic pathways.[1-3,42-45] Although chest radiographs may show mediastinal and/or hilar lymphadenopathy with resultant large airway narrowing, the location, degree, and extent can be better evaluated with CT with 2D/3D reconstructions (Fig. 52.8).[1-3] Direct tracheobronchial infection from TB eventually may result in irreversible large airway stricture/stenosis, again best assessed with CT.[1-3,42-45] Additionally, CT also can show lung abnormalities associated with TB infection such as “tree-in-bud” nodular opacities and airspace consolidation.

***Treatment and Follow-up.*** Pediatric TB patients currently are treated for 6 months with a combination of antibiotics. Large airway narrowing due to extrinsic compression from the enlarged mediastinal lymph nodes often resolves after medical treatment, whereas irreversible stricture/stenosis from direct tracheobronchial TB infection may require surgical management, including primary end-to-end anastomosis after stricture resection.

### Histoplasmosis

***Etiology.*** Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. Although *H. capsulatum* is found throughout the world, it is endemic in certain areas, including states bordering the Ohio River valley, the lower Mississippi River, and caves in southern and East Africa. Although acute histoplasmosis is attributed to airborne primary infection, chronic progressive histoplasmosis is the consequence of reactivation of a prior infection. Large airway involvement from histoplasmosis often results from fibrosing mediastinitis.[46-48] Affected pediatric patients may present with respiratory or esophageal symptoms related to complete or partial obstruction of large airways and the esophagus.[47,48] The definitive diagnosis of histoplasmosis is made by finding the fungus in samples taken from sputum, blood, or infected organs, and by identifying antigens in blood or urine samples.

***Imaging.*** On chest radiographs, typical imaging findings include multiple, ill-defined pulmonary nodules (1–3 cm in diameter) and hilar and/or mediastinal lymphadenopathy, both of which often are calcified.[44] CT currently is the imaging modality of choice for evaluating large airway compromise, particularly related to underlying fibrosing mediastinitis.[1-3] These patients typically show heterogeneous and often calcified mediastinal soft tissue densities resulting in complete or partial obstruction of mediastinal structures such as the tracheobronchial airway, superior vena cava, and esophagus (Fig. 52.9).[1-3,47,48] CT also can demonstrate abnormal lung findings from histoplasmosis infection.

***Treatment and Follow-up.*** In severe cases, antifungal medications are used to treat acute, chronic, and disseminated histoplasmosis infection. Unfortunately, no pharmacologic treatment has been shown to affect the outcome of histoplasmosis-related fibrosing mediastinitis. Large airway occlusion due to fibrosing mediastinitis is particularly difficult to treat because surgery often is ineffective and placement of metallic airway stents is avoided because of recurrent obstruction from ingrowth of granulation tissue.

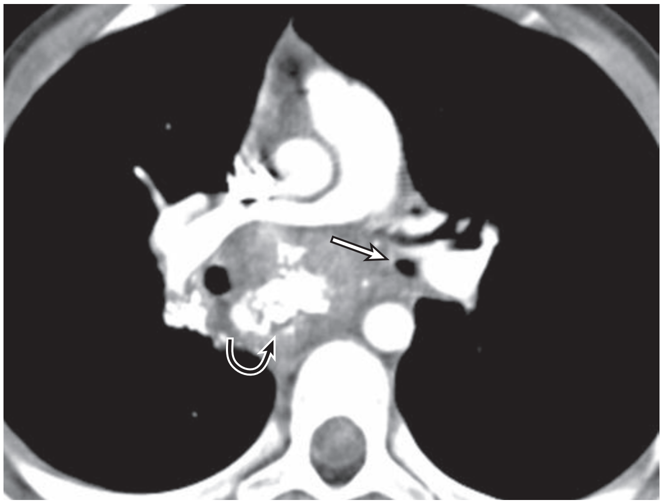

**Figure 52.9. Fibrosing mediastinitis caused by histoplasmosis in a 9-year-old girl who presented with 1 month of cough and dyspnea.** Axial contrast-enhanced CT image shows narrowing of the left main stem bronchus *(straight arrow)* from a heterogeneously enhancing and partially calcified subcarinal soft tissue mass *(curved arrow)*. *(From Lee EY, Greenberg SB, Boiselle PM. Multidetector computed tomography of pediatric large airway diseases: state-of-the-art.* Radiol Clin North Am. *2011;49[5]:886.)*

## Neoplasm

Tracheobronchial tumors are rare in children. Two of the most common primary benign large airway neoplasms, subglottic hemangioma and recurrent respiratory papillomatosis, were discussed in Chapter 51. The most common malignant lower large airway primary neoplasm, carcinoid tumor, is discussed in the next section.

### Carcinoid Tumor

***Etiology.*** A carcinoid tumor is a neuroendocrine neoplasm that encompasses a spectrum of histology ranging from slow-growing, locally infiltrative lesions to a metastasizing neoplasm.[49-54] Carcinoid tumors traditionally have been classified into two types based on typical or atypical histologic findings. Affected patients often present with a cough, wheezing, and recurrent pneumonia as a result of airway obstruction. Because of the underlying hypervascularity of carcinoid tumors, hemoptysis may be the presenting symptom. The carcinoid syndrome rarely occurs in pediatric patients with a large airway carcinoid tumor. The diagnosis is confirmed by bronchoscopy and biopsy.

***Imaging.*** Imaging findings of a carcinoid tumor within the large airway depend on the size and location of the tumor.[49-54] Most tracheobronchial carcinoid tumors are intrabronchial (Fig. 52.10). Centrally located carcinoid tumors may mimic foreign bodies and may cause postobstructive air trapping, atelectasis, recurrent infection, abscess, or bronchiectasis.[53] Peripherally located carcinoid tumors usually are not associated with bronchial obstruction and have the appearance of a pulmonary nodule.[53] Chest radiographs may be normal in 10% of cases or may show either a well-defined hilar or perihilar opacity representing an underlying tumor, or secondary signs such as focal air trapping or consolidation.[49-54] CT characteristically shows an enhancing spherical or ovoid mass with a well-defined lobulated contour.[53,54] Although calcification may not be clearly visible on chest radiographs, either punctate or diffuse calcifications may be detected in up to 30% of cases on CT.[54]

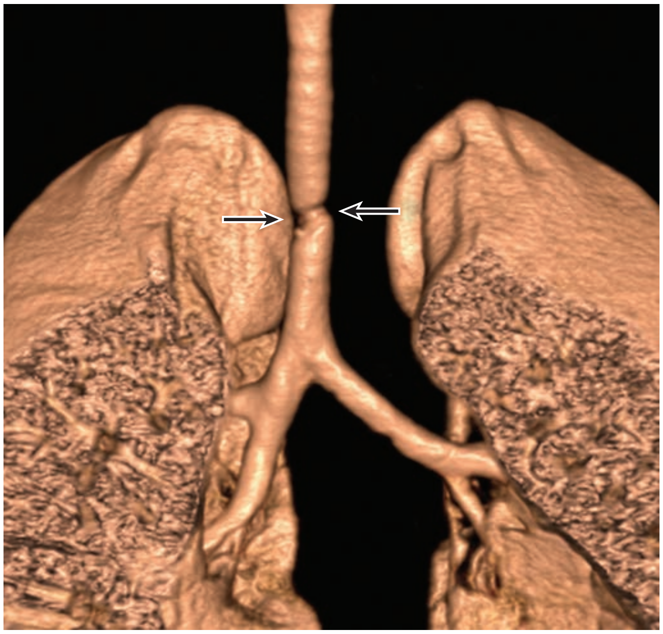
***Treatment and Follow-up.*** The current treatment of choice for large airway carcinoid tumors is complete surgical resection with primary reanastomosis or sleeve resection.

## Trauma

### Acquired Tracheobronchial Stenosis

***Etiology.*** Acquired tracheobronchial stenosis in children usually is caused by previous instrumentation such as endotracheal intubation or use of a tracheostomy tube.[1-3] Granulation tissue and fibrosis can develop at the stoma, at the tip of the tube, or at the site of the cuff. Scott and Kramer[55] reported tracheostomy-related complications in 26% of intubated children. The duration of intubation is a major factor in determining the incidence and severity of complications. Microscopic lesions occur after approximately 48 hours of intubation. Epithelial metaplasia is seen in children intubated for longer than 7 days, although occasionally granuloma may develop after very brief periods of intubation. Bronchial stenosis, like tracheal stenosis, usually is acquired and occurs at the site of surgical anastomosis in pediatric patients after lung transplantation.[1-3]

***Imaging.*** The diagnosis of tracheobronchial stenosis may be suspected on chest radiographs when large airway narrowing is observed. However, CT, which can measure cross-sectional areas of the large airways accurately, is the current choice for evaluating tracheobronchial stenosis, especially preoperatively.[1-3] Such stenosis may be weblike or fusiform, or it may have an irregular shape (e-Fig. 52.11).[1-3,56] Newer techniques such as paired inspiratory and expiratory CT or real-time dynamic four-dimensional CT can help differentiate a fixed tracheobronchial stenosis from TBM.[56-61]



**e-Figure 52.11. Acquired tracheobronchial stenosis in a 4-year-old girl with progressively worsening stridor after long-term endotracheal tube placement.** Frontal 3D volume-rendered CT image of the central airways and lungs shows a focal irregular narrowing *(arrows)* at the level of the previous endotracheal tube placement.

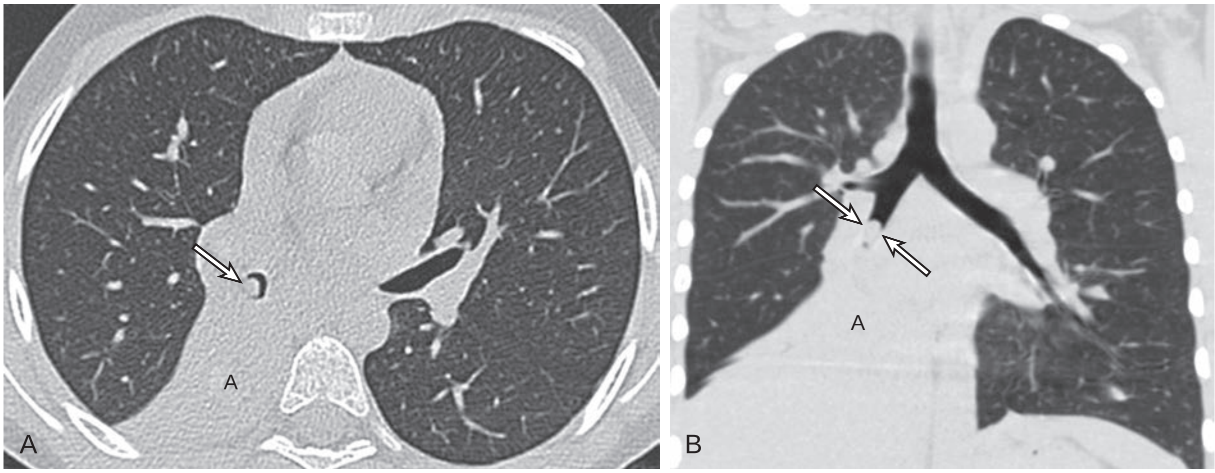


**Figure 52.10. Endobronchial carcinoid tumor in a 17-year-old girl who presented with a cough and recurrent right lower lobe pneumonia for the past 18 months.** Surgical pathology confirmed the diagnosis of an endobronchial carcinoid tumor. (A) Axial bone window CT image shows an endobronchial mass *(arrow)* located within the right bronchus intermedius with postobstructive atelectasis *(A).* (B) Coronal lung window CT image demonstrates an endobronchial mass *(arrows)* in the right bronchus intermedius with postobstructive atelectasis *(A).* The overall shape, size, and location of the mass are better visualized on this coronal image than on the axial image.

***Treatment and Follow-up.*** A short tracheobronchial stenosis may be treated by balloon dilation, stent placement, or end-to-end anastomosis after surgical resection of the stenotic segment. A longer stenosis may require a patch or autograft repair.[60]

### Tracheobronchial Injury

***Etiology.*** Tracheobronchial injury is a potentially life-threatening condition that may be caused by either penetrating or blunt chest trauma.[62-67] Although tracheobronchial injury is relatively rare with a reported incidence between 0.7% and 2.9%, it is associated with a substantial mortality rate of 30%.[62-73] Tracheobronchial injury typically occurs within 2.5 cm of the carina.[62-71] In the setting of trauma, abnormal endotracheal tube position, rib fractures (particularly involving the anterior ends of the first three ribs), and persistent pneumothoraces and/or pneumomediastinum despite the presence of a well-functioning chest tube and/or mediastinal tube should raise the possibility of underlying tracheobronchial injury.[72,73]

***Imaging.*** Radiographic imaging findings of a traumatic tracheobronchial injury depend on the location and degree of injury. In the setting of mild injury, a small amount of pneumothorax and/or pneumomediastinum may be the only findings. Such nonspecific and subtle radiographic findings often delay the accurate diagnosis of tracheobronchial injury, particularly in pediatric patients.[62,63,68] Extensive pneumothorax and/or pneumomediastinum, often extending into subcutaneous tissues of the neck and chest wall, typically are seen with severe injuries such as a displaced laceration or transection.[62-73] MDCT with thin-section axial and 2D/3D reconstruction can provide accurate diagnosis and preoperative guidance (Fig. 52.12).[1,70,72,73]

***Treatment and Follow-up.*** Individualized surgical repairs depend on the location and severity of injury and are performed via primary anastomosis or reimplantation.

## Dynamic Tracheobronchial Disorder

### Tracheobronchomalacia

***Etiology.*** TBM is attributed to an abnormal weakness of the underlying airway walls and/or supporting cartilage.[59,60,74] Despite increasing recognition of this condition in recent years, diagnosing TBM continues to be challenging mainly because clinical symptoms of affected pediatric patients are nonspecific and overlap with those of other chronic respiratory disorders.[59,60,74] TBM can be divided into two types: primary and secondary.[60,74] Primary TBM often is seen in premature infants or children with a variety of syndromes and in persons with systemic disease affecting cartilage, such as Larsen syndrome and relapsing polychondritis.[60,74] Secondary TBM is seen in infants or children with tracheoesophageal fistula, extrinsic pressure by vessels, and mediastinal masses.[60,74] It also may arise as a result of tracheal injury, most commonly intubation. Affected patients typically present with expiratory stridor and a cough that often is described as barking or brassy. Undiagnosed TBM may result in chronic tracheobronchial and lung infections.

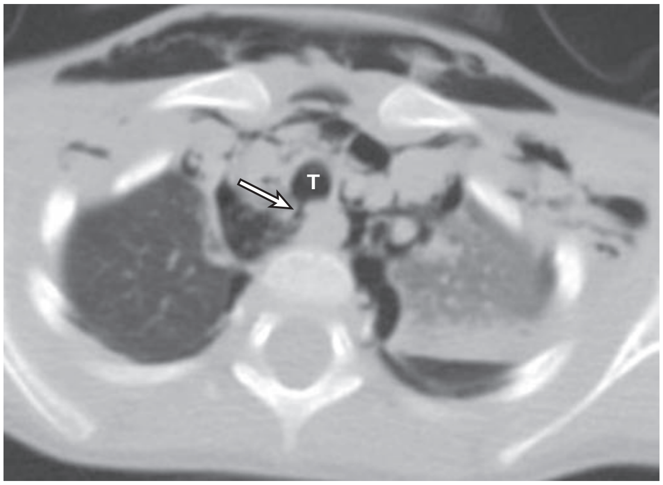

**Figure 52.12. Traumatic tracheal injury in a 3-year-old boy as a result of a motor vehicle accident.** Axial CT image shows a focal disruption *(arrow)* of the posterior wall of the trachea at the 7 o'clock position, with an adjacent collection of air within the mediastinum, indicating tracheal rupture. Extensive pneumomediastinum and subcutaneous emphysema also are seen. *T,* Trachea.

***Imaging.*** Chest radiographs and airway fluoroscopy have been used to evaluate TBM in pediatric patients in the past.[1] Fluoroscopy may show an exaggerated decrease (>50%) in the caliber of the trachea during expiration in patients with tracheomalacia[1,2] (Fig. 52.13); however, evaluation of the bronchi is markedly limited with this technique. MDCT is the imaging modality of choice for a complete assessment of TBM and underlying causes in pediatric populations.[57-61] MDCT provides noninvasive evaluation of TBM with diagnostic accuracy similar to bronchoscopy, and 2D and 3D evaluation with MDCT in particular has become an important preoperative assessment by offering information regarding the precise location, accurate degree and extent, and underlying predisposing conditions of TBM.[59,60,74] For the diagnosis of TBM with MDCT in children, tracheobronchial collapse greater than 50% currently is used (Fig. 52.14).[59,60] The very large detector array CT scanners currently available allow real-time evaluation of large airway collapsibility even in nonsedated infants and young children.[1,2] Magnetic resonance imaging is also becoming a viable technique for the dynamic evaluation of the airway.[75]

***Treatment and Follow-up.*** Conservative therapies such as treatment of underlying respiratory infections, humidified oxygen therapy, and pulmonary physiotherapy are the mainstay of management in pediatric patients with a mild to moderate degree of TBM.[74,76,77] However, pediatric patients with severe and progressively worsening TBM may require more aggressive treatment, including tracheostomy placement, stent placement, and surgical intervention such as a tracheoplasty.[78-89]

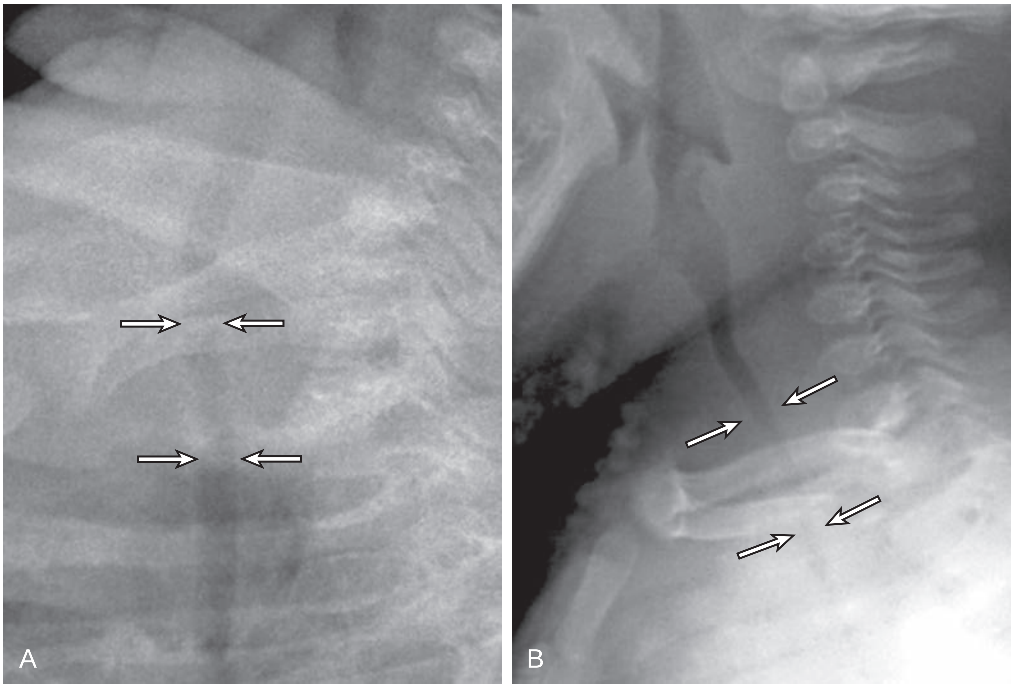

**Figure 52.13. Tracheomalacia in a 2-year-old girl who presented with a chronic cough and recurrent pulmonary infections.** (A) Lateral radiograph obtained at end-inspiration during airway fluoroscopy study shows a patent trachea *(arrows).* (B) Lateral radiograph obtained at end-expiration during airway fluoroscopy study demonstrates marked (>75%) collapse of the trachea *(arrows),* consistent with tracheomalacia.

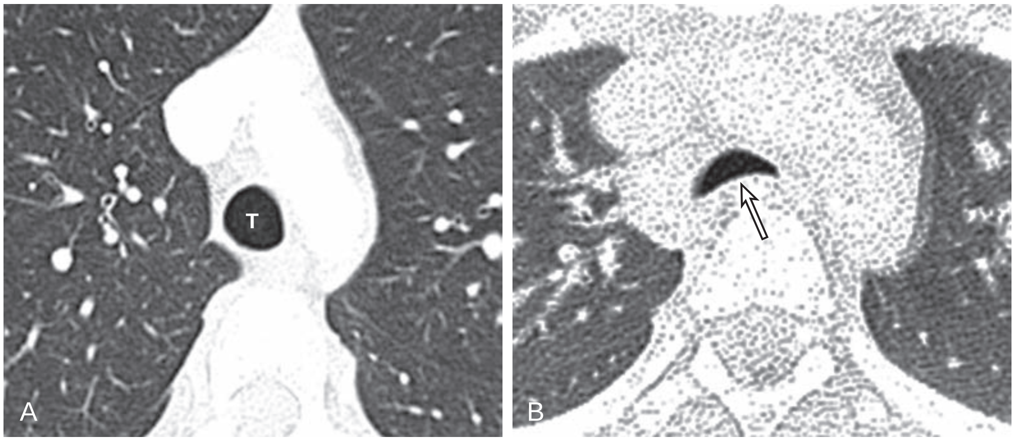

**Figure 52.14. Tracheomalacia in a 15-year-old girl who presented with a chronic cough and recurrent pulmonary infections.** (A) Axial CT image obtained at end-inspiration shows a normal patent trachea *(T).* (B) Axial CT image obtained at end-expiration demonstrates a greater than 50% collapse of the trachea *(arrow),* which is consistent with tracheomalacia. Increased attenuation of the lungs is a result of decreased lung volume related to end-expiration. Bronchoscopy showed marked tracheomalacia.

## KEY POINTS

- Congenital and acquired lower large airway disorders are common and may be life threatening in the pediatric population.
- The diagnosis of lower large airway disorders is frequently missed or delayed, particularly in infants and young children, mainly because of nonspecific clinical symptoms.
- After careful investigation of the clinical history and physical examination, imaging evaluation is the next management step and plays an important role in the diagnosis of a variety of congenital and acquired lower large airway disorders.
- Although conventional radiographs may be sufficient for making an accurate diagnosis of several lower large airway disorders, such as radiopaque foreign body aspiration, CT is often necessary for a complete assessment, particularly for surgical lesions.
- Bronchoscopy is still the reference standard in evaluating lower large airway diseases, but CT with 2D/3D/4D reconstructed images may provide sufficient information to avoid this invasive procedure in many patients. In selected cases, CT may provide information to help guide diagnostic and therapeutic bronchoscopic procedures.

# Congenital Lung Anomalies

Monica Epelman, Edward Y. Lee, and Beverley Newman

Congenital lung anomalies represent a heterogeneous group of pulmonary developmental disorders that affect the lung parenchyma, its arterial supply, venous drainage, or a combination thereof. The reported incidence of congenital lung anomalies ranges from 30 to 42 cases per 100,000 population.[1] Although prenatal sonography, fetal magnetic resonance imaging (MRI) and advances in postnatal imaging have enhanced our understanding of congenital lung anomalies, substantial controversy continues regarding the nomenclature, classification, pathogenesis, description, and management of these lesions. In addition, considerable variability exists in their prenatal clinical presentation and outcome, ranging from in-utero involution to severe hydrops and fetal demise. Likewise, their postnatal clinical presentation also is variable, ranging from marked neonatal respiratory distress to a completely asymptomatic newborn to an older child or young adult with recurrent pneumonias. In this chapter, the underlying etiology, clinical presentation, imaging findings, and management of various congenital lung anomalies are discussed.

## SPECTRUM OF CONGENITAL LUNG ANOMALIES

The classification of congenital lung anomalies is challenging and controversial from embryologic, radiologic, pathologic, and clinical viewpoints. Several classifications and terminologies with particular advantages and disadvantages have been suggested.[2–4] Some investigators have used embryology as a basis and have classified congenital lung anomalies according to the stage of intrauterine development in which the insult resulting in the malformation developed.[2] Others have categorized lesions based on their morphologic-radiologic features and divided them into two groups: whole lung malformations (e.g., lung hypoplasia) and focal malformations (e.g., bronchial atresia).[3,5] Recently the Langston[4] classification has become one of the most accepted classification systems for congenital lung anomalies, particularly from the pathologic standpoint, although it is by no means used by all clinical groups. Langston categorizes the wide spectrum of respiratory tract malformations primarily as bronchial atresia, congenital pulmonary airway malformation (CPAM), extralobar bronchopulmonary sequestration (BPS), congenital lobar overinflation (CLO), and bronchogenic cysts. These five congenital lung anomalies comprise approximately 90% of the anomalies seen in clinical practice. However, this classification system is limited because other congenital lung anomalies (e.g., pulmonary arteriovenous malformation [AVM]) are not included.

For the purpose of relatively clear classification, easy differentiation on imaging studies, and preoperative assessment of surgical lesions, congenital lung anomalies discussed in this chapter are categorized according to their morphologic-radiologic-pathologic features. Such a classification system views congenital lung anomalies as a continuum ranging from predominantly parenchymal abnormalities (i.e., abnormal lung parenchyma with variable airway/foregut components and relatively normal vasculature, e.g., CPAM), to combined parenchymal and vascular abnormalities (e.g., pulmonary sequestration and scimitar syndrome) in which foregut and airway components play an important role and the major abnormalities are intertwined (Fig. 53.1), and lastly predominantly vascular abnormalities, such as pulmonary AVM or absent or interrupted pulmonary artery with secondary lung/airway abnormalities.

Given that specific terminology for these lesions may be controversial and occasionally confusing, we and other authors[1,6–10] recommend that radiologists thoroughly describe all imaging findings of congenital lung anomalies rather than try to categorize the lesions by pathologic terminology. Specific imaging findings that need to be evaluated and described include (1) location of lesions; (2) vascular supply and drainage of the lesions; (3) internal architecture, presence of cystic components, and degree of aeration; (4) airway abnormality; (5) exclusion of communication with the gastrointestinal (GI) tract; (6) integrity of the diaphragm; and (7) an assessment of associated anomalies, such as vertebral anomalies.[6,8,11]

## PREDOMINANTLY PARENCHYMAL LESIONS

### Bronchial Atresia

***Etiology.*** Bronchial atresia refers to atresia of a lobar, segmental, or subsegmental bronchus at or near its origin resulting in a blind-ended atretic proximal bronchus. Bronchial atresia has been categorized as proximal or peripheral.[12] While proximal atresia is less common, it is often lethal during pregnancy. Peripheral bronchial atresia most frequently affects a segmental bronchus and may be isolated or part of another congenital lung malformation. Peripheral bronchial atresia may be diagnosed as an incidental finding on chest radiographs later in life in asymptomatic older children or adults.[4] However, it is increasingly being diagnosed in utero, given the widespread use of prenatal imaging.[4,7–9,12,13]

The precise etiology of bronchial atresia remains unknown, but etiologies such as a vascular insult to the involved atretic or stenotic portion have been proposed.[4] Several authors who used modern dissecting techniques found that bronchial atresia is more common than originally thought.[4,13–15] Furthermore, bronchial atresia and BPSs coexist in nearly all cases,[4,13–15] whereas it is found in nearly 70% of CPAM lesions.[14] A malformation sequence resulting from airway obstruction during development has been proposed as the unifying element for such a wide spectrum of imaging appearances of the major bronchopulmonary malformations. Differences in degree, level, and timing of the bronchial obstruction are thought to be responsible for these variations.[4,6,14,15]

***Imaging.*** Prenatally, the involved portion of the lung appears hyperexpanded and shows increased homogenous echogenicity on US and high T2 signal on fetal MRI (Fig. 53.2).[12,16] The appearance may be difficult to distinguish from CLO, pulmonary sequestration, and microcystic CPAM. Identification of a centrally located, mucus-filled bronchocele/mucocele on prenatal US or MRI strongly suggests bronchial atresia (e-Fig. 53.3).[7,12,17]

Characteristically, the apicoposterior segmental bronchus of the left upper lobe is most commonly affected, followed by the segmental bronchi of the right upper, right middle, and lower lobes.[18] In children, radiographic and computed tomography (CT) imaging features of bronchial atresia are characterized by a tubular or glove-shaped opacity representing mucus plugging in the region distal to the atretic bronchus, surrounding segmental hyperlucency

## Abstract:

The most common clinically significant congenital lung anomalies span a continuum of maldevelopment and can be classified into three main groups: predominantly parenchymal abnormalities, combined parenchymal and vascular abnormalities, and predominantly vascular abnormalities.

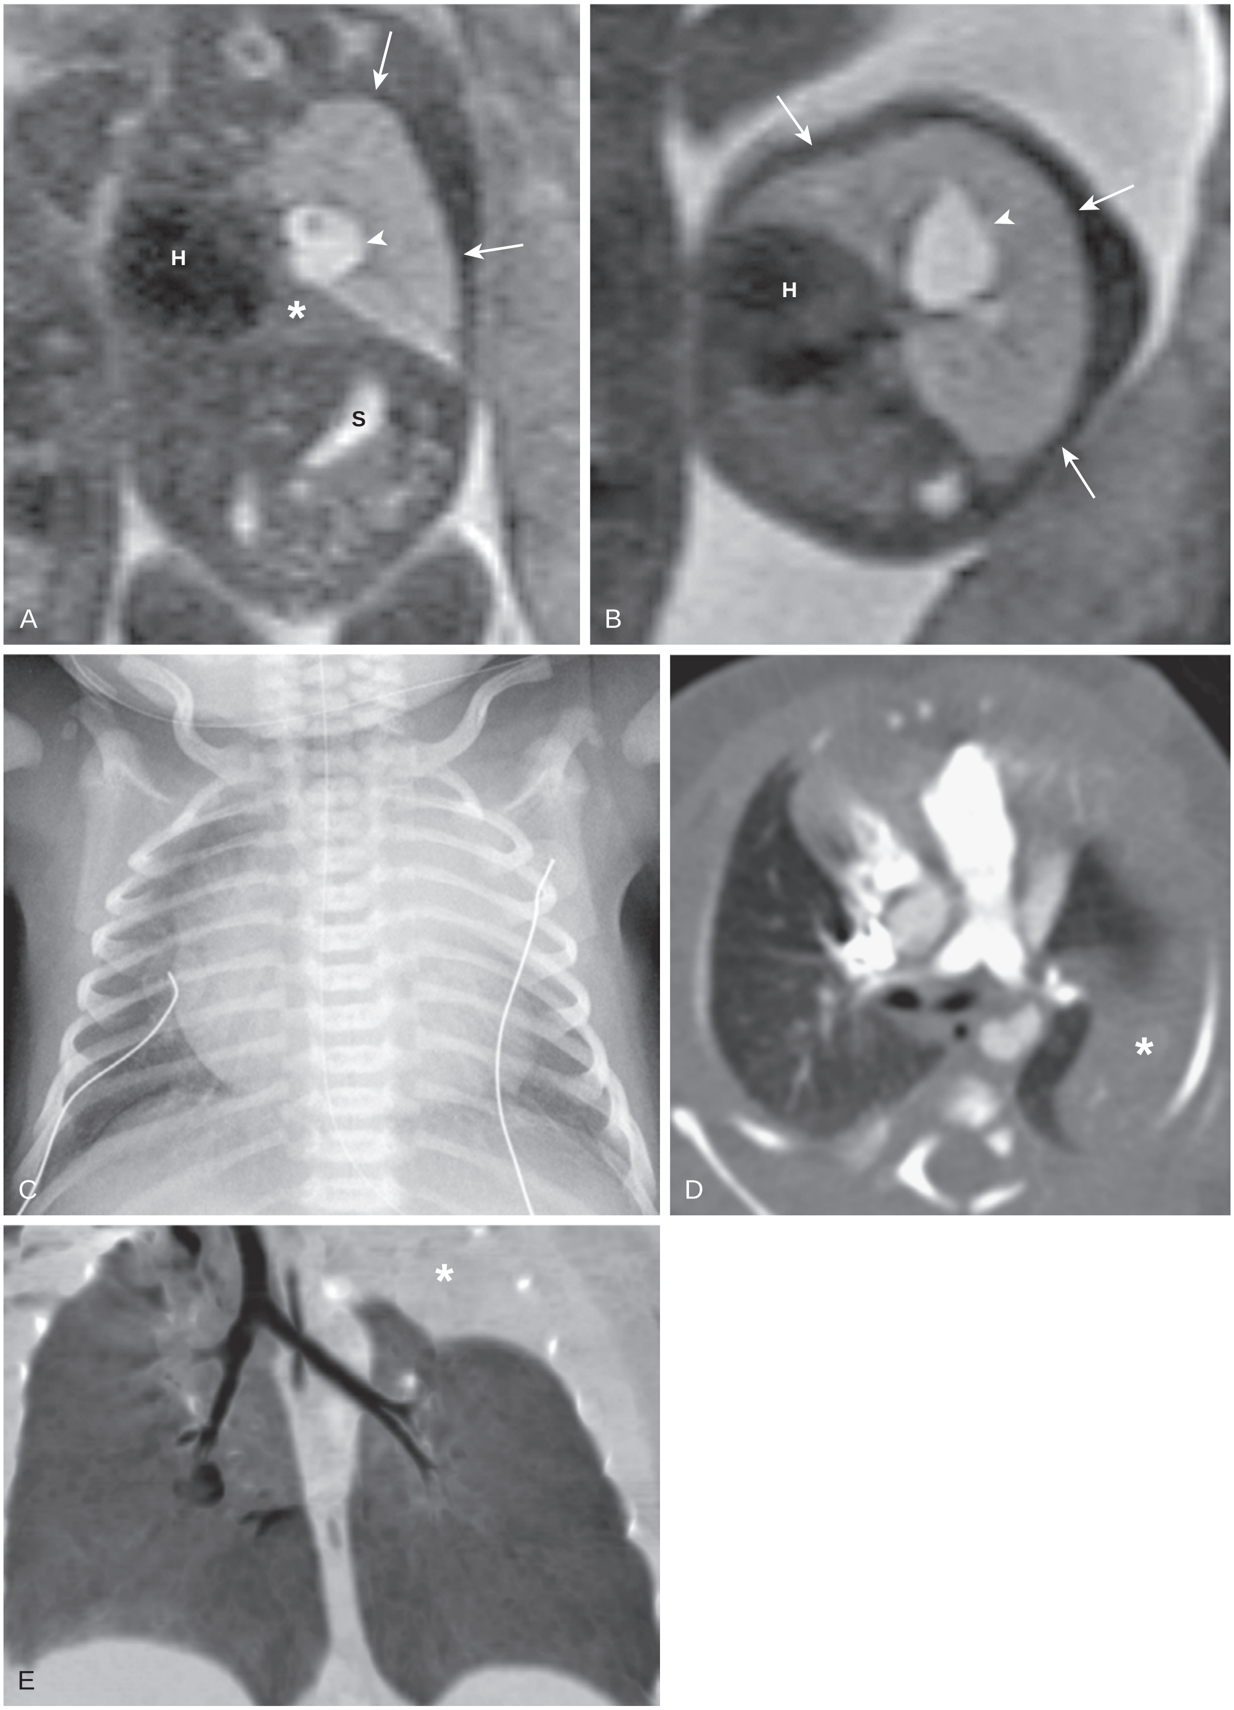
Despite advancements in pre- and postnatal imaging considerable controversy exists regarding nomenclature, classification, pathogenesis, description, and management of congenital lung anomalies.

Bronchial atresia and other congenital lung anomalies are believed to be the result of an obstruction malformation sequence. Differences in degree, level, and timing of the bronchial obstruction are thought to be responsible for the various imaging appearances. The obstruction is believed to occur at the time of differentiation of the diaphragm and gastrointestinal tract, this could explain some of the associated extrapulmonary anomalies. Given that specific terminology for these lesions may be controversial and occasionally confusing, it is recommended that careful description of all imaging findings is more important than specific categorization of the lesions by pathologic terminology. Imaging findings of congenital lung anomalies that need to be evaluated and described include (1) location of lesions, (2) associated anomalous vascular supply and drainage of the lesions, (3) internal components and the degree of aeration, (4) airway abnormality ,(5)exclusion of communication with the gastrointestinal (GI) tract, (6) integrity of the diaphragm, and (7) an assessment of associated anomalies.

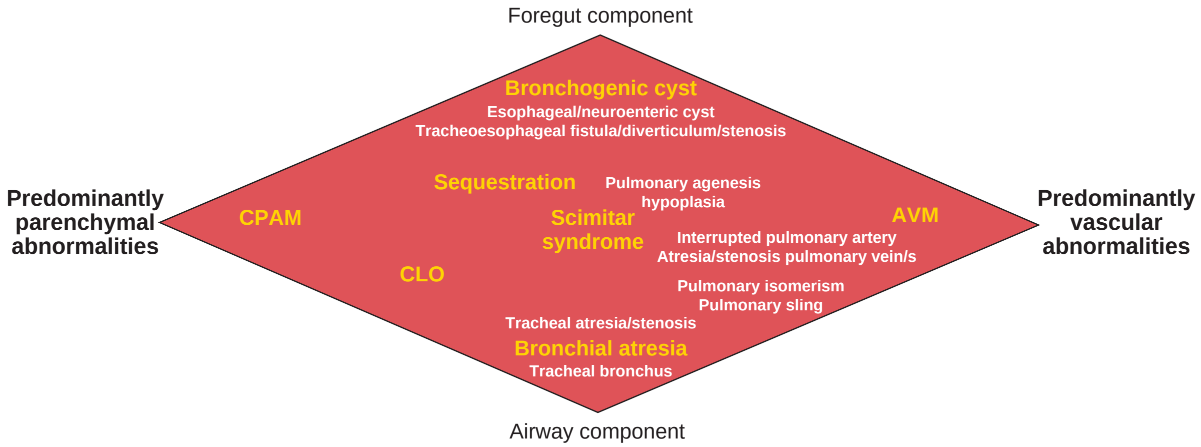
In this chapter, the underlying etiology, clinical presentation, imaging findings, and management of the most common congenital lung anomalies encountered in the pediatric population are discussed and illustrated.

## Keywords:

Bronchial Atresia
bronchogenic cyst
congenital lobar overinflation
congenital pulmonary airway malformation
bronchopulmonary sequestration
hypogenetic lung syndrome
anomalies of the pulmonary arteries and veins



**e-Figure 53.3. Bronchial atresia.** Coronal (A) and axial (B) T2-weighted fetal MR images show a large hyperintense, homogeneous lesion in the left upper lobe *(arrows)* in a 21-week gestational age fetus. The left lower lobe *(asterisk)* is displaced and compressed inferiorly. The heart *(H)* is shifted to the right. Very large central fluid-filled bronchi are noted *(arrowheads)*. *S,* Stomach. (C) Frontal chest radiograph at birth shows complete opacification of the left upper lobe, presumably as a result of retained fetal fluid and mucostasis related to bronchial atresia. Axial CT angiography (D) and minimum intensity projection (E) images performed at day 2 of life show complete collapse of the left upper lobe *(asterisk)*. In addition, the left upper lobe bronchus could not be delineated, a finding suggestive of bronchial atresia. Three-dimensional reconstructions are invaluable in showing the “interrupted connection” to the remainder of the airway.



Foregut component
Bronchogenic cyst
Esophageal/neuroenteric cyst
Tracheoesophageal fistula/diverticulum/stenosis
Predominantly parenchymal abnormalities
CPAM
Sequestration
Pulmonary agenesis hypoplasia
Scimitar syndrome
Interrupted pulmonary artery
Atresia/stenosis pulmonary vein/s
AVM
Predominantly vascular abnormalities
CLO
Pulmonary isomerism
Pulmonary sling
Tracheal atresia/stenosis
Bronchial atresia
Tracheal bronchus
Airway component

**Figure 53.1. Diagram of the spectrum of congenital lung anomalies, including foregut and airway components.** The lesions in *yellow* denote those most commonly encountered in this entity, whereas the lesions in *white* represent additional lesions that can be considered part of the spectrum. *AVM,* Arteriovenous malformation; *CPAM,* congenital pulmonary airway malformation; *CLO,* congenital lobar overinflation. *(Adapted from Newman B. Congenital bronchopulmonary foregut malformations: concepts and controversies.* Pediatr Radiol. *2006;36:773–791.)*

due to air trapping (associated with collateral aeration), and decreased underlying vascularity (e-Fig. 53.4).[1,17] However, in neonates, a portion of the lung distal to the atretic segment may remain atelectatic as a result of the in-utero mucostasis. Therefore some authors recommend avoiding immediate postnatal imaging evaluation because the underaerated lung related to bronchial atresia may be difficult to differentiate from the normal lung with expected fetal fluid retention in the newborn period.[8] Identification of the hallmark atretic bronchus and the "bronchocele/mucocele" by means of two-dimensional (2D) multiplanar or three-dimensional (3D) reconstructions either on prenatal or postnatal imaging may be helpful.[6,8,19]

***Treatment and Follow-up.*** In general, surgical resection is the treatment of choice in symptomatic pediatric patients, with conservative management possible in asymptomatic children with small lesions.[12,20,21] Although opinions vary, some centers advocate elective surgical resection of bronchial atresia even in asymptomatic pediatric patients because of potential future lung infection and especially when associated with CPAM.[22]

## Bronchogenic Cysts

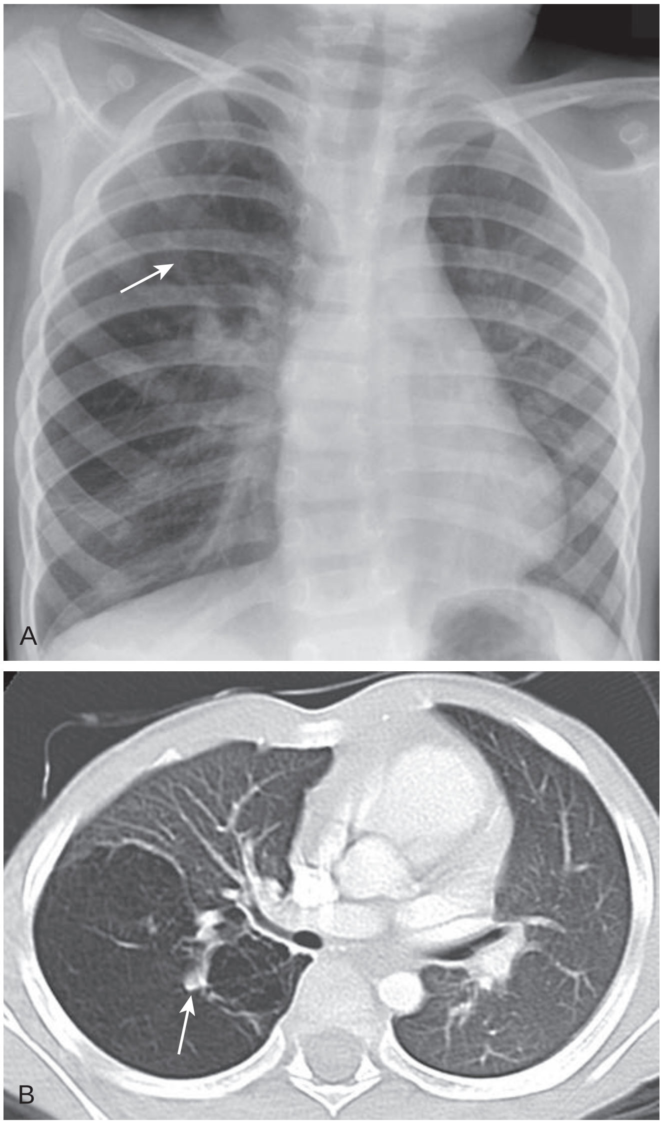
***Etiology.*** Bronchogenic cysts result from abnormal tracheobronchial branching and probably originate from an aberrant bud of the developing foregut, similar to other foregut duplication cysts. Bronchogenic cysts typically are unilocular, fluid-filled or mucus-filled cysts lined by respiratory epithelium and are attached to, but usually do not communicate with, the tracheobronchial tree.[1,4,20] Although most bronchogenic cysts are located within the mediastinum (predominantly near the carina), they may be encountered anywhere from the suprasternal area to the retroperitoneum. Bronchogenic cysts also may be found within the lung parenchyma, usually in the lower lobes located close to an adjacent airway.[1,20] Such intrapulmonary bronchogenic cysts usually do not communicate with the airway unless superimposed infection occurs,[4] which may further predispose them to recurrent infections. Symptoms depend on the mass effect the cyst exerts on neighboring structures including the airway, GI tract, and cardiovascular structures. Airway compression is usually mild, but it may be life-threatening in some instances when large bronchogenic cysts are located near the carina.[23]

***Imaging.*** A bronchogenic cyst typically presents as a round or oval-shaped cystic lesion located near the right paratracheal or subcarinal area within the middle mediastinum. Bronchogenic cysts are anechoic on prenatal ultrasound and show high signal intensity on T2-weighted prenatal MRI (e-Fig. 53.5).[16,20] On chest radiographs, a bronchogenic cyst manifests as a well-delineated round or oval-shaped middle mediastinal mass. On CT, approximately 50% of bronchogenic cysts demonstrate fluid attenuation value (~0 Hounsfield unit) (Fig. 53.6). The remaining bronchogenic cysts may have CT attenuation higher than water because of thick mucoid, milk-of-calcium, proteinaceous, or hemorrhagic contents. MRI, which can confirm the cystic nature of the bronchogenic cysts on T2-weighted images, is helpful for differentiating bronchogenic cysts with high attenuation value from a solid mass on CT. Typically, no internal contrast enhancement is seen within uncomplicated bronchogenic cysts. The presence of an air-fluid level, thick wall enhancement, or surrounding inflammatory changes often is associated with superimposed infection.[1,9,18]

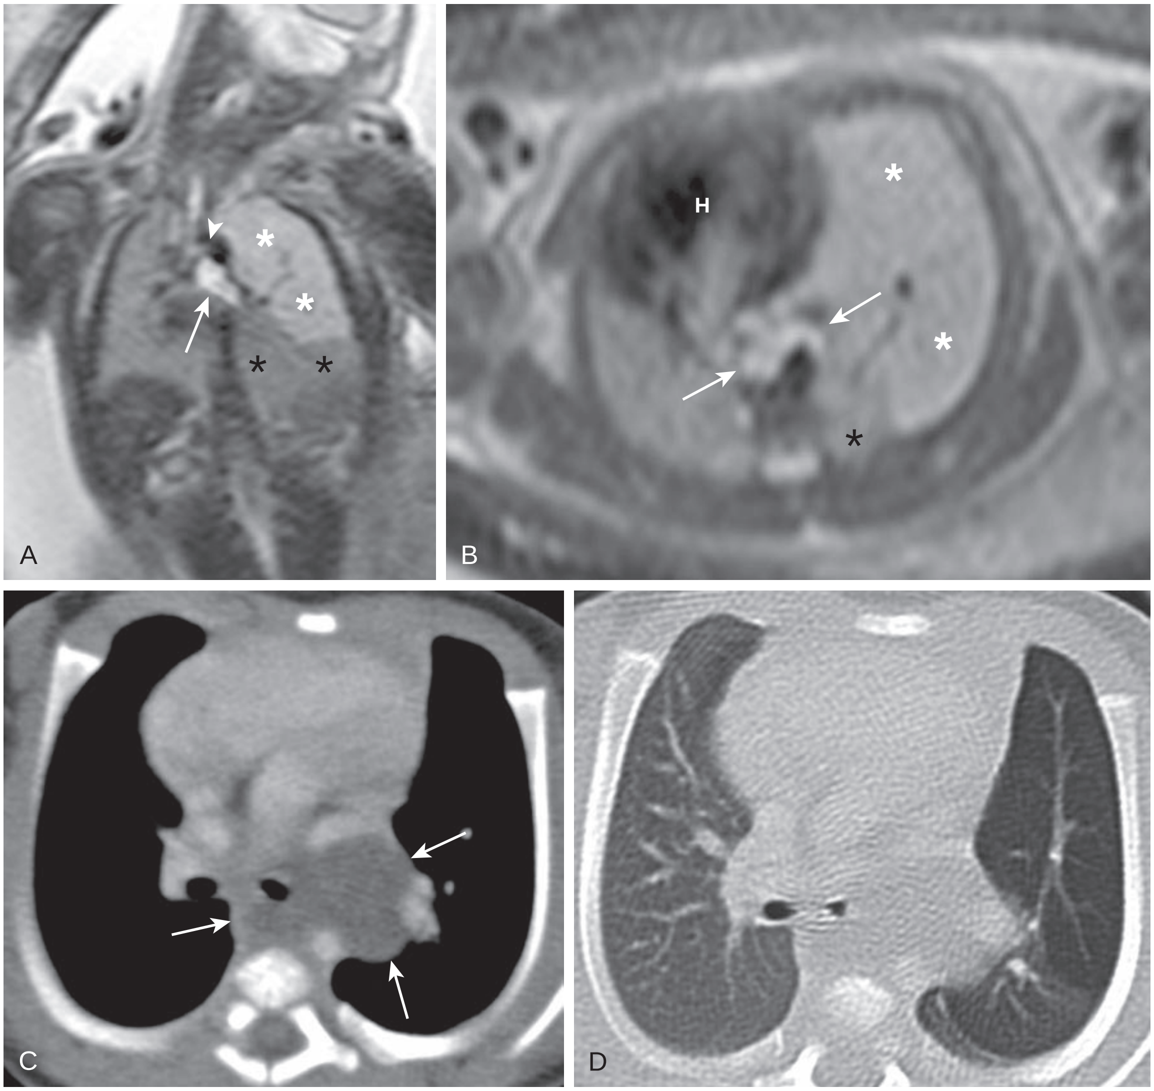
***Treatment and Follow-up.*** Complete surgical resection is the current management of choice for bronchogenic cysts, particularly in symptomatic pediatric patients.[24] Temporizing or palliative procedures such as transparietal, transbronchial, or mediastinal aspiration may be considered in symptomatic patients who are not surgical candidates.

## Congenital Lobar Overinflation

***Etiology.*** CLO, also referred to as infantile/congenital lobar emphysema or congenital lobar hyperinflation, is thought to be caused by an intrinsic or extrinsic bronchial narrowing, resulting in marked alveolar overdistension or overinflation of at least one pulmonary segment or lobe.[10,25] The alveolar walls are maintained, therefore true emphysematous change is not present.[10] Intrinsic bronchial narrowing can be caused by weakness or absence of underlying bronchial cartilage, whereas extrinsic bronchial narrowing may be due to the compression from adjacent mediastinal masses or enlarged vessels. Most cases of segmental overinflation, and some with lobar abnormality, are due to underlying bronchial atresia. CLO presents clinically with respiratory distress in the newborn period[1,16,20] in nearly half of the symptomatic cases, and by the age of 6 months in 80% of cases.[26] There is a slight male



**e-Figure 53.4. Bronchial atresia in an older child.** Frontal chest radiograph (A) and axial CT (B) image in a 3-year-old show right upper lobe hyperlucency and branching linear density *(arrows)* reflecting mucoid impaction in the bronchi distal to the atresia.



**e-Figure 53.5. Bronchogenic cyst.** Coronal (A) and axial (B) T2-weighted fetal MR images in a 26-week gestational age fetus show a cystic structure in the posterior mediastinum *(arrows)* apparently compressing the left mainstem bronchus *(arrowhead)* and resulting in hyperexpansion with increased fluid signal in the left upper lobe *(white asterisks)*. The left lower lobe is compressed and displaced inferiorly *(black asterisks)*. The fetal heart *(H)* and mediastinum have shifted to the right. Postnatal contrast-enhanced CT images in mediastinal (C) and lung (D) windows show the fluid-filled cystic structure consistent with a bronchogenic cyst *(arrows)* centered at the left hilum and extending posteriorly and inferiorly. The cyst compresses the left mainstem bronchus and results in air trapping in the left upper lobe.

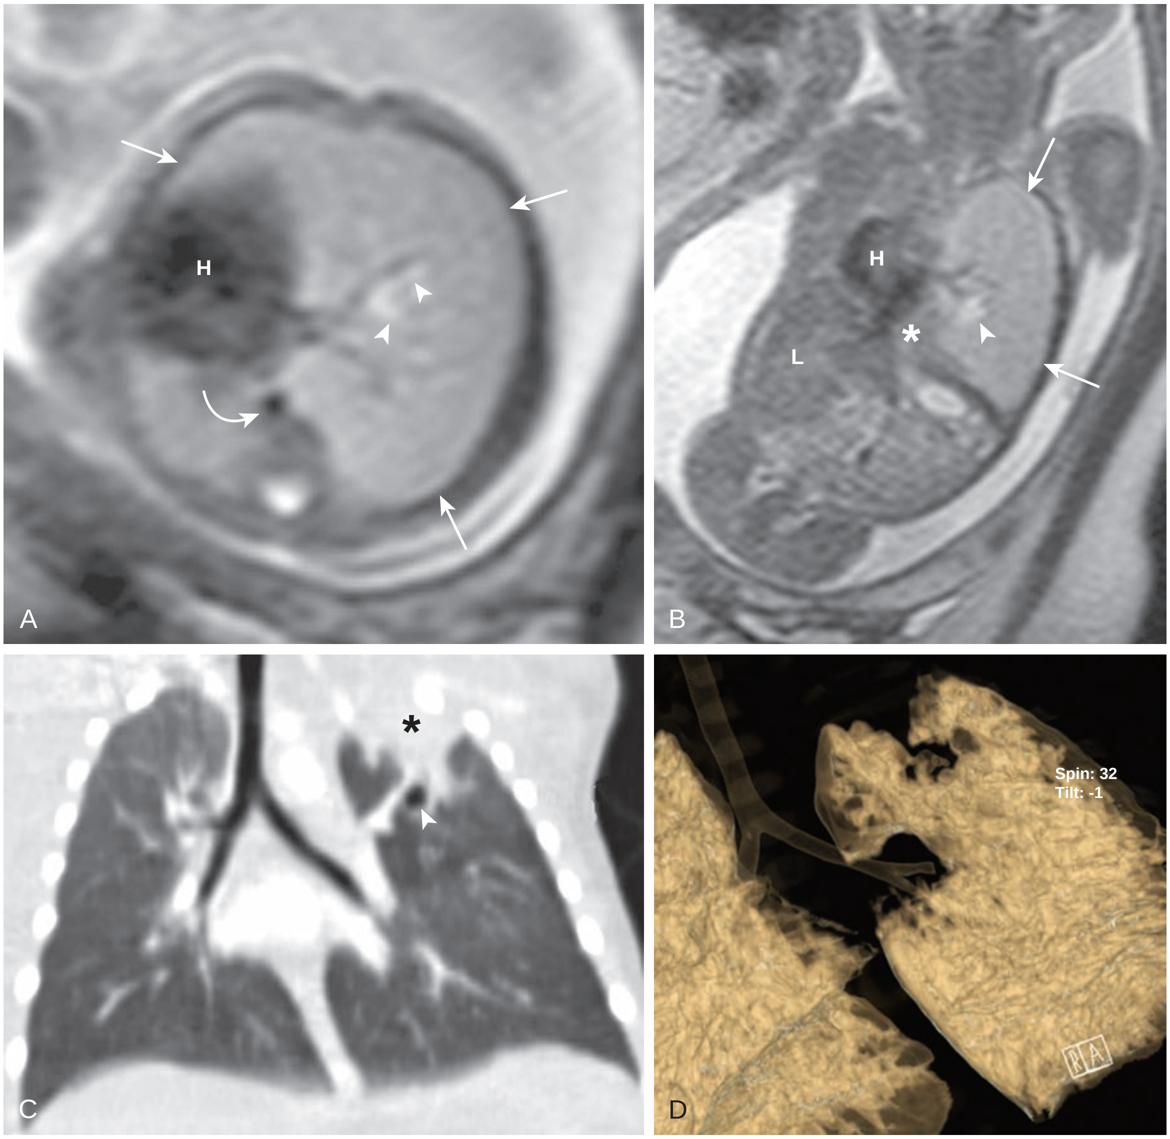


**Figure 53.2. Bronchial atresia.** Axial (A) and coronal (B) T2-weighted fetal MR images in a 22-week gestational age fetus demonstrate a large hyperintense, homogeneous lesion in the left upper lobe *(arrows)*. Central fluid-filled bronchi are noted *(arrowheads)*. The left lower lobe *(asterisk)* is compressed inferiorly and displaced medially adjacent to the fetal heart *(H)*. The *curved arrow* denotes the aorta, which is also displaced to the right. *L,* Liver. (C) Coronal postnatal multiplanar reconstruction CT image shows partial opacification *(asterisk)* of the left upper lobe, presumably due to mucostasis related to bronchial atresia. In addition, a small air bubble is seen *(arrowhead)*, reflecting a bronchocele. (D) Volume-rendered reconstructed CT image could not delineate the left upper lobe bronchus.

predominance, and the upper lobes are affected more frequently than the lower lobes, with the left lung affected more often than the right (see also Chapter 50).[10,26]

***Imaging.*** On prenatal imaging, CLO manifests as a homogeneously hyperechogenic lesion on US or as a T2 hyperintense lesion on MRI without visible cysts. CLO often is indistinguishable from other congenital lung anomalies, particularly in the presence of bronchial atresia.[7,10,27] In the immediate postnatal period, CLO initially may appear as an area of increased opacity related to retained fetal lung fluid, which will clear on subsequent studies.[1,4,20,24] CLO usually is diagnosed postnatally by its typical clinical presentation and characteristic radiographic features of progressive lobar hyperexpansion and hyperlucency, producing displacement or compression of adjacent structures. Similar imaging findings are noted on CT, and the attenuated pulmonary vasculature is a helpful clue to distinguish CLO from a pneumothorax or other entities in cases of inconclusive chest radiographic findings (Fig. 53.7).[1] Similar to bronchial atresia, early CT imaging should be avoided because of a confusing appearance when the affected lung is still fluid-filled.

***Treatment and Follow-up.*** Surgical lobectomy is the current management for symptomatic pediatric patients with CLO.[24,28] Some medical centers advocate expectant management for cases with minimal or no symptoms.[25,28]

## Congenital Pulmonary Airway Malformation

***Etiology.*** CPAMs, formerly known as cystic adenomatoid malformations of the lung, were first described by Ch'In and Tang in 1949 as rare lung lesions occurring in premature or stillborn

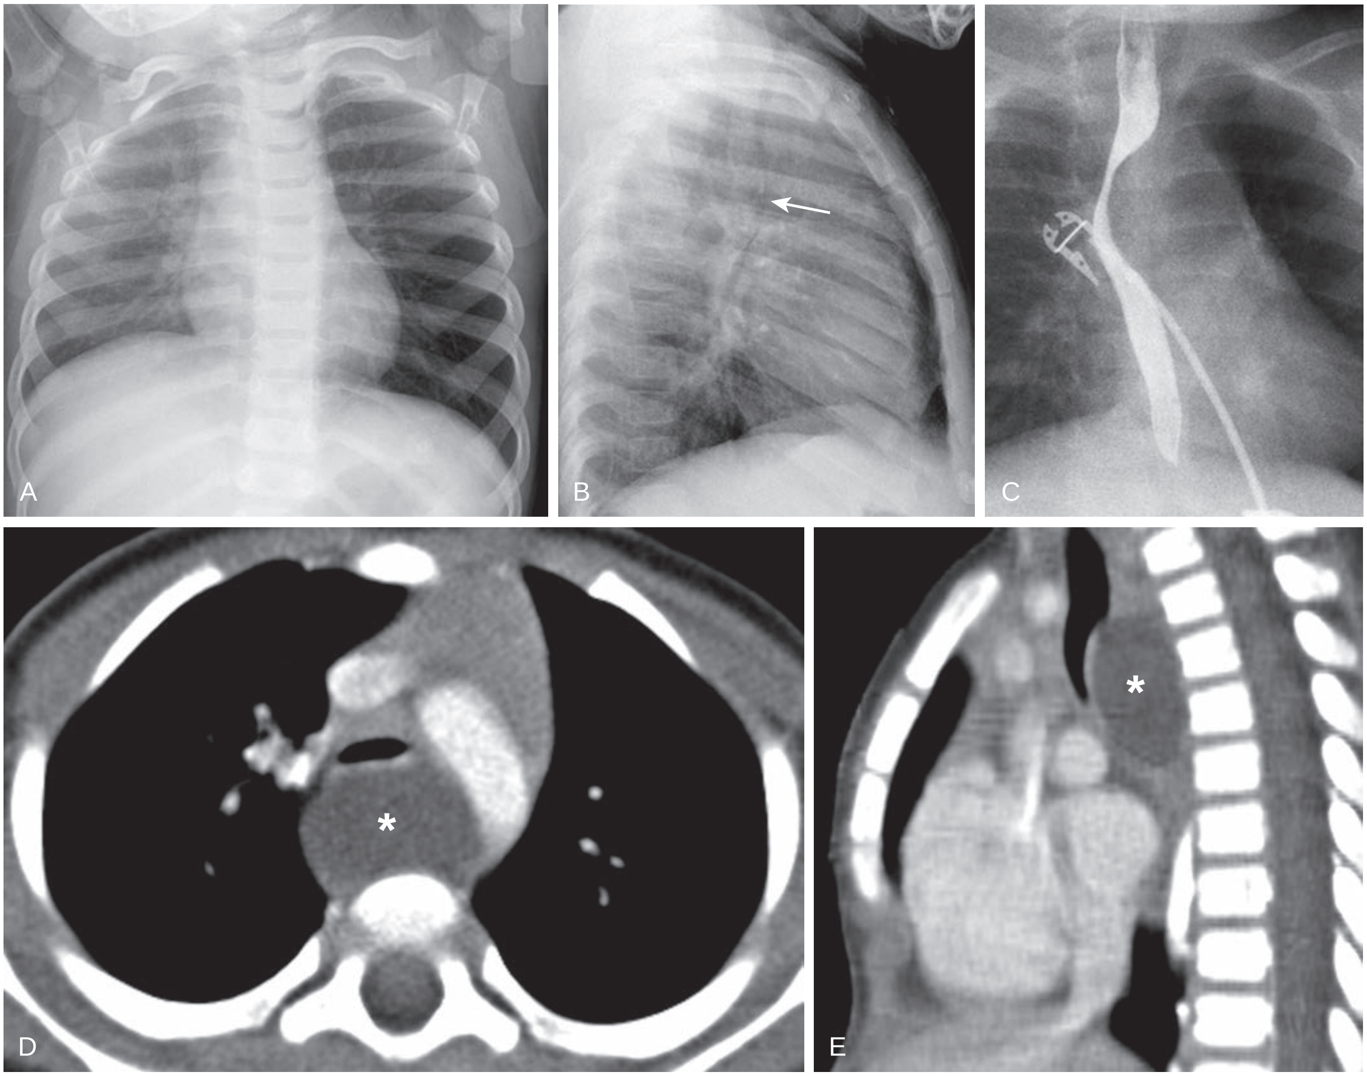

**Figure 53.6. Bronchogenic cyst in a 15-month-old child with stridor.** Frontal chest radiograph (A) shows hyperinflation of the left lung. Lateral radiograph (B) reveals the effect of the mass and anterior displacement of the airway *(arrow)*. (C) Upper gastrointestinal image shows esophageal displacement to the right by a soft tissue density mass. Contrast-enhanced axial (D) and sagittal (E) CT images show a fluid density lesion *(asterisks)* posterior to the lower trachea consistent with a bronchogenic cyst.

infants with significant hydrops.[29,30] CPAMs are currently one of the most common congenital lung anomalies accounting for about 30% to 40% of the cases.[10,15] CPAMs are characterized by a heterogeneous group of congenital cystic lung masses with an abnormal bronchial communication or bronchial atresia.[6,15,31]

In 1977, Stocker et al.[31] classified these lesions based on their clinical and pathologic features, with subdivisions based on the size of the cysts (types 1, 2, and 3) and according to the location of suspected development of the malformation along the airway. Type 1 CPAMs consist of cysts larger than 2 cm, with presumed bronchial/bronchiolar origin. Type 2 CPAMs consist of cysts smaller than 2 cm, with presumed bronchiolar origin. Type 3 CPAMs appear solid/microcystic, with a presumed bronchiolar/alveolar origin. However, Stocker later expanded his classification into five types that included type 0 CPAMs, with presumed tracheobronchial origin (hypoplastic lungs, usually lethal, not recognizable on imaging), and type 4 CPAMs, with presumed distal acinar origin. The term CPAM was implemented instead of cystic adenomatoid malformations, because cystic changes were observed in only three of the aforementioned types (types, 1, 2, and 4), and adenomatoid change was observed only in type 3.[1,7,32,33] This expanded classification has proven problematic with increasing evidence indicating that the type 4 CPAM lesions is the same entity as type 1 cystic pleuropulmonary blastoma.[4,34] Langston[4] classifies CPAM lesions into two types, and terms the Stocker type 1 CPAM as “large cyst-type lesions” and the Stocker type 2 CPAMs as “small cyst-type lesions” based on cyst size and pathologic criteria. Langston proposed that the type 3 CPAM actually represents a form of pulmonary hyperplasia/dysplasia and should be excluded from the CPAM classification.[4] On radiographs and CT imaging, these lesions are typically divided into large cyst (type 1, most common), small cyst (type 2), and solid (microcystic, type 3, very rare) lesions.

***Imaging.*** Prenatally, CPAMs have been classified on the basis of cyst size as microcysts (<5 mm) and macrocysts (≥5 mm) on fetal US and MRI.[35] Type 1 CPAMs may contain one, several, or multiple macrocysts, some of which are ≥5 mm in diameter (Fig. 53.8).[7] Type 2 CPAMs have variable appearances, ranging from

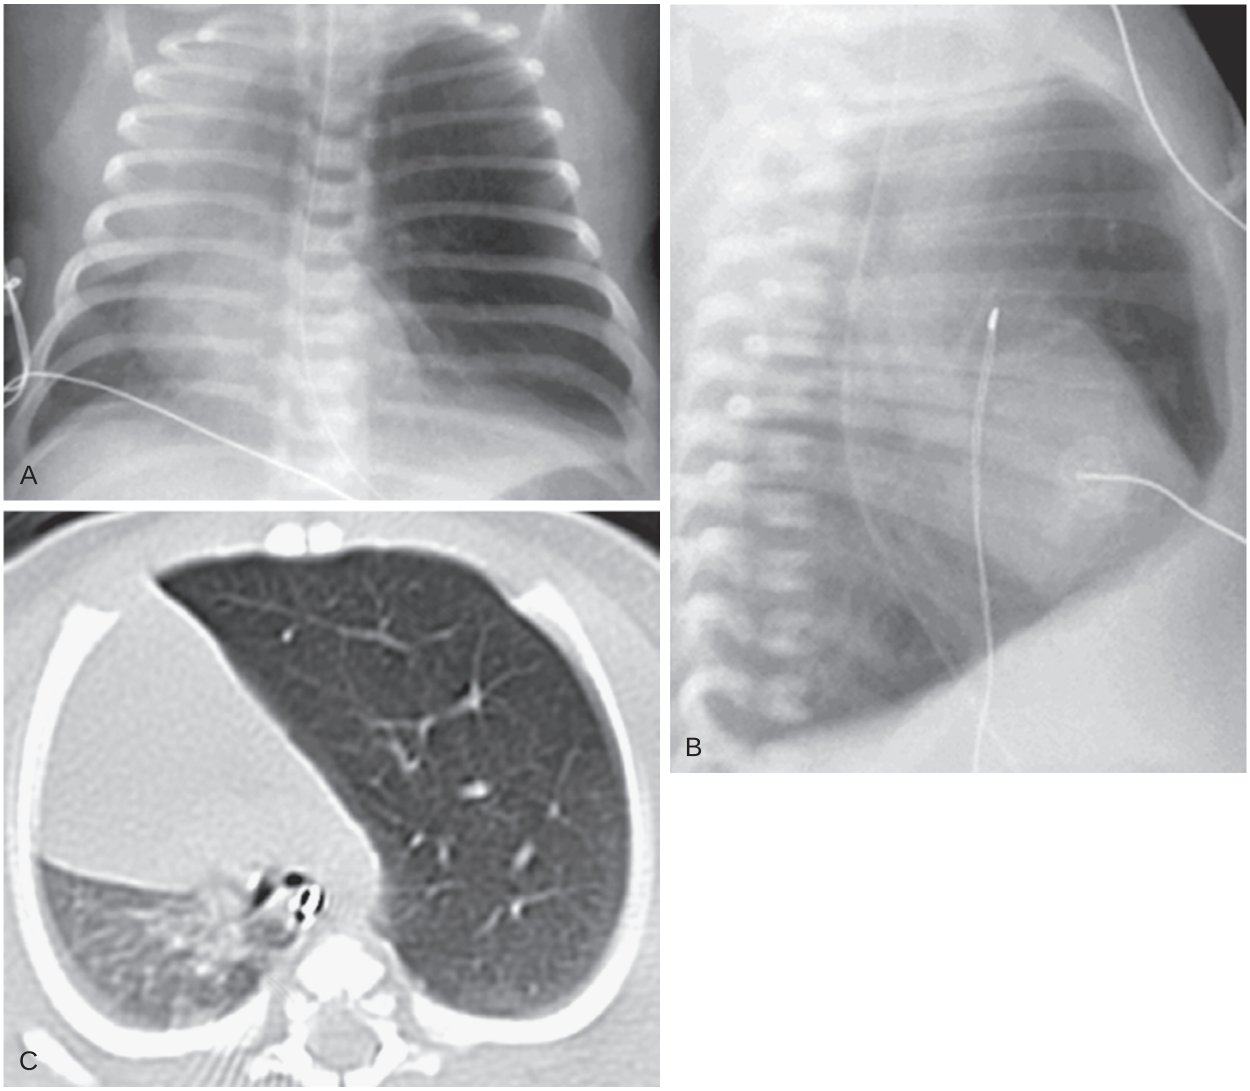

**Figure 53.7. Congenital lobar overinflation in a 3-day-old with increasing tachypnea.** Frontal (A) and lateral (B) chest radiographs and an axial CT image (C) show hyperexpansion and hyperlucency of the left upper lobe with contralateral cardiomediastinal shift consistent with congenital lobar emphysema.

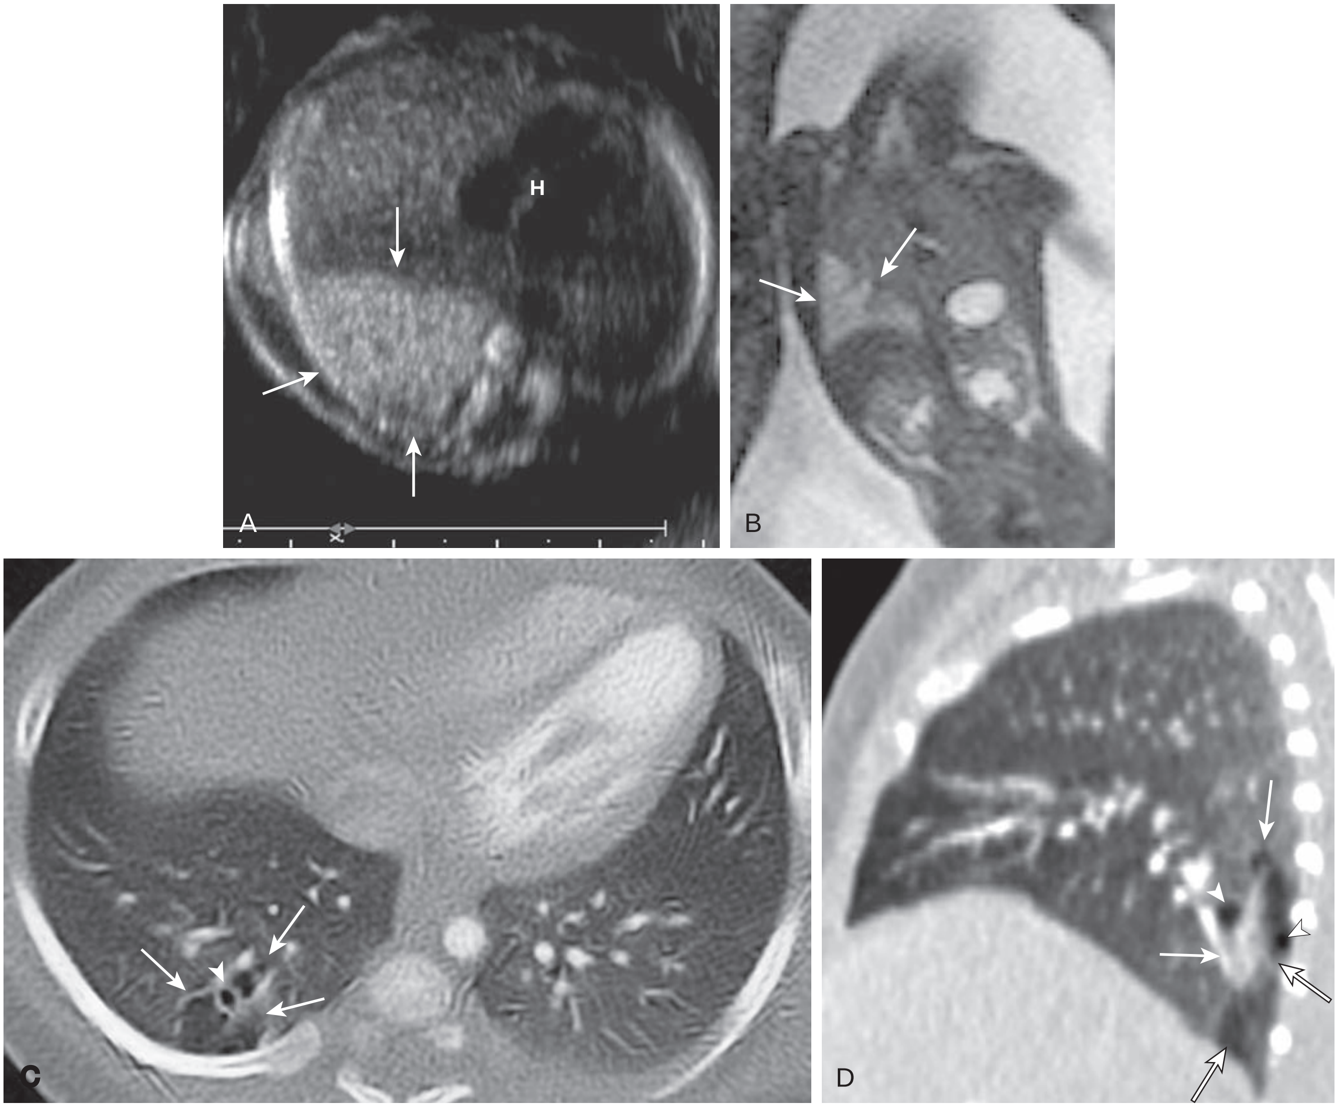
homogeneously hyperechoic or hyperintense lesions to microcystic lesions exhibiting multiple, uniform cysts that measure <5 mm (e-Figs. 53.9 and 53.10).[7,16,20]

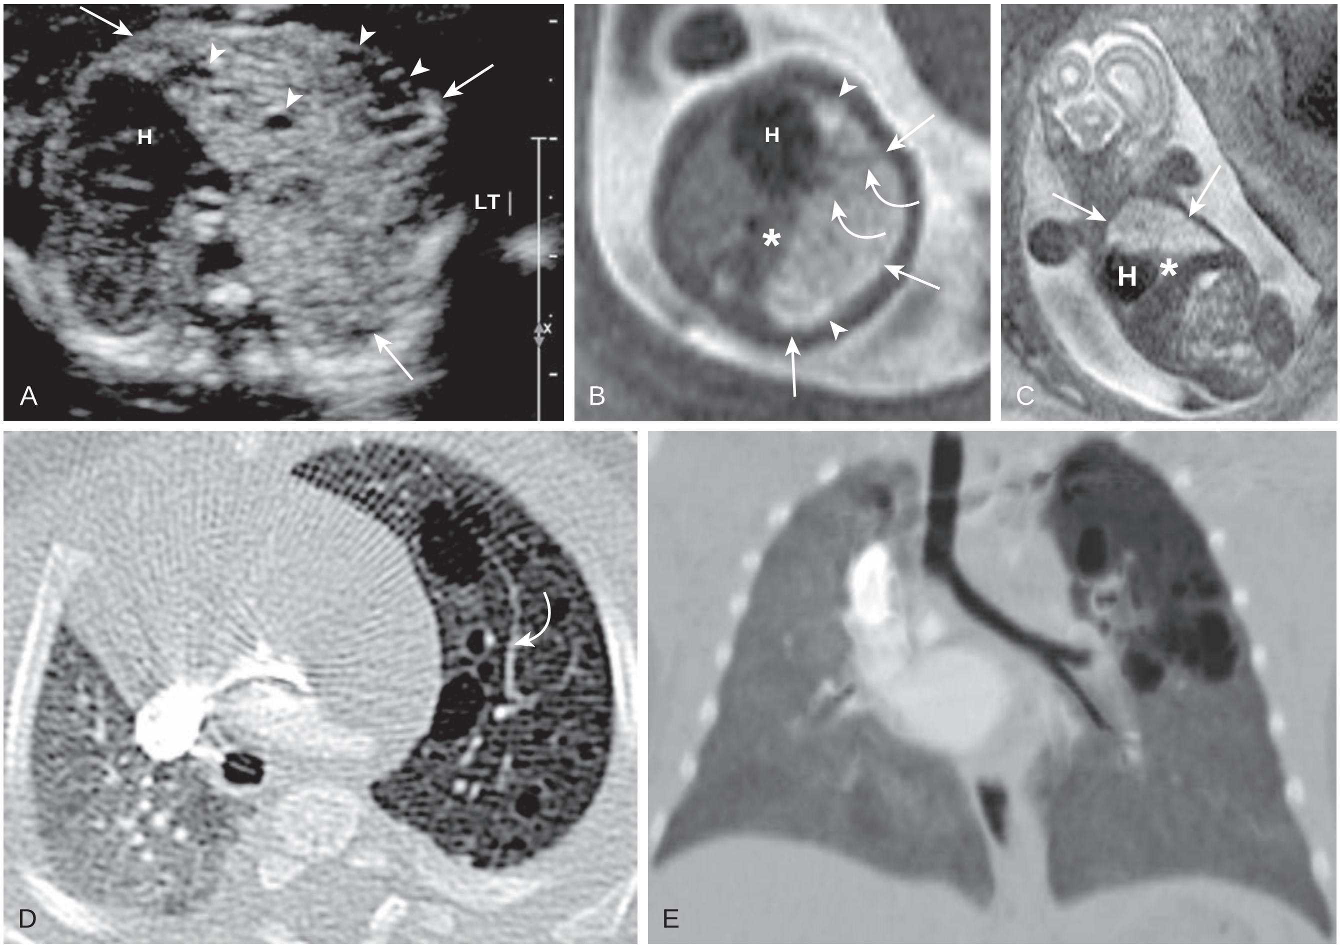
Postnatal imaging findings of CPAMs usually correlate with underlying histopathologic features.[1] Large cyst-type CPAMs typically present with one or several larger air-filled cystic structures with intervening solid, unaerated lung parenchyma. The cysts of type 1 CPAMs are larger than 2 cm and may be accompanied by several smaller cysts, whereas small cyst type or type 2 CPAMs usually manifest as partially air-filled multicystic masses, with individual cysts smaller than 2 cm and with variable degrees of solid-appearing, unaerated lung tissue.[1,8] Type 3 CPAMs typically appear as solid lesions with mild contrast enhancement because of microscopic cysts that can be identified only at histologic evaluation. Pleuropulmonary blastoma in infancy usually present as large cysts arising from the peripheral portion of the lung, this lesion may be difficult to distinguish radiographically from other cystic lung lesions (see Chapter 55) (e-Fig. 53.11).

CPAM blood supply is often from the pulmonary artery and venous drainage is into the pulmonary veins, although hybrid sequestration/CPAM lesions with systemic arterial supply are common (especially CPAM type 2). Although unilobar involvement of CPAM is far more common, multilobar and even bilateral lung involvement may occur.[30,33,36] Although any lobe of the lung can be involved, predilection exists for the lower lobe.[36] CPAMs that are complicated as a result of superimposed infection may have an imaging appearance similar to pneumonia or a lung abscess (Fig. 53.12).

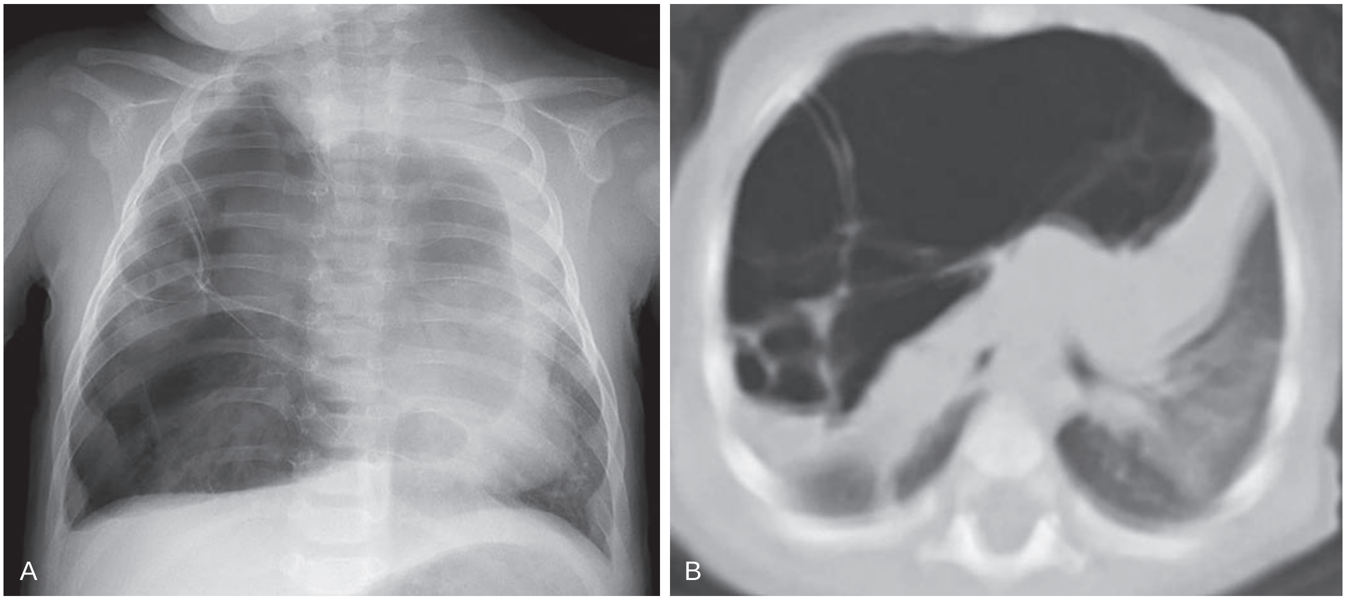
***Treatment and Follow-up.*** The generalized consensus is that symptomatic CPAMs should be resected, typically by lobectomy, regardless of the patient's age at presentation.[15,24,28] However, considerable controversy exists with regard to the management of prenatally diagnosed, asymptomatic, small CPAM lesions, and no consensus exists on the timing of or need for resection.[15,37–39] Although there is some support for a nonsurgical strategy with imaging follow-up, most medical centers advocate surgical resection before 1 year of age because of the potential risk of associated complications, such as infection, pneumothorax, and the small risk of malignant transformation, particularly in the case of CPAM type 1 lesions.[23,24,36,40,41]



**e-Figure 53.9. Congenital pulmonary airway malformation (CPAM) type 2.** (A) Transverse fetal sonogram through the chest in a 20-week gestational age fetus shows an echogenic right lower lobe lung lesion with tiny cysts only seen on high-resolution images *(not shown)* consistent with a CPAM type 2 lesion *(arrows)*. The heart *(H)* and mediastinum are only mildly shifted without cardiac compression. Coronal (B) fetal T2-weighted MR image shows a mildly heterogeneous lesion *(arrows)* with slightly nodular contours but no visible cysts. Postnatal axial and sagittal CT images (C and D) at 1 month of age show an ill-defined, relatively smaller hyperlucent lesion *(arrows)* in the right lower lobe with tiny, subcentimeter internal cysts *(arrowheads)*. This lesion also demonstrated bronchial atresia components on histologic examination.



**e-Figure 53.10. Congenital pulmonary airway malformation type 2.** (A) Transverse fetal sonogram through the chest in a 19-week gestational age fetus shows an echogenic left upper lobe lesion with several internal cysts *(arrowheads)*, findings consistent with a CPAM type 2 lesion *(arrows)*. The heart *(H)* and mediastinum are moderately shifted to the right without cardiac compression. *LT,* Left. Axial (B) and coronal (C) fetal T2-weighted MR images show a heterogeneous lesion *(arrows)* with internal cysts *(arrowheads)*; some of them even appear as "macrocysts." Normal-appearing lung tissue is noted as being compressed posteriorly and inferiorly *(asterisks)*. However, on postnatal axial (D) and minimum intensity projection (E) CT images at 3 months of age, the lesion appears relatively smaller and exerts less mass effect and no mediastinal shift. All the cysts are aerated and measure less than 2.0 cm. Note that some slightly prominent, tortuous internal pulmonary vessels are seen within the lesion in both the fetal MR image (B) and the postnatal CT image (D) *(curved arrows)*.



**e-Figure 53.11. Cystic pleuropulmonary blastoma in a 6-month-old with increased work of breathing.** (A) Frontal chest radiograph demonstrates a large radiolucent lesion with fine septations and multiple cysts within the right lung resulting in a mediastinal shift. (B) Axial computed tomography image reveals multiple cysts of varying sizes with mass effect demonstrated on the mediastinum and contralateral left lung.

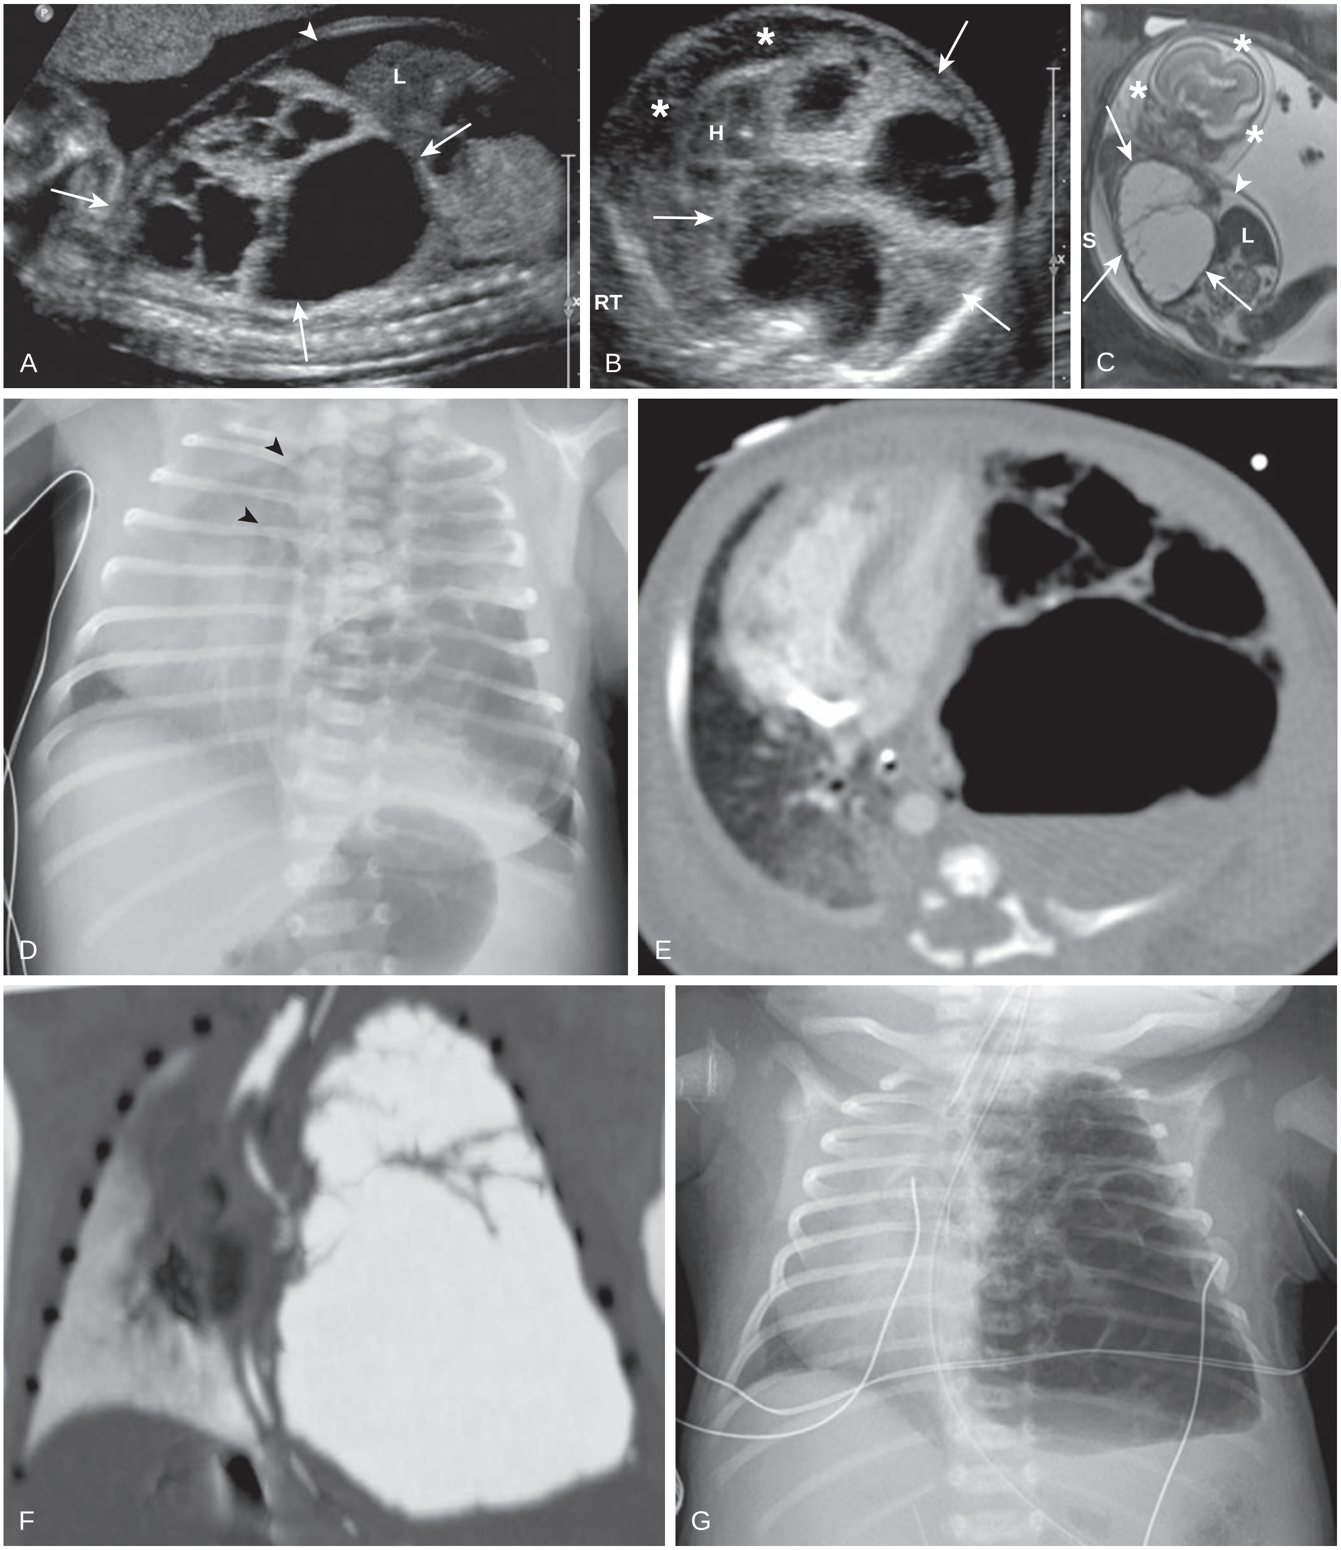


**Figure 53.8. Congenital pulmonary airway malformation type 1.** Sagittal ultrasound (A), axial ultrasound (B), and fetal sagittal T2-weighted MR (C) images in a 22-week gestational age fetus show a large, heterogeneous, multicystic lesion occupying the vast majority of the left hemithorax *(arrows)* and resulting in inversion of the left hemidiaphragm. Note the ascites in the abdomen *(arrowhead)* and the skin thickening and edema *(asterisks)*, which are reflective of hydrops. *H,* Heart; *L,* liver. (D) Radiograph immediately after delivery shows the complex, partially aerated lesion resulting in significant mediastinal shift. The *arrowheads* denote the severe tracheal deviation. Axial computed tomography angiography (E) and coronal inverted minimum intensity projection (F) images obtained the following day show the large, heterogeneous lesion with multiple macrocysts of varying sizes. Fluid is identified in some of the cysts. (G) As fetal fluid is cleared from the lungs, the lesion appears more aerated and further mediastinal shift occurs.

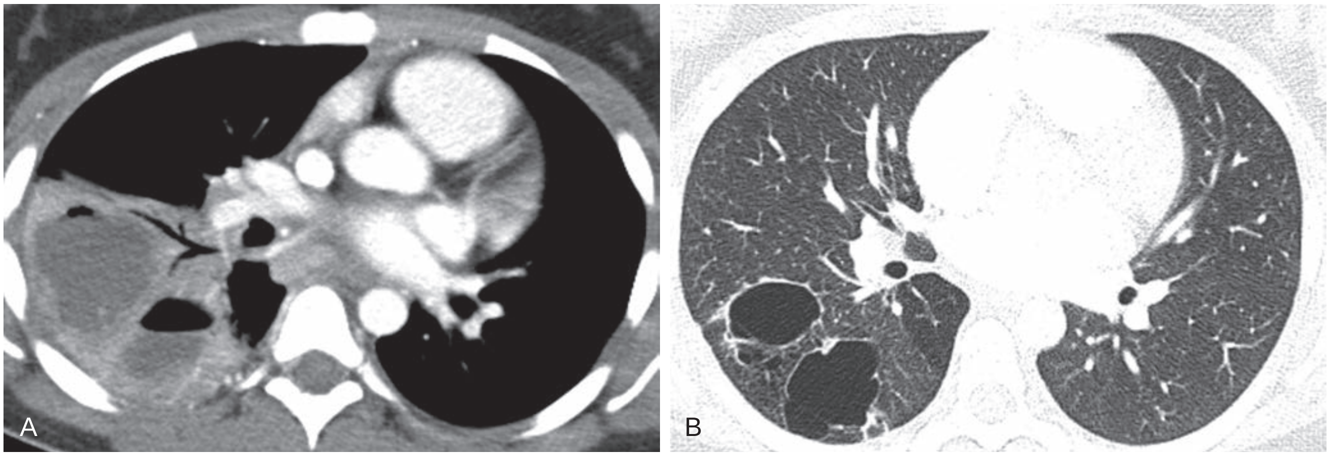

**Figure 53.12. Infected CPAM type 1 in a 15-year-old girl.** (A) Initial axial contrast-enhanced CT image shows consolidation, with areas of low attenuation representing superimposed infection with air–fluid levels in the cystic components. (B) Follow-up CT image obtained 7 months later shows resolution of the infection and visualization of the air-filled CPAM cysts.

## COMBINED PARENCHYMAL AND VASCULAR LESIONS

### Bronchopulmonary Sequestration

***Etiology.*** BPSs are congenital lung malformations that consist of nonfunctioning lung tissue that does not connect with the tracheobronchial tree. A BPS has a systemic arterial supply, usually from the aorta, although occasionally it may arise from branches of the celiac, splenic, intercostal, or subclavian arteries.

Sequestrations are classified as either extralobar (25%) or intralobar (75%). Extralobar sequestration (ELS) is defined as an isolated mass of lung tissue with its own pleural investment and aberrant systemic vascular supply. An ELS is believed to develop from a supernumerary lung bud that separates from the tracheobronchial tree and parasitizes its own vascular supply from the systemic circulation and is usually unaerated.[4,10,42] Venous drainage is into the azygos or hemiazygos systems in most cases. However, an ELS may drain into the pulmonary veins or other systemic veins, including the subclavian and intercostal veins, as well as the portal venous system.[4,8,42] Although most ELSs are identified in isolation, occasionally an ELS may be associated with congenital heart defects, abnormal communications with the GI tract, pulmonary hypoplasia, ectopic pancreas, vertebral anomalies, and congenital diaphragmatic hernia, which is the most commonly associated anomaly.[1,4,8,20,42] ELS may show spontaneous regression.[43] Associated microcystic maldevelopment or CPAM type 2 components have been described in many of these cases,[8,44] referred to as hybrid lesions.[45,46] Most patients with an ELS are asymptomatic.

Intralobar sequestration (ILS) is defined as a developmental malformation composed of isolated, nonfunctioning lung tissue without communication to the tracheobronchial tree and with an aberrant systemic vascular supply, typically embedded within a normal lobe.[4,20,47] Unlike ELS, ILS lesions do not have their own pleural coat, and venous drainage primarily occurs into the pulmonary veins.[8,9,20,47] In the past, ILS has been considered an acquired lesion resulting from a chronic inflammatory process that recruited collateral flow from aortic branch arteries.[47] Increasing reports of antenatal ILS detection, confirmed by postnatal resection, has challenged this previous concept. Pediatric patients with ILS often clinically present with recurrent lung infection.

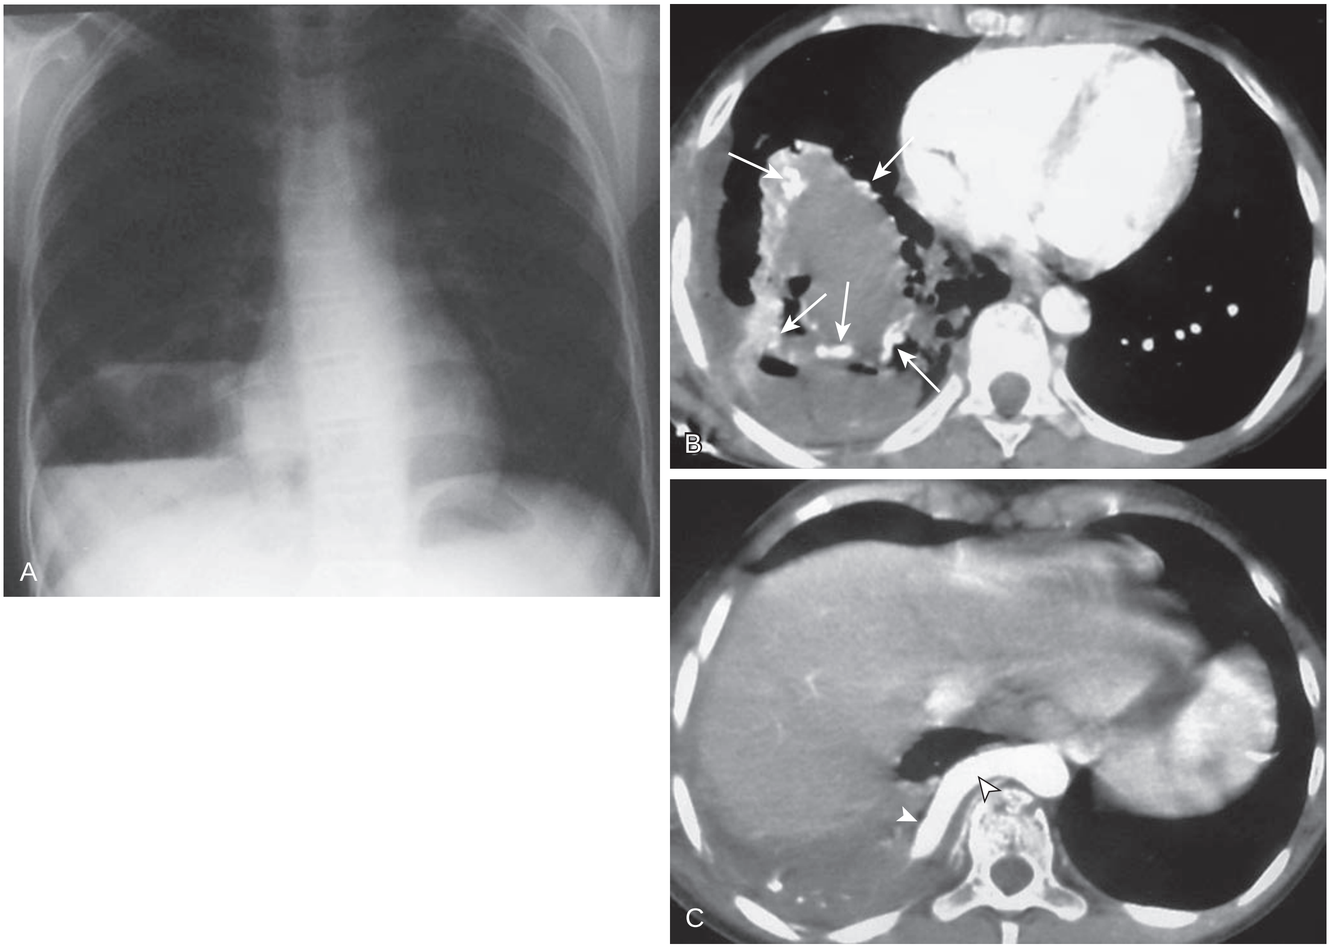
***Imaging.*** Imaging findings of BPS vary, primarily on the basis of association with superimposed infection (e-Fig. 53.13), CPAM lesions (Fig. 53.14), or GI tract communication.[1,8] In fetal imaging, BPS lesions are echogenic on ultrasound and hyperintense on T2-weighted magnetic resonance (MR) images.[27] The supplying systemic artery may be identified prenatally. Similar to CPAM and bronchial atresia, BPS can be detected as early as in the 12th week of gestation,[24] although most usually are diagnosed on routine ultrasound at 19 to 20 weeks. They exhibit a characteristic increase in volume from the 20th to the 26th week and usually reach a plateau by the 28th week of gestation.[7,24,27,36,41] BPS usually decrease in size during the third trimester and seem to vanish in nearly half of the cases. Because complete regression is extremely unusual, follow-up cross-sectional postnatal imaging is recommended in all cases,[7,27,36] because these lesions may be overlooked on chest radiographs.[48]

On chest radiographs, ELS lesions typically present as a focal nonaerated lung mass. ILS lesions often present as a focal lung mass and/or cyst but also may manifest as an area of consolidation or lung abscess, particularly in the setting of recurrent superimposed infection. Although ELSs may be encountered anywhere from the neck to below the diaphragm, they are found most commonly within the lower hemithorax, more often on the left side.[4,8,42]

On CT, ELS lesions characteristically appear as solid, unaerated lesions, although in nearly half of the cases, coexistent pathology with CPAM type 2 has been reported (Fig. 53.15). In these cases, internal cystic components may be identified.[4,8,44] Because ILS lesions do not have a pleural investment, they typically manifest as aerated lesions, presumably from collateral air drift, if enough time has elapsed to adequately clear any retained fetal lung fluid (Fig. 53.16).[8] Anomalous vascular components of BPS can be evaluated postnatally with either CT or MRI, with interpretation facilitated by multiplanar and 3D reconstructions.[1,8,49]

***Treatment and Follow-up.*** Many authors support the elective surgical resection of ILS because of the risk of complications, such as superimposed infection, pneumothorax, hemorrhage, sudden respiratory compromise, and the small risk of malignant transformation.[23,24,28,40] Lobectomy via video-assisted thoracoscopic surgery is performed in many institutions, because segmentectomies may result in incomplete resection and air leaks.[23,24,40] Segmentectomies are usually reserved for smaller lesions or for children with bilateral, multilobar involvement.[28]

Management of ELS is more controversial, because there is a lower risk of complications.[23] Nonoperative, expectant management frequently is applied to an extrathoracic ELS, whereas an intrathoracic ELS usually is resected. Arterial embolization has been



**e-Figure 53.13. Infected hybrid lesion in a 12-year-old girl with a history of recurrent right lower lobe pneumonia.** (A) Frontal chest radiograph shows a large right lower lobe lesion with an air fluid level. (B) Axial CTA image shows rounded, fluid-filled lesions with peripheral brisk, enhancing *(arrows)* margins. A small associated pleural effusion is present. (C) Axial CTA image shows a large aortic feeder *(arrowheads)* providing arterial systemic supply to the lesion.

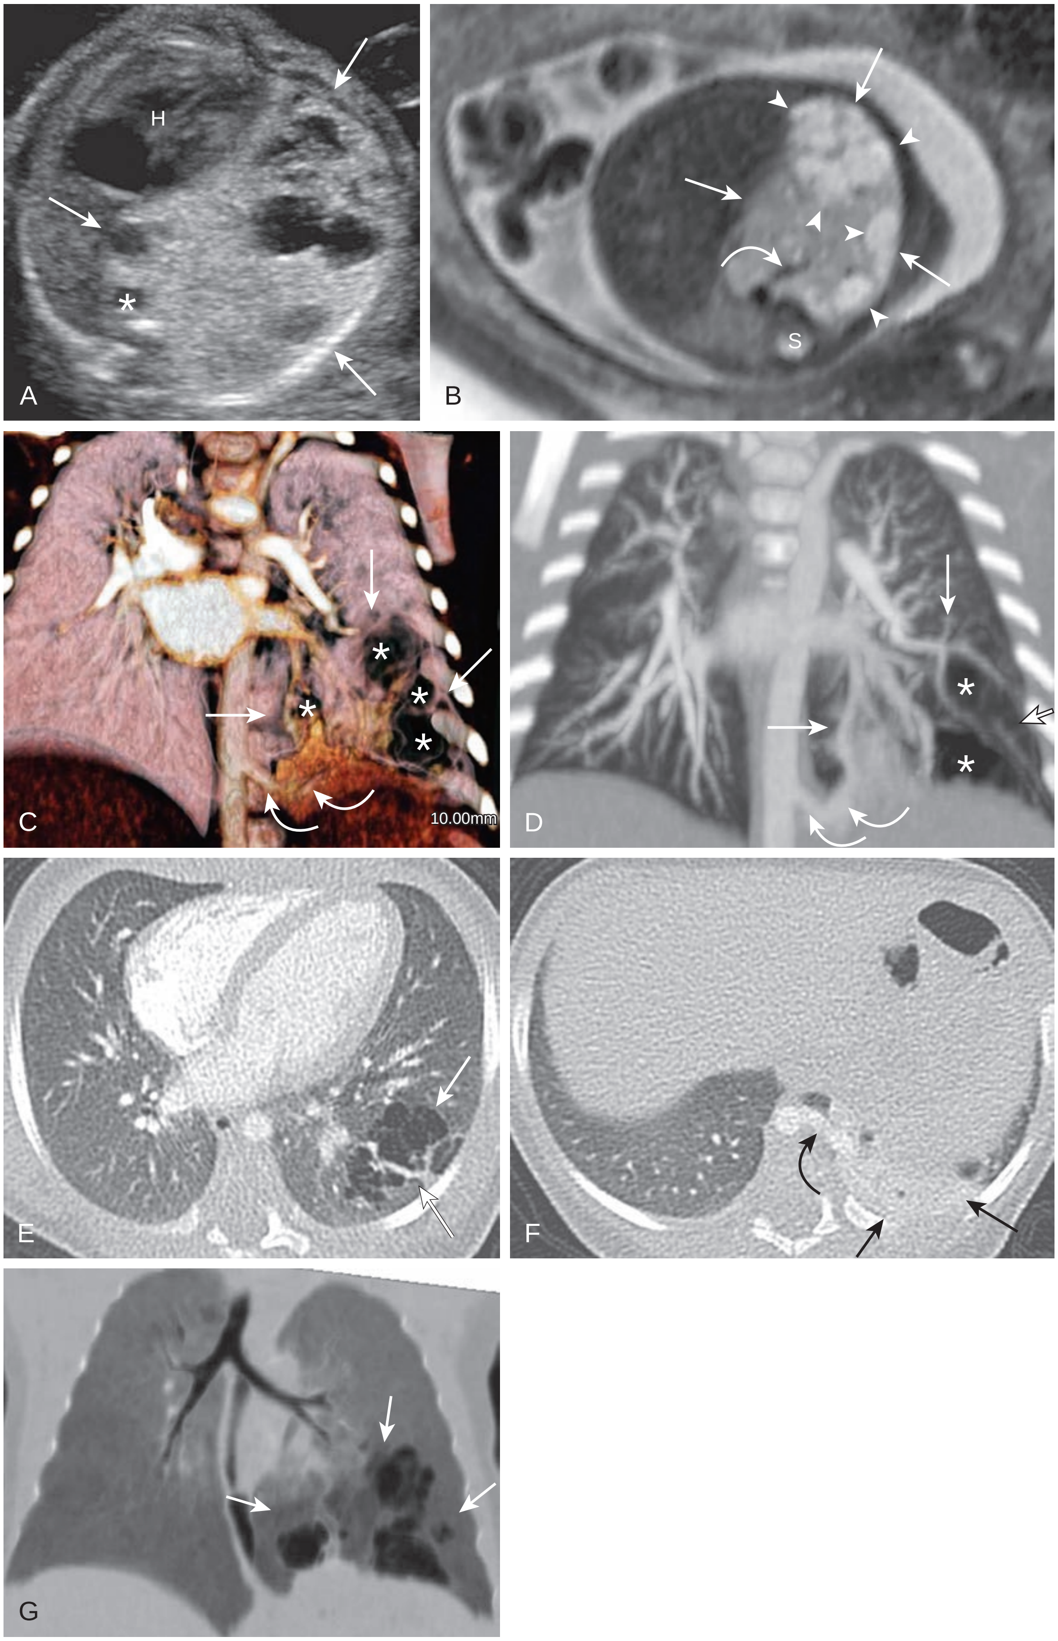


**Figure 53.14. Hybrid lesion, intralobar sequestration, and microcystic maldevelopment (CPAM type 2).** (A) Transverse fetal sonogram shows a large left lower chest lesion *(arrows)* resulting in significant heart *(H)* and aortic *(asterisk)* displacement. Internal cystic components are noted mainly at the periphery of the lesion. (B) Axial T2-weighted fetal MR image shows the extensive hyperintense lesion within the left lower lobe. Cystic peripheral components consistent with CPAM are noted *(arrowheads)*. An aortic feeder *(curved arrow)* is seen supplying the lesion. *S,* Spine. (C–F) Postnatal CT imaging shows a complex, partially aerated left lower lesion supplied by an aberrant aortic vessel *(curved arrows)* with aerated, mainly peripheral cysts *(asterisks)* and overall findings consistent with a hybrid lesion *(arrows)*. The lesion appears relatively smaller when compared with the prenatal images. Coronal volume-rendered (C), maximum intensity projection (D), and axial CTA (E and F) images show a systemic, aortic feeder *(curved arrows)* to the lesion *(arrows)*. Internal cystic components are noted predominantly at the periphery *(asterisks)* of the lesion. A portion of unaerated lung is seen at the base of the lesion. (G) A coronal reformatted minimum intensity projection image shows the internal cystic CPAM components *(arrows)* to better advantage.

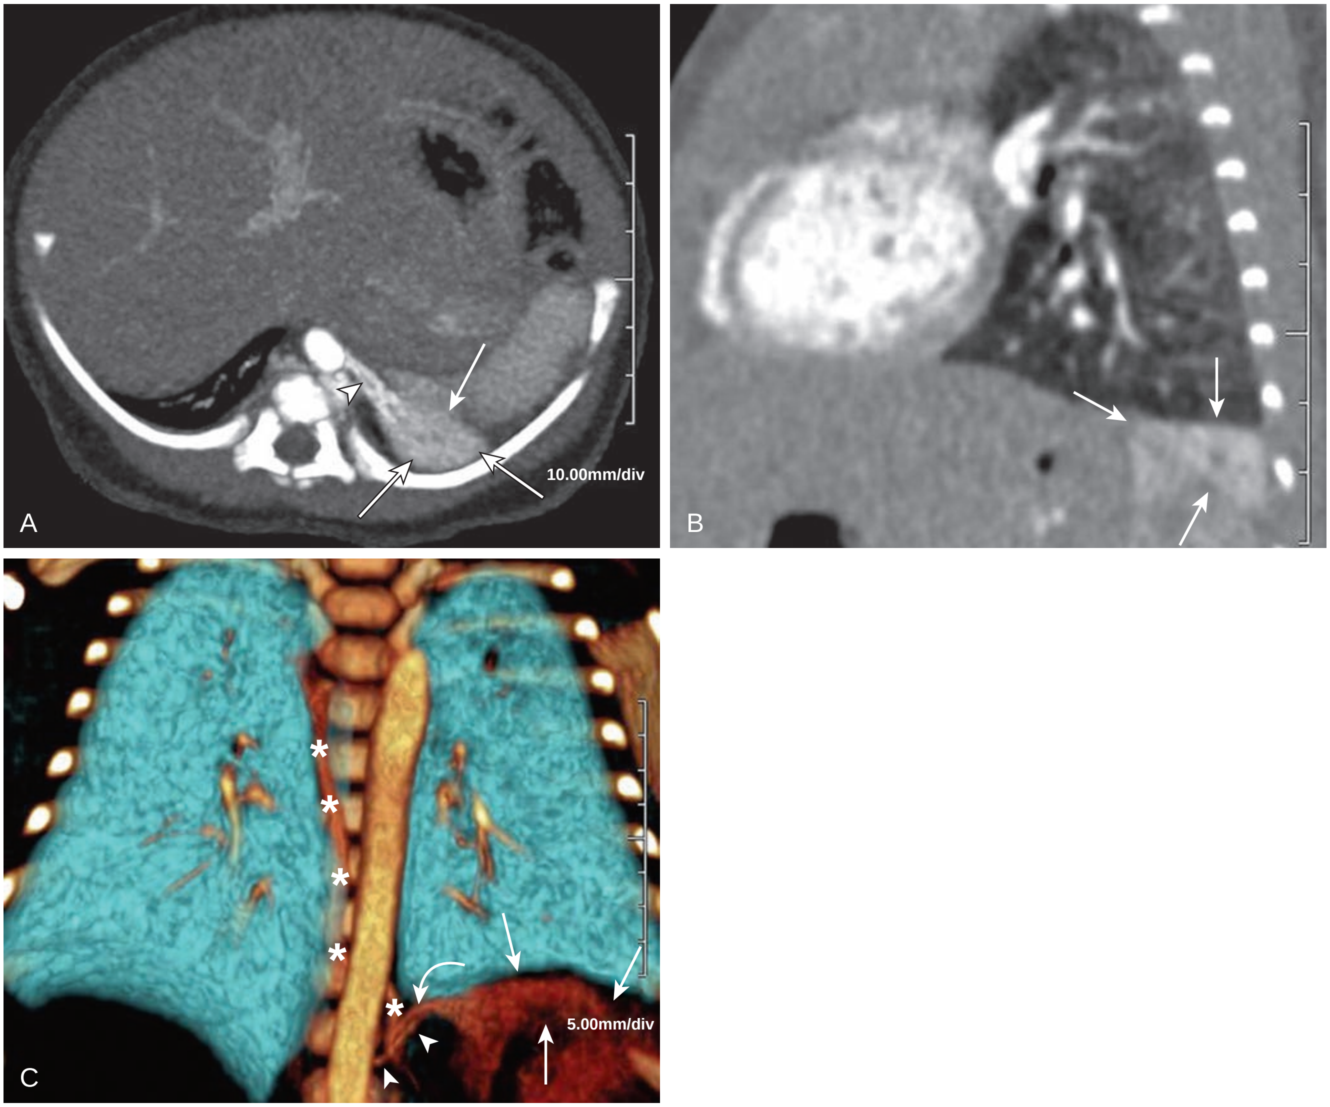

**Figure 53.15. Extralobar bronchopulmonary sequestration in a 1-month-old infant.** Axial maximum intensity projection (A) and a sagittal multiplanar reconstruction (B) CT images show unaerated, enhancing lung tissue in the left costophrenic sulcus with a small aortic feeder *(arrowhead)*, consistent with extralobar sequestration (ELS) *(arrows)*. If the aberrant arterial supply was not identified, the appearance of the lung could easily be ascribed to atelectasis. A coronal volume-rendered three-dimensional image (C) demonstrates the relationship of the small sequestration *(arrows)* to the left lung and depicts the course of the aortic feeder *(arrowheads)* and the draining vein *(curved arrow)* into the azygos system *(asterisks)*.

reported as a successful alternative management for sequestration, particularly for infants presenting with congestive heart failure,[23] as evidenced by shrinkage of the lesion on follow-up imaging.[50,51]

## Hypogenetic Lung Syndrome (Scimitar Syndrome)

***Etiology.*** Hypogenetic lung syndrome, also known as scimitar syndrome, refers to an anomalous connection of the right pulmonary veins to the inferior vena cava, in which an anomalous pulmonary vein drains part of or the entire right lung. The anomalous vein may on occasion drain into the hepatic veins, portal veins, azygos vein, coronary sinus, or right atrium. The anomalous vein often resembles a scimitar, a curved Turkish sword, hence the name “scimitar syndrome.” Hypogenetic lung syndrome frequently is associated with various degrees of right lung hypoplasia and abnormal lobation, and a hypoplastic pulmonary artery along with heart dextroposition.[49] Additional reported anomalies associated with hypogenetic lung syndrome include bronchogenic cyst, horseshoe lung, accessory diaphragm, hernia, and arterial supply of parts of the right lung by collateral arterial blood vessels, usually from the descending aorta.[1,49,52] Affected infants may present with clinical signs and symptoms related to congestive heart failure from right-heart volume overload. Hypogenetic lung syndrome also may be seen as an incidental finding in older children or alternatively may manifest as recurrent right basilar pneumonia (see also Chapter 71).[1,9,15]

***Imaging.*** The classic vertically oriented curvilinear opacity, representing the scimitar vein, which projects over the right lower hemithorax in conjunction with a hypoplastic right lung, is usually seen on frontal chest radiographs. On lateral chest radiographs, a dense retrosternal band of variable width typically is observed, which is a result of the decrease in anteroposterior diameter of the hypoplastic lung, resulting in a lung–soft tissue interface.[5,53] CT or MRI are the preferred imaging modalities for confirming

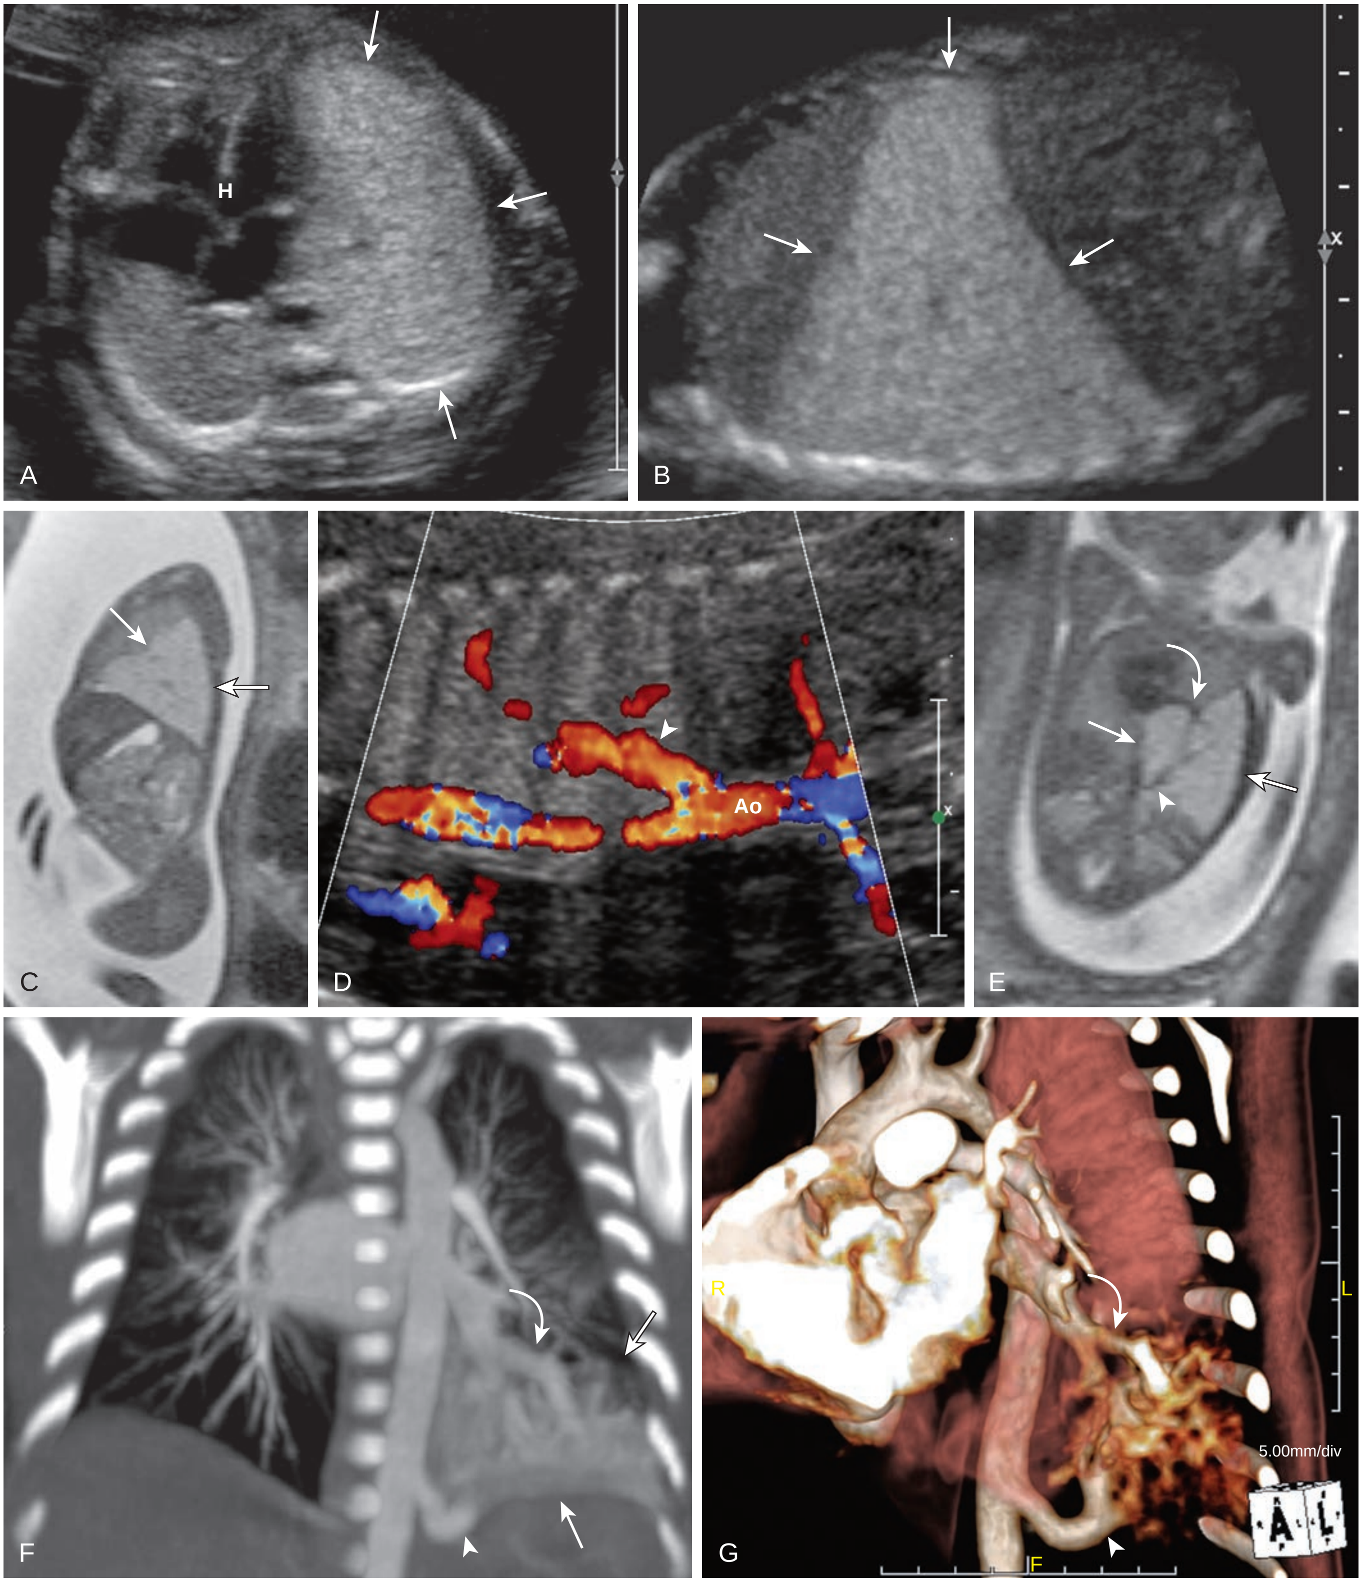

**Figure 53.16. Intralobar sequestration.** (A) Transverse sonogram through the chest shows a large, homogeneously hyperechoic lesion *(arrows)* in the left lower chest resulting in mild mediastinal shift and cardiac heart *(H)* displacement. Sagittal ultrasound (B) and sagittal T2-weighted fetal MR (C) images show a homogeneous large left lower lesion without visible cysts *(arrows)*. (D) Coronal fetal sonogram shows an aortic feeder *(arrowhead)*. *Ao,* Aorta. (E) Coronal oblique T2-weighted fetal MR image also shows a prominent aortic feeder *(arrowhead)* and a slightly prominent pulmonary vein *(curved arrow)* draining the large hyperintense lesion *(arrows)* within the left lower lobe. Coronal maximum intensity projection (F) and volume-rendered (G) CTA images at 7 days of age show a prominent aortic feeder *(arrowhead)*. The lesion *(straight arrows)* is only partially aerated and drains into a prominent pulmonary vein *(curved arrows)* consistent with an intralobar bronchopulmonary sequestration. Note the relative decrease in the size of the lesion compared with prenatal imaging.

and characterizing hypogenetic lung syndrome in pediatric patients (e-Figs. 53.17 and 53.18). Multidetector CT with 2D and 3D reformatted images have are particularly useful for preprocedural evaluation by displaying the entire course of the anomalous vein.[9,49] They are also helpful for evaluating postoperative complications, including thrombosis or stenosis of a reimplanted anomalous vein. Furthermore, abnormal lung parenchymal changes, abnormal lung lobation, and anomalous bronchial branching patterns often are seen in patients with hypogenetic lung syndrome and also can be well evaluated.[9,49] The absence of an ipsilateral inferior pulmonary vein is a helpful finding that supports the diagnosis.

***Treatment and Follow-up.*** For symptomatic pediatric patients with scimitar syndrome, surgical techniques aim to reconnect the anomalous vein to the left atrium with or without the creation of an intracardiac baffle. Complications related to either restenosis or baffle obstruction are not uncommon.[54] In addition, occlusion of the collateral arteries may be necessary in affected patients; this may be performed angiographically to reduce the amount of shunting and to improve the clinical symptoms of congestive heart failure, if present.[55,56] The presence of associated pulmonary hypertension plays an important role in the incidence of postoperative complications.[56]

## PREDOMINANTLY VASCULAR LESIONS

This section emphasizes vascular anomalies that are associated with or produce secondary lung parenchymal or airway abnormalities. Purely vascular lesions such as isolated partial anomalous venous return (see Chapter 71) and pulmonary varix (see Chapter 82) are covered elsewhere in the book.

### Anomalies of the Pulmonary Artery

#### Pulmonary Agenesis, Aplasia, and Hypoplasia

***Etiology.*** Pulmonary underdevelopment may be classified into three main types: (1) lung agenesis, consisting of the absence of the lung, bronchus, and pulmonary artery; (2) lung aplasia, that is, the presence of a rudimentary bronchus but the lack of lung tissue and pulmonary artery; and (3) lung hypoplasia, which consists of a hypoplastic bronchial tree and pulmonary artery with a variable amount of lung parenchyma.[15,57,58]

The etiology of lung agenesis or aplasia remains uncertain. Genetic, teratogenic, and mechanical factors may play a role.[1] Pulmonary agenesis associated with ipsilateral radial ray defects or hemifacial microsomia may be the result of an abnormal development of the first and second arch derivatives or abnormal blood flow at this level inciting the developmental event, given the common association.[59] On the other end of the spectrum, no identifiable cause has been found for primary lung hypoplasia.[1]

Persons with pulmonary agenesis, aplasia, and hypoplasia either are asymptomatic or present with variable degrees of respiratory distress, depending on the extent of lung underdevelopment and associated anomalies. Other congenital malformations occur in 50% to 80% of cases including cardiovascular, GI, musculoskeletal, and genitourinary anomalies.[1,59–61]

***Imaging.*** On chest radiographs, there may be a small, radiopaque or radiolucent hemithorax, depending on the degree of abnormality. Ipsilateral displacement of mediastinal structures and elevation of the hemidiaphragm usually are present. The normal contralateral lung shows compensatory hyperinflation and herniation across the anterior midline, which is best seen on the lateral projections as a band of increased retrosternal lucency (Fig. 53.19).[1] Left lung agenesis is more common than right lung agenesis. CT with multiplanar 2D and 3D imaging capabilities can be used to distinguish among pulmonary agenesis, pulmonary aplasia, and pulmonary hypoplasia by clearly identifying the bronchial stump and/or the rudimentary bronchial tree (e-Figs. 53.20 and 53.21, Fig. 53.22, and e-Fig. 53.23).[1,49] Additional vascular, airway, or lung abnormalities can also be defined.

***Treatment and Follow-up.*** The prognosis of pediatric patients with pulmonary underdevelopment primarily depends on the extent of underdevelopment and the severity of other associated congenital malformations. Treatment usually is aimed at improving the respiratory status and symptoms related to concomitant congenital malformations.

#### Proximal Interruption of the Pulmonary Artery

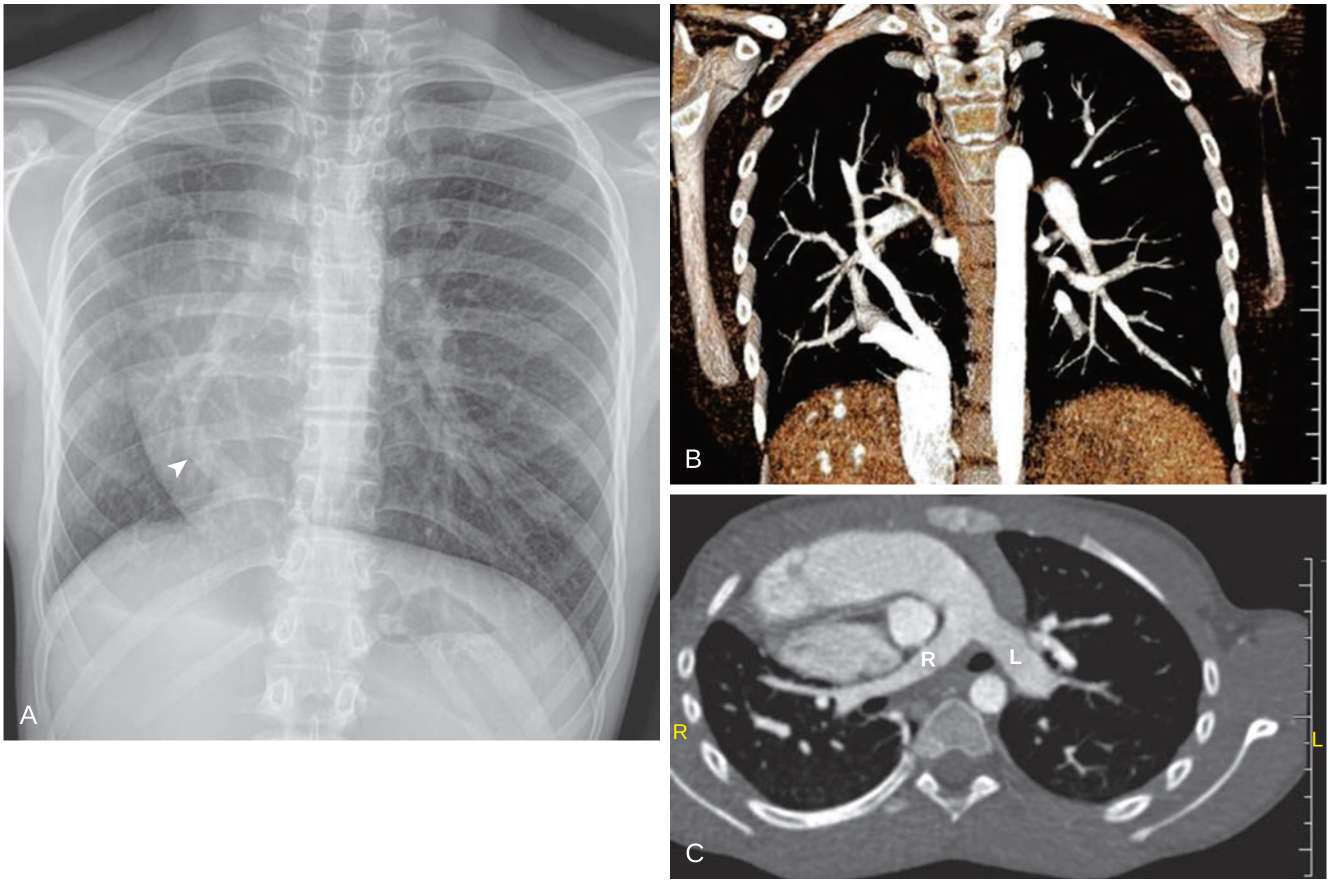
***Etiology.*** Proximal interruption of the pulmonary artery results from the abnormal involution of the proximal sixth aortic arch. Such involution causes the “absence” of the proximal pulmonary artery and a persistent connection of the hilar pulmonary artery to the distal sixth aortic arch, which ultimately becomes the ductus arteriosus. The hilar pulmonary artery supplying the ipsilateral affected lung continues to develop via the blood supply received from the ductus arteriosus (which originates either from the base of the right innominate artery or occasionally from an aberrant right subclavian artery).[1,6] Progressive closure of the ductus arteriosus eventually results in loss of blood supply to the hilar pulmonary artery and the lung. Perfusion of the affected lung subsequently becomes dependent on collateral systemic vessels, mainly aortopulmonary and bronchial arteries but also transpleural branches of the intercostal, internal mammary, subclavian, and innominate arteries.[62–64] Although asymptomatic pediatric patients with this anomaly may be detected incidentally, some children present with symptoms related to recurrent pulmonary infections, hemoptysis, and pulmonary hypertension.[6,9,15]

***Imaging.*** The interrupted proximal pulmonary artery is characteristically located on the contralateral side to the aortic arch and is more commonly seen on the right side. Interruption of the proximal left pulmonary artery is less common and frequently is associated with congenital heart disease, typically tetralogy of Fallot and ventricular septal defect.[1,6,49] On chest radiographs, the affected lung and hilum are smaller than those of the contralateral side (Fig. 53.24). Ipsilateral mediastinal shift, narrowed intercostal spaces, or rarely rib notching in the case of prominent intercostal collaterals also may be present.[9,15,64] On CT or MRI, the interrupted pulmonary artery terminates within 1 cm of its origin from the main pulmonary artery. However, the hilar portion of the pulmonary artery and the intrapulmonary vascular network remain patent (e-Fig. 53.25). A small ductal diverticulum is usually present at the base of the innominate artery, the remnant of the prior ductal supply to the pulmonary artery. Serrated pleural thickening and subpleural parenchymal bands also may be observed, which reflect the direct anastomosis of transpleural systemic collaterals with peripheral pulmonary arterial branches. Airway branching and pulmonary lobation anomalies are not uncommon. Additional imaging findings may include tiny peripheral cystic and possibly dysplastic lung changes, areas of mosaic attenuation, bronchiectasis, and an asymmetric thoracic cage.[1,6,15,49,63]

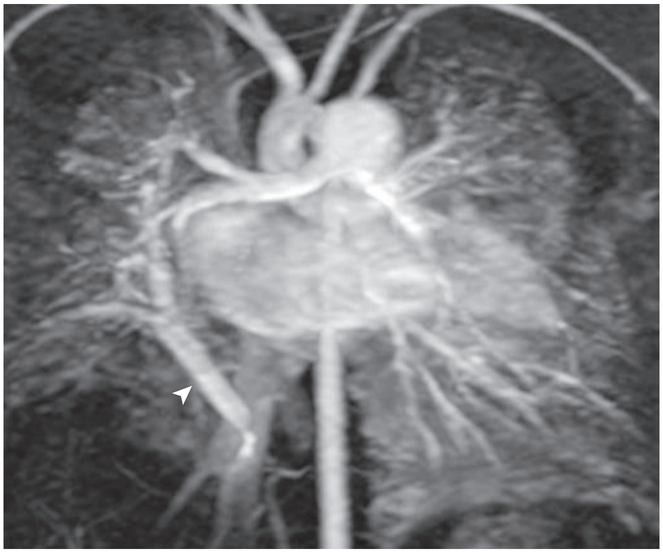
***Treatment and Follow-up.*** Prompt diagnosis and early surgical intervention may provide adequate blood supply to the affected lung, allowing improved pulmonary arterial supply and lung growth. Surveillance is indicated for patients with a late presentation who are considered unsuitable for intervention. Patients who present with recurrent hemoptysis or pulmonary hypertension may benefit from coil embolization of large systemic collaterals.[1,6,65]

#### Pulmonary Artery Sling

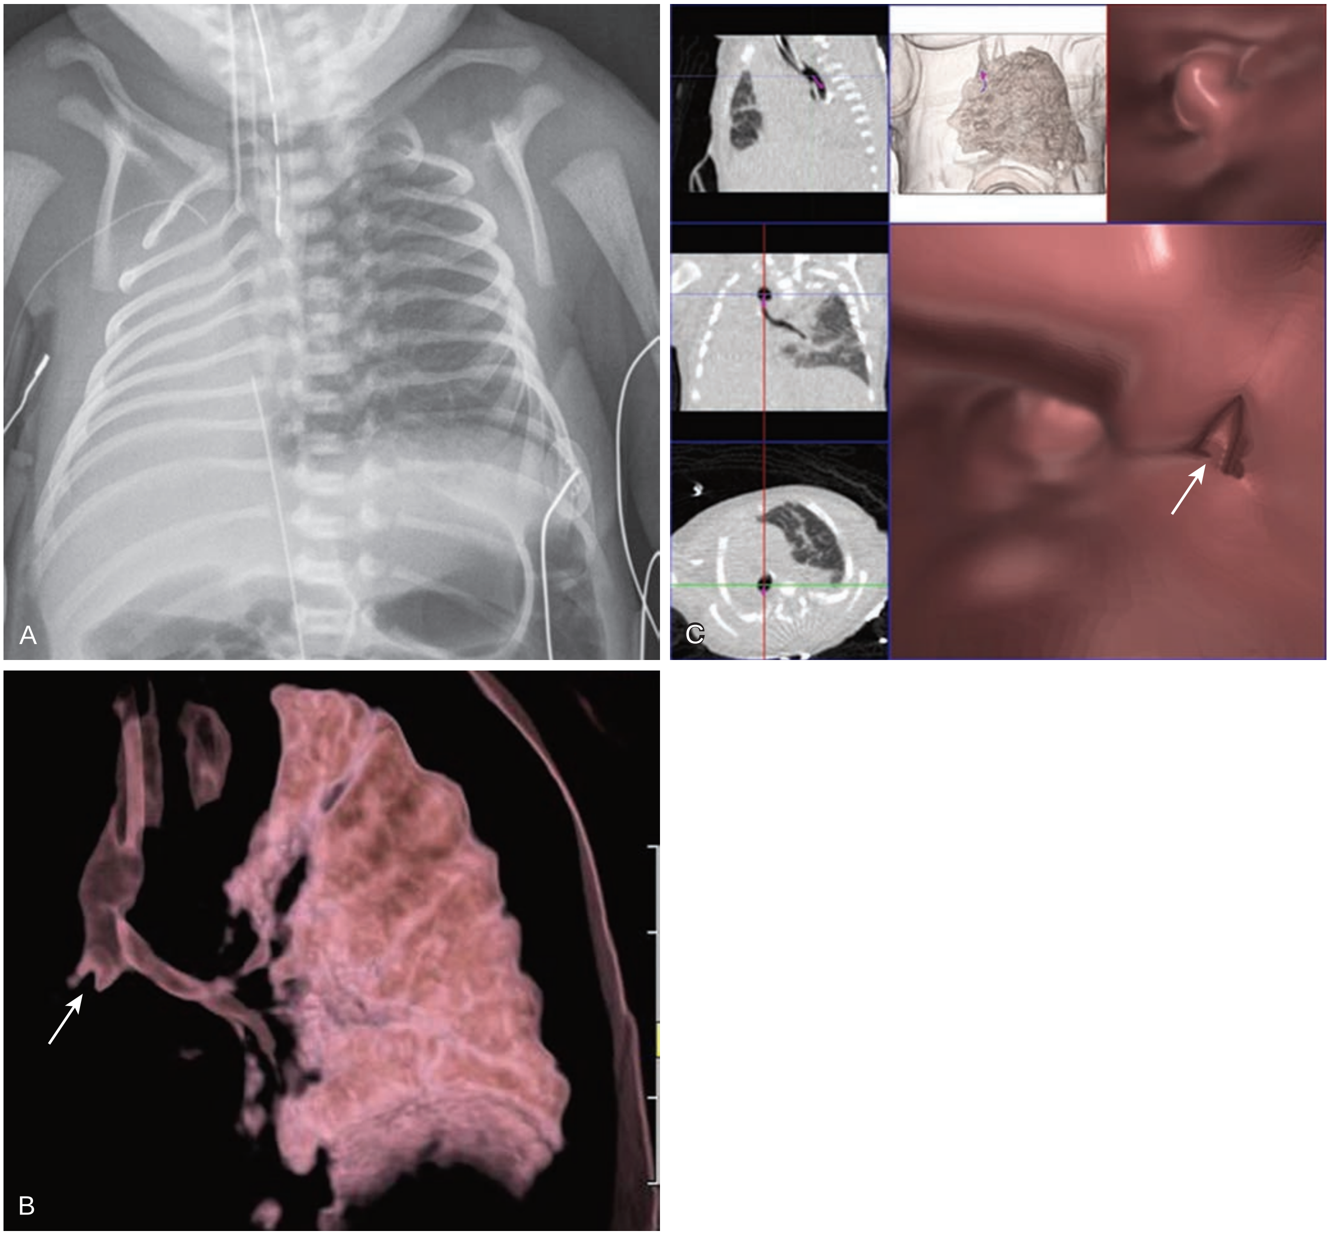
***Etiology.*** Pulmonary artery sling (PAS) is a rare congenital anomaly in which the left pulmonary artery arises anomalously from the posterior aspect of the right pulmonary artery and courses between the trachea and esophagus to reach the left hilum.[15] The anomalous left pulmonary artery forms a sling around the distal



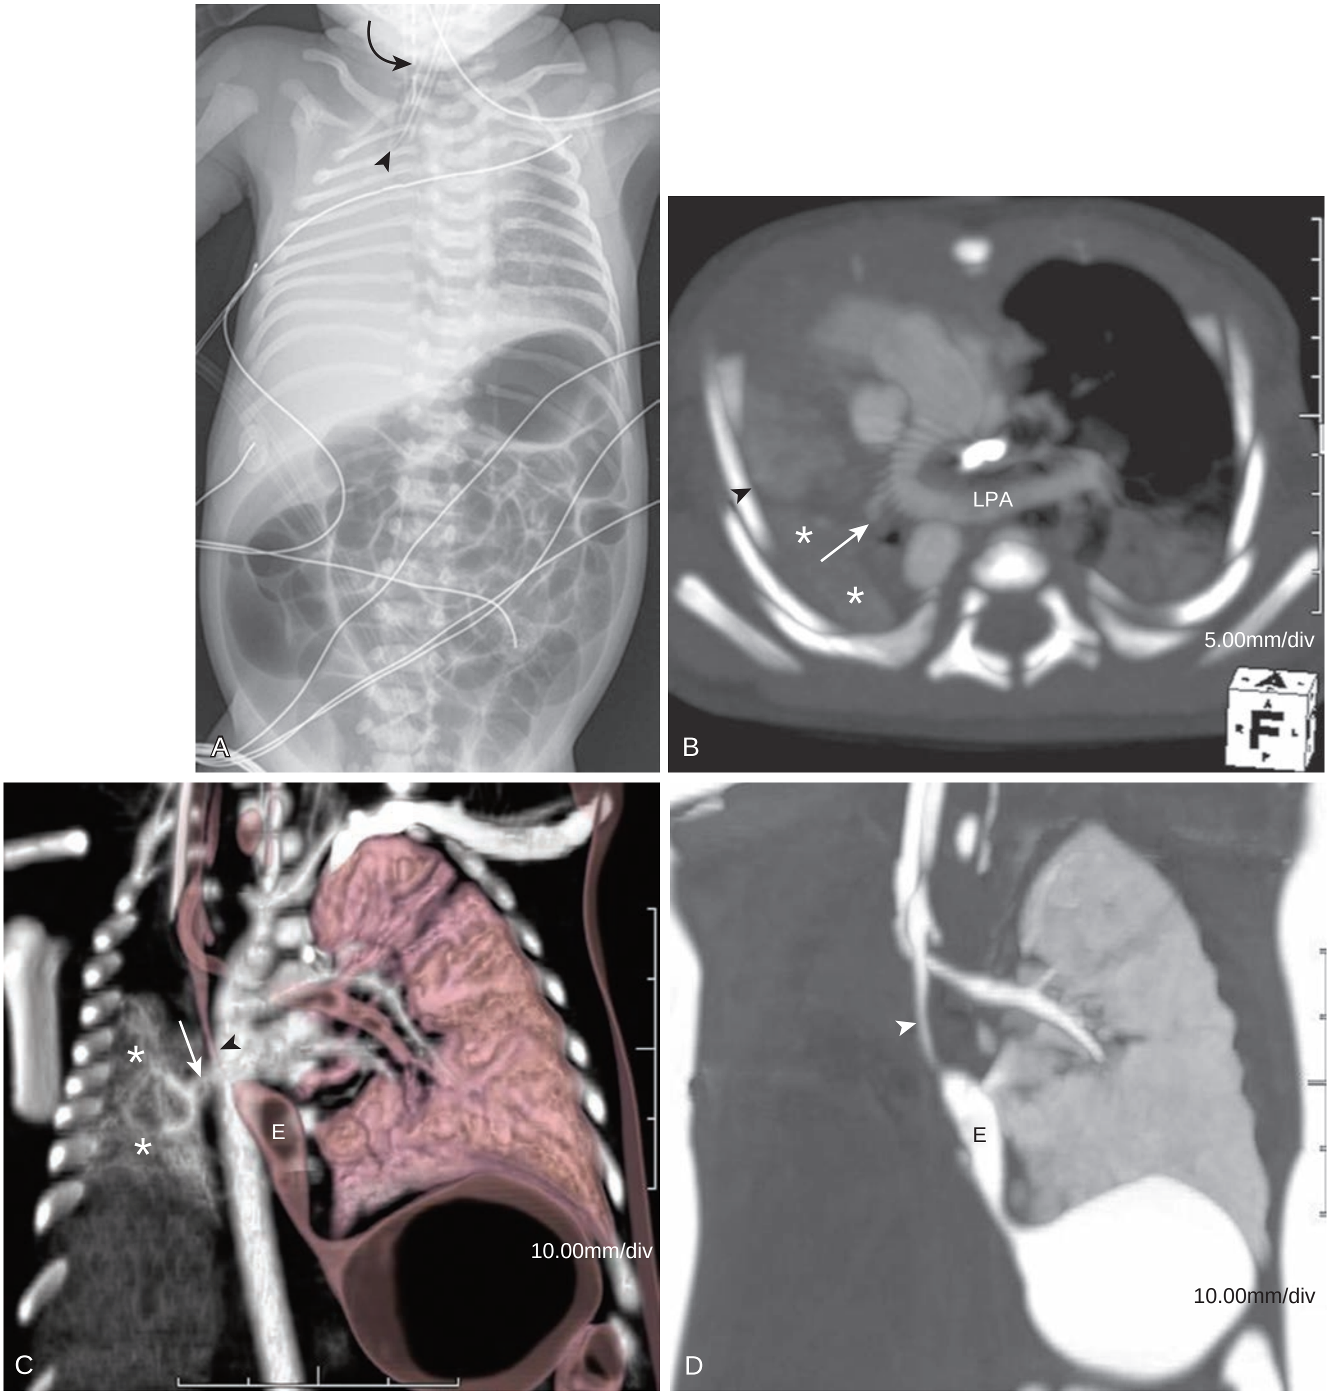
**e-Figure 53.17. Hypogenetic lung syndrome in a 13-year-old with exercise intolerance.** (A) Frontal chest radiograph shows a scimitar vein *(arrowhead)* extending to the medial right hemidiaphragm and heart dextroposition consistent with hypogenetic lung syndrome. (B) Coronal volume-rendered CTA image shows partial anomalous pulmonary venous drainage of the right lung to the inferior vena cava via two scimitar veins. A small portion of the right lung drains as expected into the left atrium. (C) An axial maximum intensity projection CT image shows dextroposition of the heart and hypoplasia of the right pulmonary artery *(R)* relative to the left pulmonary artery *(L)*.



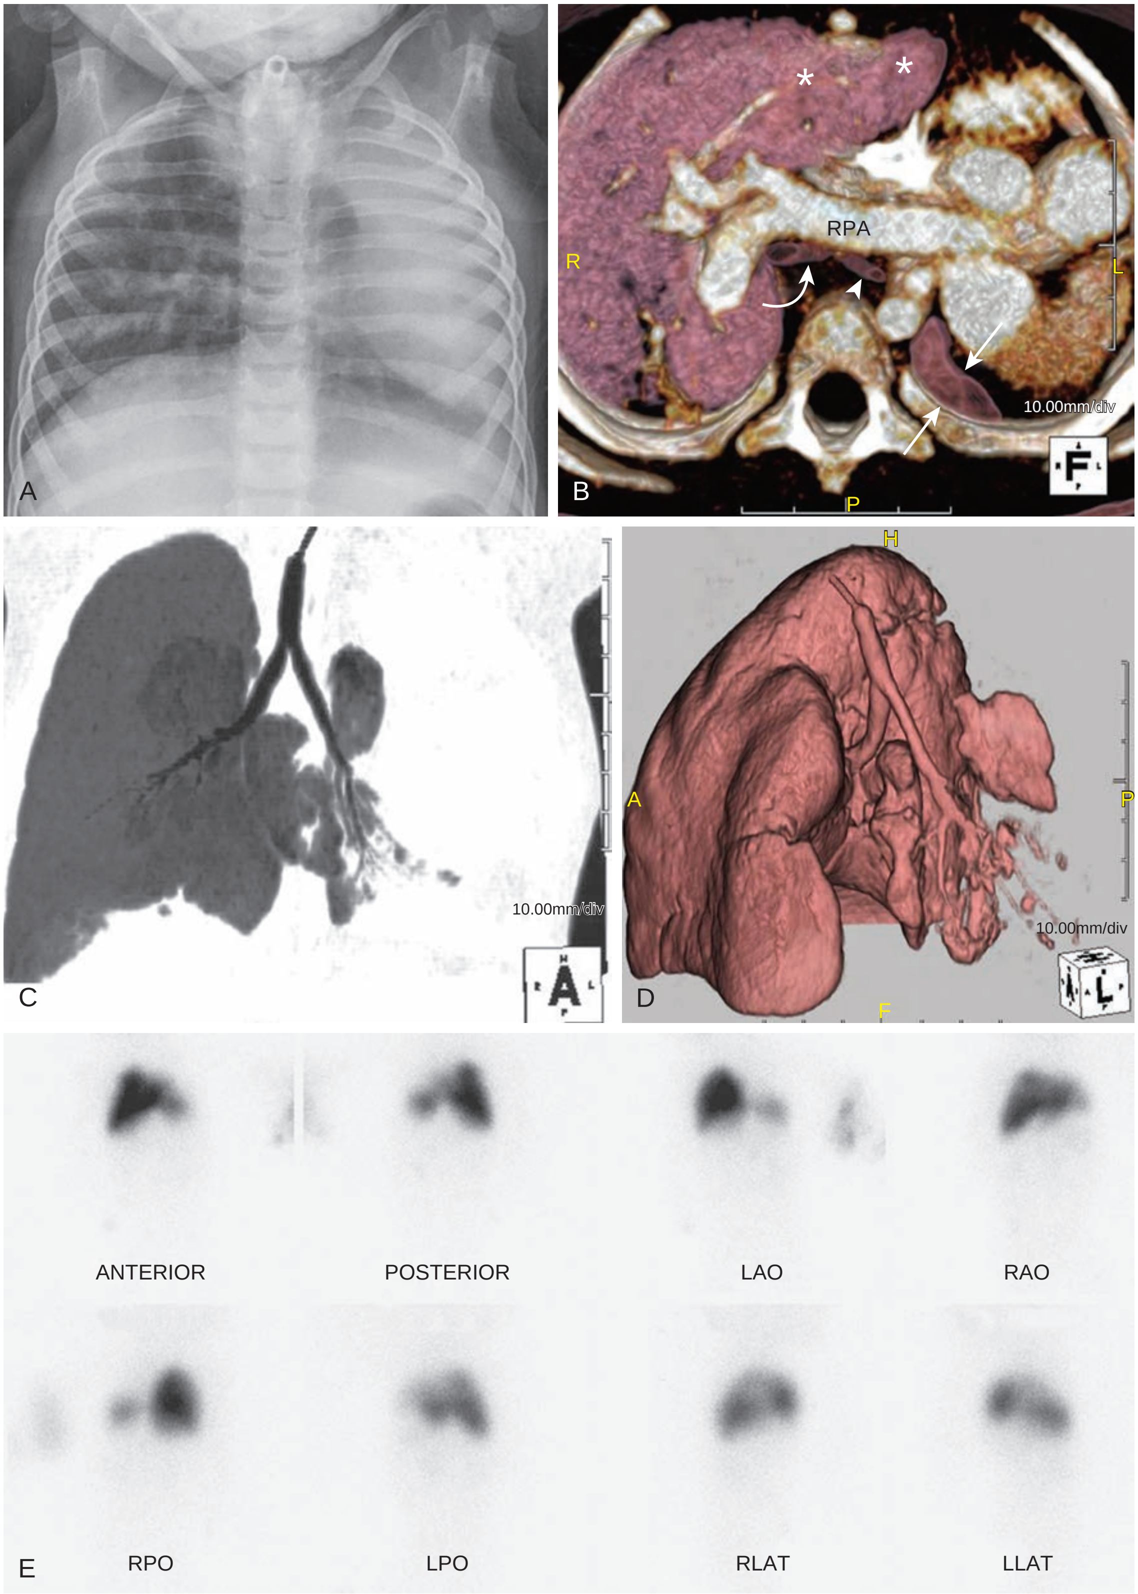
**e-Figure 53.18. Hypogenetic lung syndrome in a 3-month-old with a history of an abnormal chest radiograph.** Coronal maximum intensity projection MR image reveals anomalous pulmonary venous drainage of the right hypoplastic lung via a scimitar vein *(arrowhead)* into the inferior vena cava.



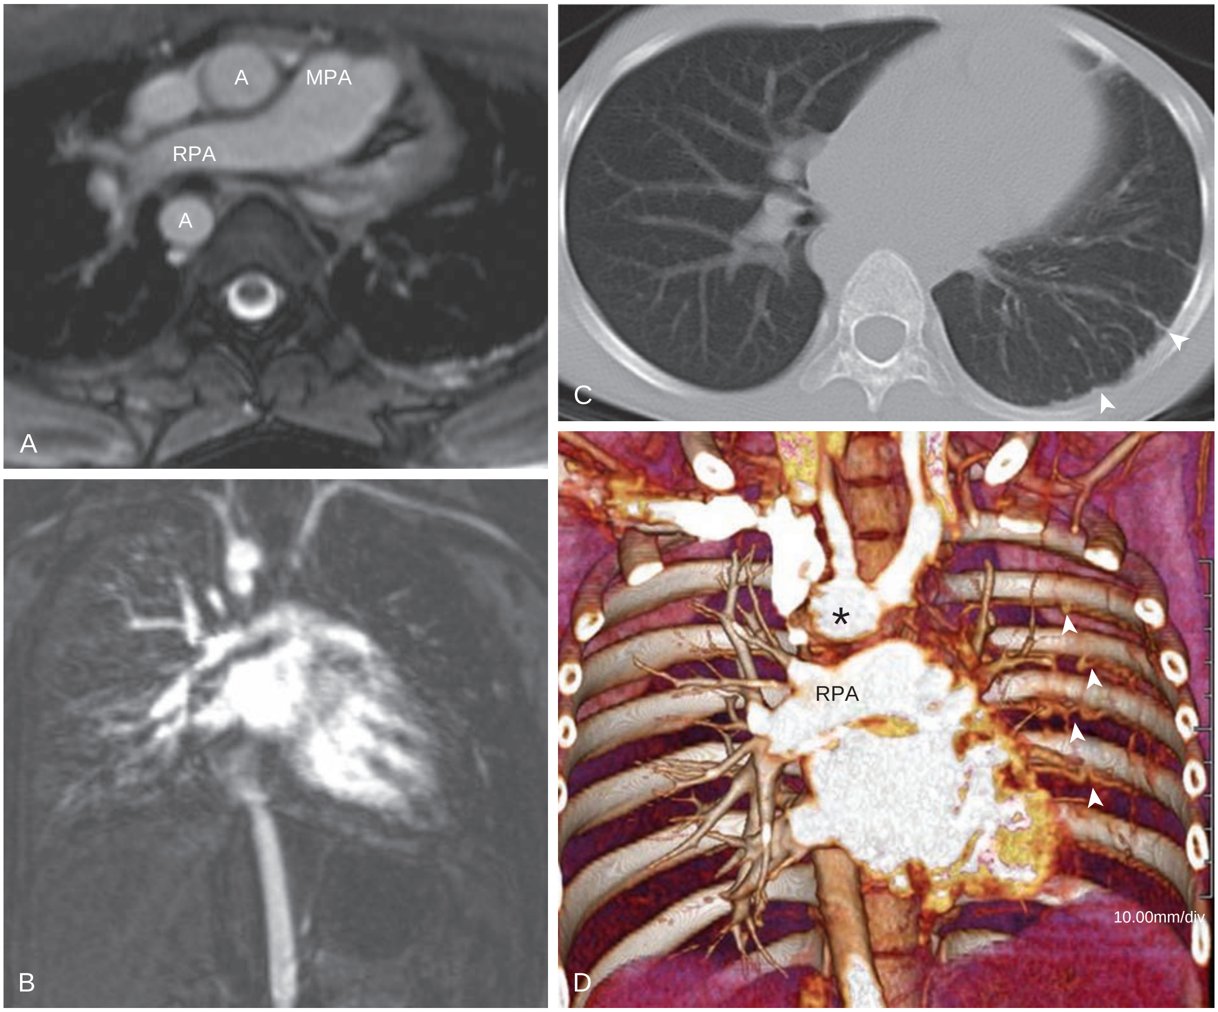
**e-Figure 53.20. Lung aplasia, absent right pulmonary artery, esophageal atresia, and distal tracheoesophageal fistula in a 1-day-old.** (A) Frontal chest radiograph shows complete opacification with volume loss in the right hemithorax. The airway and mediastinum are shifted to the right with associated dextroposition of the heart. A nasogastric tube terminates in the upper esophageal pouch consistent with esophageal atresia. The anterior view of a volume-rendered CT image of the central airway and lungs (B) and virtual bronchoscopic (C) images demonstrate a rudimentary right main stem bronchus *(straight arrows)* consistent with lung aplasia. No right pulmonary artery is identified *(not shown)*.



**e-Figure 53.21. Hypoplastic right lung in an ex-34-weeks premature with associated esophageal atresia, distal tracheoesophageal fistula, imperforate anus, and pulmonary sling.** (A) Frontal radiograph of the chest and abdomen shows complete opacification with volume loss in the right hemithorax. The endotracheal tube *(arrowhead)* and mediastinum are shifted to the right with associated dextroposition of the heart. A nasogastric tube *(curved arrow)* terminates in the upper esophageal pouch consistent with esophageal atresia. Pronounced gaseous distension of numerous small and large bowel loops is seen that is consistent with imperforate anus and distal TE fistula. (B) An axial maximum intensity projection CT image shows an anomalous left pulmonary artery *(LPA)* arising from a tiny, hypoplastic right pulmonary artery *(arrow)* and coursing behind the mainstem bronchi in a slinglike configuration. The right lung is severely hypoplastic and collapsed *(asterisks)*. (C) A frontal volume-rendered CT image shows an aerated left lung and a collapsed, unaerated right lung *(asterisks)*. Note the hypoplastic right pulmonary veins *(arrow)*. The *arrowhead* denotes the distal TE fistulous communication. (D) An inverted coronal minimum intensity projection CT image better demonstrates the distal TE fistulous communication *(arrowhead)*. The right bronchi were fluid opacified and could not be depicted with these techniques. *E,* Esophagus.



**e-Figure 53.23. Left lung hypoplasia in a 2-year-old with multiple congenital anomalies.** (A) Frontal chest radiograph shows a small, hypoplastic left lung and leftward shift of the mediastinum. (B) Axial volume-rendered CT image confirms leftward shift of the mediastinum and heart and shows a small, hypoplastic left lung *(arrows)*, hypoplastic left bronchus *(arrowhead)* relative to the right *(curved arrow)* and compensatory hyperinflation with herniation of the right upper lobe *(asterisks)* into the left hemithorax. A secondary leftward mediastinal shift with levoposition of the heart is seen. Note the prominent right pulmonary artery *(RPA)* to the right lung. The left pulmonary artery was severely hypoplastic *(image not shown).* Coronal minimum intensity projection (C) and coronal oblique three-dimensional volume-rendered (D) CT images of the central airways and lungs show a hypoplastic left mainstem bronchus and left lung. Technetium-99m lung scan images (E) reveal significantly decreased perfusion of the left lung in comparison to the right lung. *LAO,* Left anterior oblique; *LLAT,* left lateral; *LPO,* left posterior oblique; *RAO,* right anterior oblique; *RLAT,* right lateral; *RPO,* right posterior oblique.



**e-Figure 53.25. Proximal interruption of the left pulmonary artery in a 10-year-old.** (A) Axial T2-weighted MR image shows absence of the left pulmonary artery. Pulmonary blood flow is from the main pulmonary artery *(MPA)* to the right pulmonary artery *(RPA)*. The aortic arch is right-sided. *A,* Aorta. (B) Coronal MRA image in the pulmonary arterial phase shows nearly no enhancement of the left lung. (C) Axial CT image shows a smaller left lung with slight mediastinal shift and serrated pleural thickening *(arrowheads)*, reflective of the direct anastomosis of transpleural systemic collaterals with peripheral branches of the pulmonary arteries. (D) Volume-rendered CTA image shows normal right pulmonary artery *(RPA)* arborization and poor vascularity in the left lung. Prominent left intercostal arteries *(arrowheads)* are providing collateral flow to the left lung. Note the right-sided aortic arch *(asterisk)*.

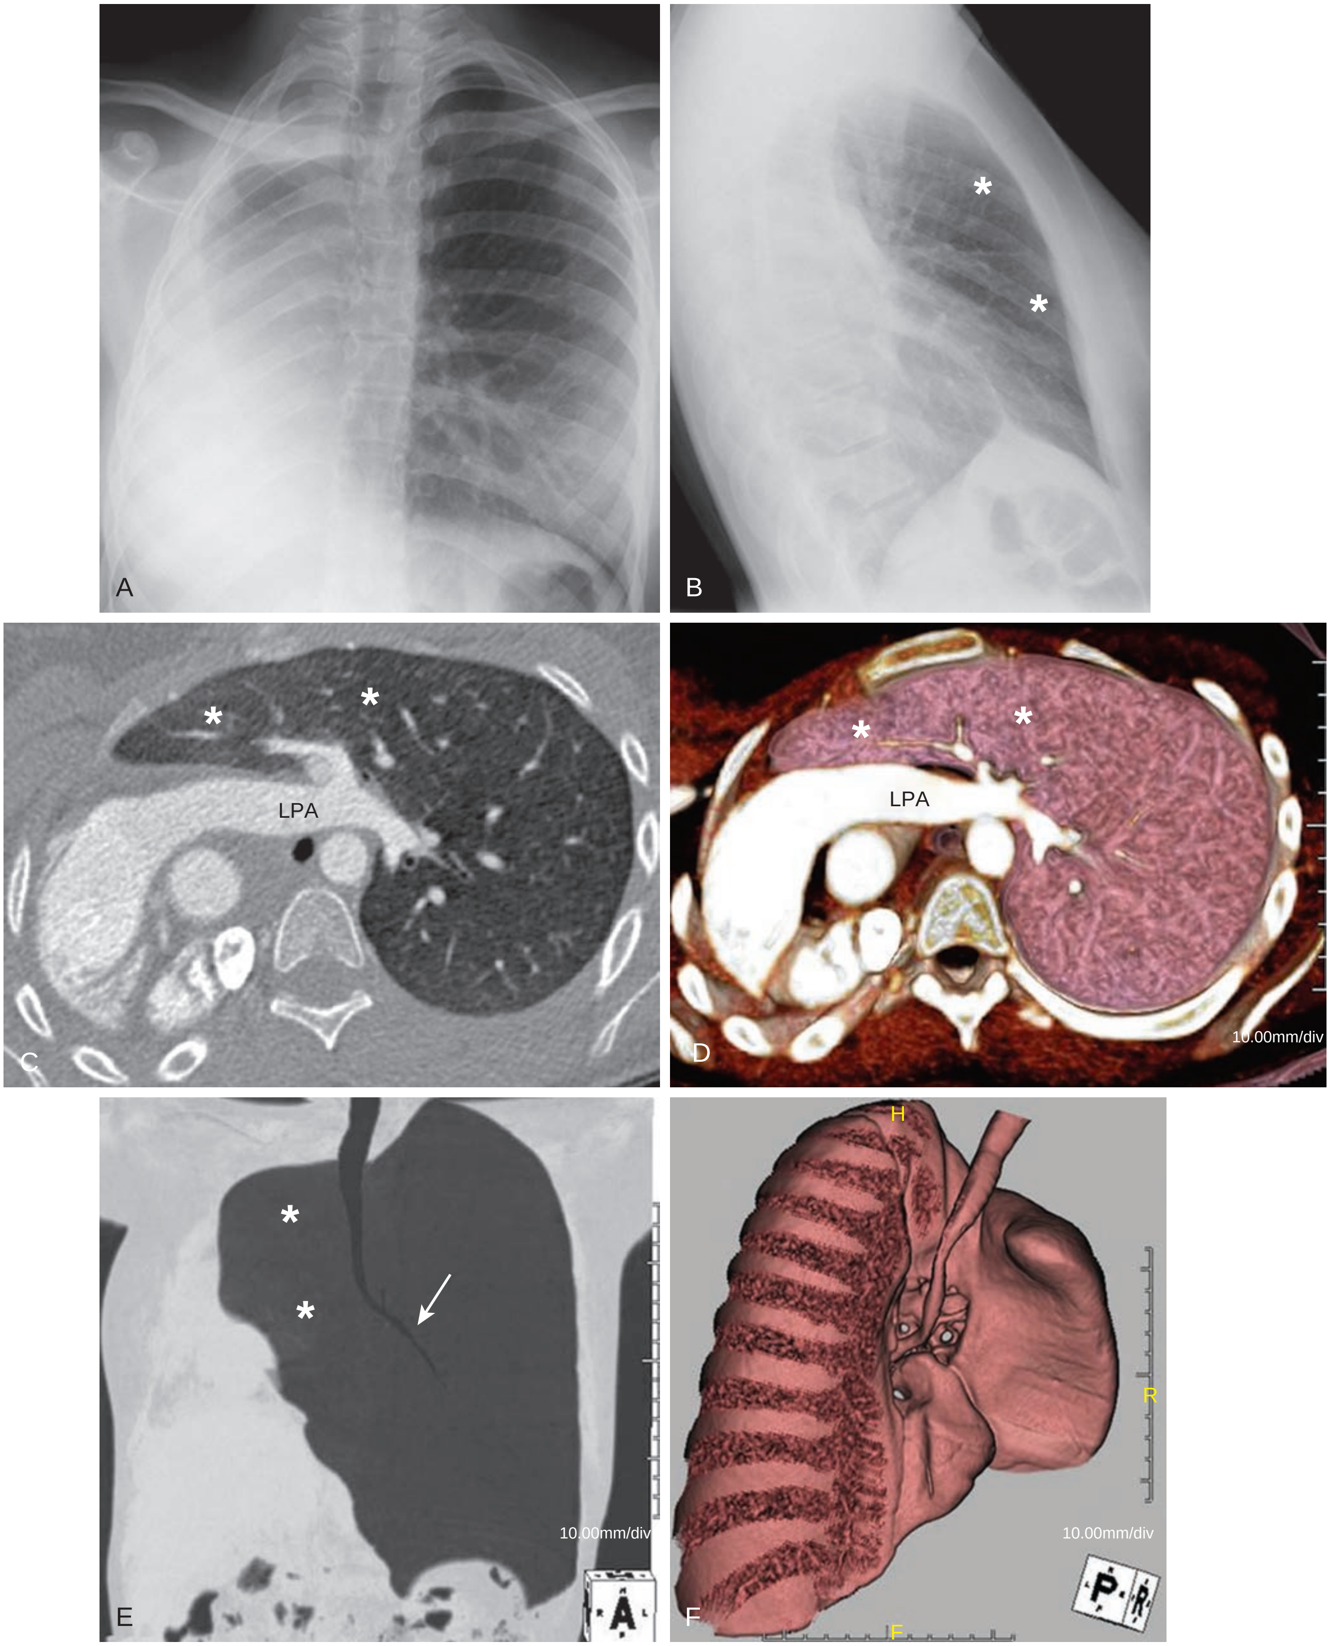


**Figure 53.19. Pulmonary agenesis.** Frontal (A) and lateral (B) radiographs in a 15-year-old with worsening asthma demonstrate marked hyperinflation of the left lung that extends across the midline anteriorly and herniates toward the right, as evidenced by a band of retrosternal lucency on the lateral projection *(asterisks)*. Associated dextroposition of the heart into the right hemithorax is seen. Contrast-enhanced axial CT (C), axial volume-rendered (D), coronal minimum intensity projection (E), and three-dimensional volume-rendered (F) images of the central airway and lungs demonstrate complete agenesis of the right bronchus, absence of the right pulmonary artery and lung. Associated dextroposition of the heart and compensatory hyperexpansion is present, particularly of the left upper lobe *(asterisks)*, which herniates into the right hemithorax. A normal left mainstem bronchus *(arrow)* is seen. *LPA,* Left pulmonary artery.

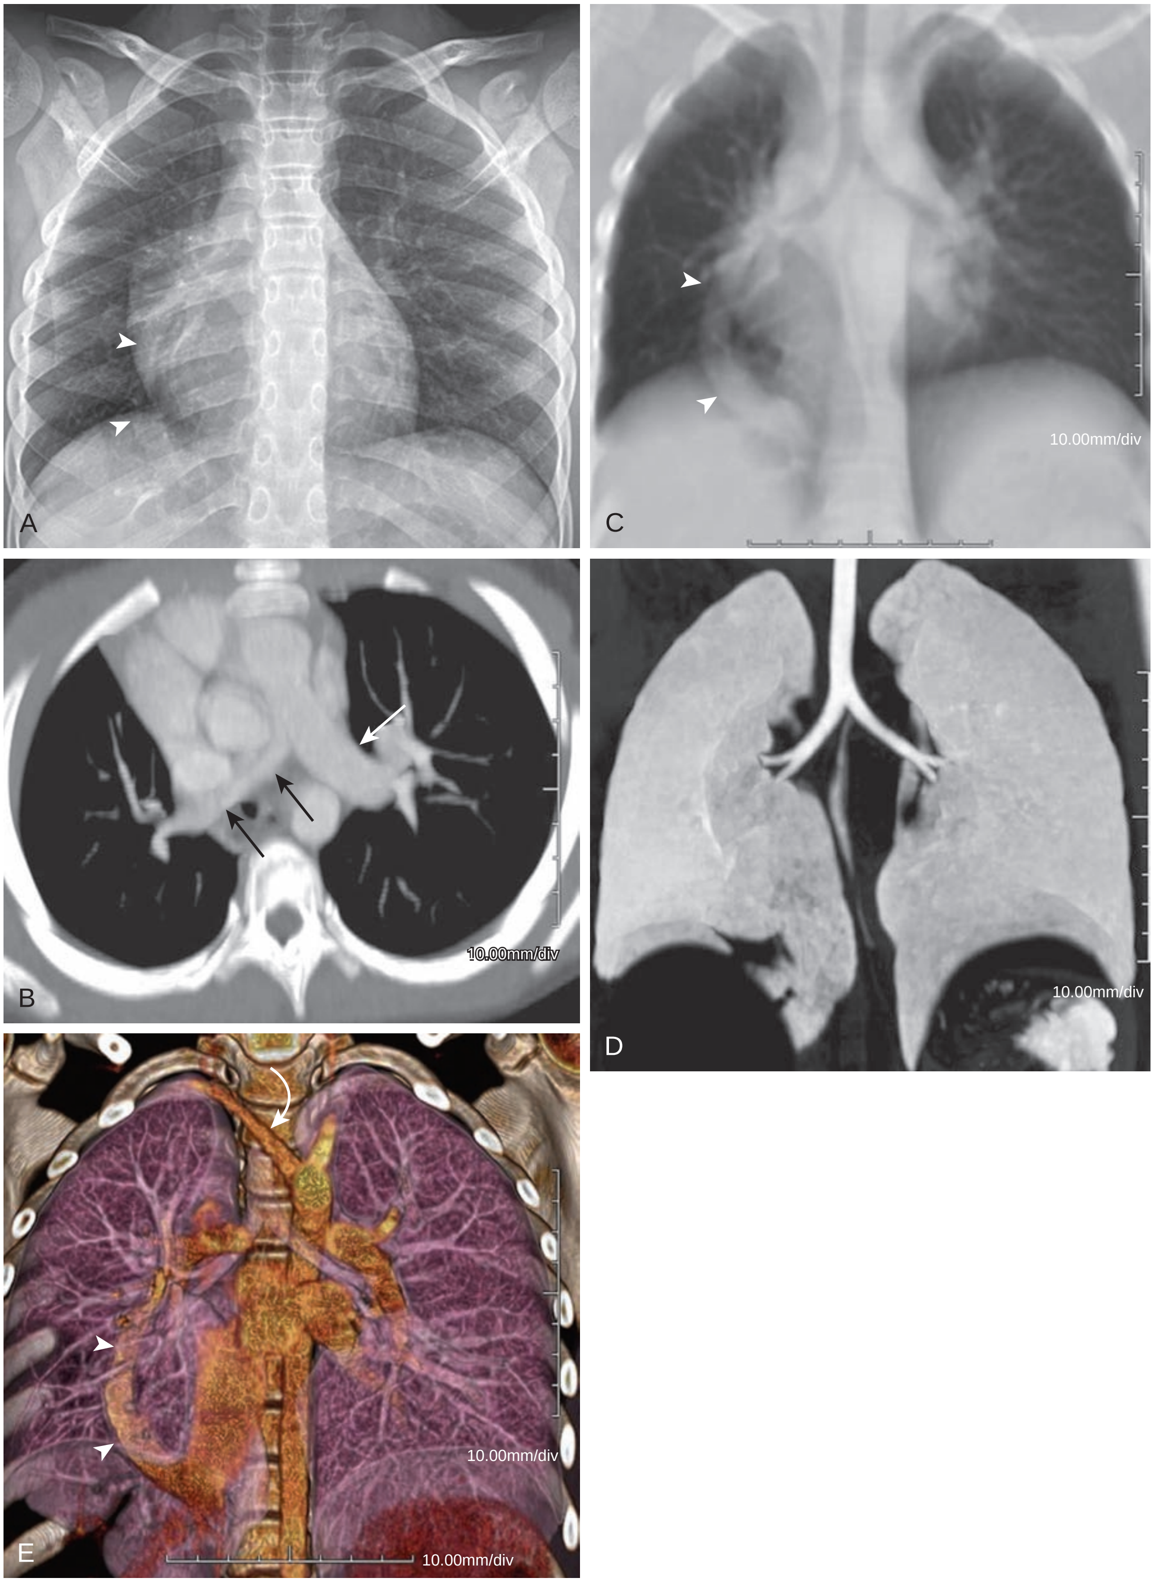

**Figure 53.22. Hypoplastic right lung and scimitar syndrome in an 8-year-old.** (A) Frontal chest radiograph shows asymmetric lung volumes with dextroposition of the heart and a vertically oriented curvilinear opacity *(arrowheads)* projecting over the right lower hemithorax. An axial maximum intensity projection CT image (B) confirms mild dextroposition of the heart and hypoplastic right lung and pulmonary artery (PA) *(black arrows)* relative to the normal left pulmonary artery *(white arrow)*. Coronal thick multiplanar reconstruction (C), inverted minimum intensity projection (D), and three-dimensional volume rendered (E) images show hypoplasia of the right lung with absence of the right upper lobe bronchus and partial anomalous pulmonary venous return of the right lung via a scimitar vein *(arrowheads)* into the inferior vena cava. Incidentally noted is a right aberrant subclavian artery *(curved arrow)*.

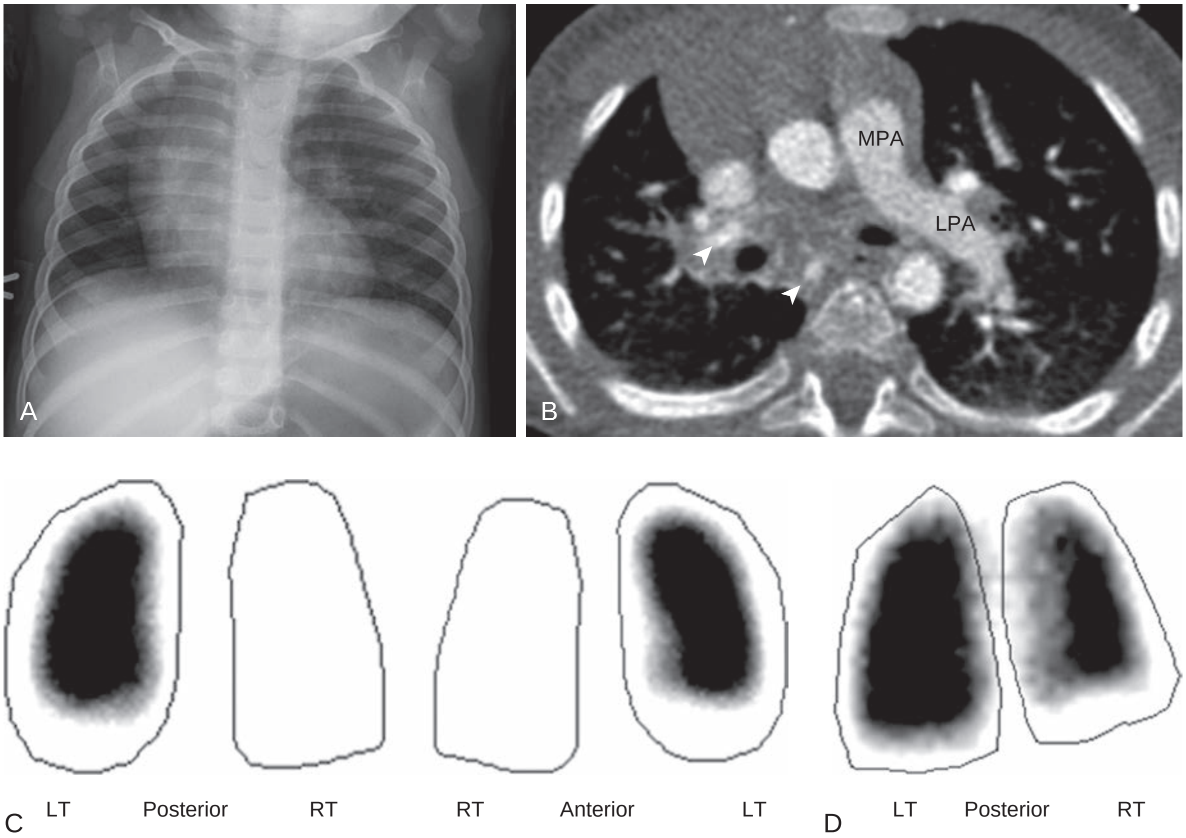

**Figure 53.24. Interrupted proximal right pulmonary artery in a 16-month-old with a persistent abnormal chest radiograph after resolution of respiratory syncytial virus bronchiolitis.** (A) Frontal chest radiograph shows a small right lung, dextroposition of the cardiomediastinal silhouette and mild asymmetry of pulmonary vascularity, decreased on the right. (B) Axial contrast-enhanced CT image reveals absence of the proximal right pulmonary artery. Several collaterals to the right lung are present *(arrowheads)*. The main pulmonary artery *(MPA)* and the left pulmonary artery *(LPA)* are intact. The aortic arch is left-sided, and overall findings are consistent with proximal interruption of the right pulmonary artery. (C) Techtetium-99m macroaggregated albumin first pass lung perfusion images show absent blood flow to the right lung. (D) Xenon-133 posterior planar image of the lungs shows decreased airflow to the right lung. *LT,* Left; *RT,* right.

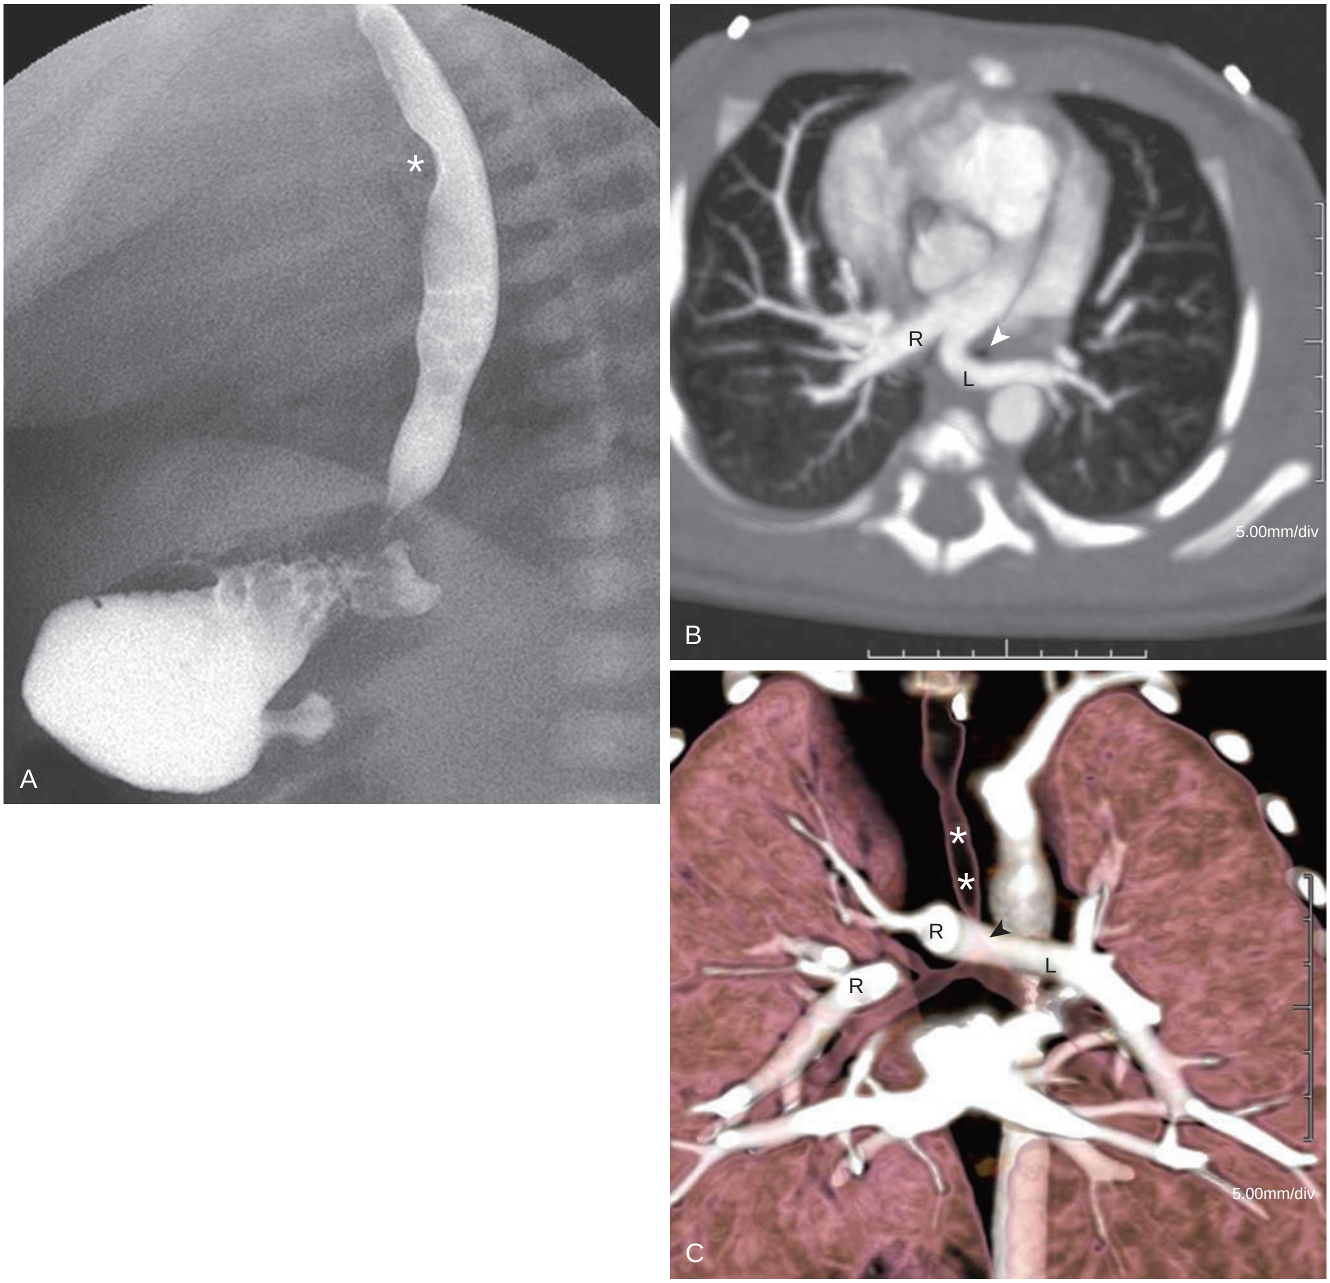
trachea and/or the proximal right mainstem bronchus.[1,52,63,66] It is hypothesized that PAS develops as a result of proximal left sixth arch involution, and a secondary connection is acquired to the right sixth branchial arch via the embryonic peritracheal primitive mesenchymal vessels.[52,63,66] The concurrent presence of a left ligamentum arteriosum connecting the main or right pulmonary artery and the left descending aorta results in a complete vascular ring that encircles the trachea but spares the esophagus.[15,52]

Two main types of PAS exist. In type I PAS, the position of the carina is normally situated at the T4–T5 level. In these instances, the airway is intrinsically normal or with an associated tracheal bronchus. The aberrant left pulmonary artery may compress the posterior wall of the distal trachea and/or the lateral aspect of the right mainstem bronchus, resulting in right lung air trapping.[6,15,66] Type II PAS is more common[66,67] and is associated with a more inferiorly located carina at the T6 level. Type II PAS often is associated with long-segment tracheal stenosis with complete cartilaginous rings and abnormal bronchial branching, including a T-shaped carina and a right-bridging bronchus. Other cardiovascular, gastrointestinal, and right lung anomalies (e.g., lung hypoplasia, aplasia, agenesis, and scimitar syndrome) may coexist.[1,6,66] Patients usually present as infants with respiratory symptoms, such as stridor, apneic spells, and/or hypoxia. The timing and severity of the respiratory symptoms depend on the severity of the accompanying airway abnormalities.[6,9,66]

***Imaging.*** Imaging findings of PAS depend on its type and other coexisting congenital anomalies. On frontal chest radiographs, either hyperinflation or hypoinflation of the right lung as a result of partial or complete obstruction of the right mainstem bronchus may present in patients with type I PAS. In patients with type II PAS associated with long-segment tracheal stenosis, bilateral hyperinflation may be observed or there may be right lung hypoplasia.[6,66] On occasion, a small, rounded soft tissue density representing the anomalous left pulmonary artery may be seen between the midtrachea and esophagus on lateral chest radiographs in patients with both types of PAS (e-Fig. 53.26A). CT or MRI with 2D and 3D reconstructions are useful for evaluating the origin, size, and entire course of the anomalous vasculature (e-Fig. 53.26B and C). CT is advantageous over MRI for evaluating associated central airway and lung abnormalities (e-Fig. 53.26C). Inspiratory and expiratory imaging is particularly useful for assessing for associated tracheobronchomalacia.[1,68]

***Treatment and Follow-up.*** Asymptomatic pediatric patients with PAS may be followed up clinically. Symptomatic pediatric patients with PAS require surgical reimplantation of the anomalous left pulmonary artery to the main pulmonary artery or anterior translocation in conjunction with excision of the coexisting patent ductus arteriosus or ductal ligament. In patients with type II PAS, reimplantation or anterior translocation of the anomalous left pulmonary artery by itself may not result in respiratory improvement



**e-Figure 53.26. Left pulmonary artery sling in a neonate with respiratory distress.** (A) Lateral esophagram shows soft tissue density *(asterisk)* between the trachea and the esophagus, suggesting an LPA sling. (B) Axial maximum intensity projection CTA image shows that the left pulmonary artery *(L)* originates from the proximal right pulmonary *(R)* before crossing behind the trachea *(arrowhead)* to feed the left lung consistent with an LPA sling. (C) Coronal volume-rendered CTA image shows severe distal trachea narrowing *(arrowhead)* at the level of the LPA *(L)* sling. The distal trachea shows long segment narrowing *(asterisks)* from complete tracheal rings. Note the low T-shaped carina.

if the coexisting long-segment tracheal stenosis is not repaired, usually by slide tracheoplasty.[66]

## Anomalies of the Pulmonary Veins

### Pulmonary Vein Atresia/Hypoplasia

***Etiology.*** Pulmonary venous atresia is an uncommon anomaly associated with high morbidity and mortality. The etiology is believed to represent the result of the unsuccessful incorporation of the common pulmonary vein into the left atrium, resulting in the lack of long segments of the central pulmonary veins. If unilateral (most common),[6] the condition may be asymptomatic or may manifest in infancy or childhood with recurrent episodes of pneumonia, hemoptysis (as a result of the systemic collateral supply to the affected lung), exercise intolerance, and pulmonary hypertension. Bilateral involvement without emergent surgical repair is typically fatal.[69,70] Nearly half of the cases are associated with other forms of congenital heart disease.[6,71,72]

***Imaging.*** Chest radiographs typically show a small affected hemithorax and hilum with ipsilateral mediastinal shift. The affected lung is hypoplastic and demonstrates circumferential pleural thickening, diffuse reticular opacities, and septal lines reminiscent of pulmonary edema, which are most pronounced in the lower lung zones.[6,71] On enhanced CT examinations, the margins of the left atrium on the affected side at the expected level of the pulmonary vein ostia appear smooth, and some adjacent enhancing soft tissue density may be present, reflecting collateral pulmonary-to-systemic venous channels. Additional collaterals may be seen in other portions of the mediastinum. The ipsilateral pulmonary artery appears small. On lung windows, diffuse ground-glass attenuation and smooth thickening of the interlobular septa and bronchovascular bundles may be observed.[71] This constellation of findings is believed to represent prominent bronchial veins, dilated lymphatics, and patchy parenchymal fibrosis as a result of pulmonary infarcts (e-Fig. 53.27).[71]

***Treatment and Follow-up.*** In cases of unilateral pulmonary venous atresia, surgical repair usually is not possible, depending on the age at diagnosis. Most patients present late in life once irreversible changes have occurred. Pneumonectomy may be necessary to prevent repeated pulmonary infections, to relieve the left-to-right shunt, and to remove the dead space contributing to exercise intolerance.[72]

### Pulmonary Vein Stenosis

***Etiology.*** Congenital pulmonary vein stenosis (PVS) may be congenital or acquired.[15] Congenital PVS is believed to be the result of an uninhibited myofibroblast-like proliferation causing endoluminal thickening and narrowing of the pulmonary veins.[9,73] However, the term “primary” pulmonary vein stenosis would be more accurate, because increasing evidence exists that the disease is progressive and may not be present at the time of delivery. Association with other congenital heart defects is high, ranging from 30% to 80%.[74,75] A strong association between PVS and prematurity has been recently reported, with a preponderance in premature newborns with cardiac shunt lesions.[76] However, PVS also may occur in isolation, and in these cases PVS usually progresses rapidly.[74]

The age at diagnosis and severity of symptoms are contingent on the number of pulmonary veins involved and the severity of pulmonary venous obstruction to individual pulmonary veins.[69,74] Patients with more than three stenotic pulmonary veins have a poorer prognosis; their mortality rate approaches 85% versus 0% in patients with one or two stenosed pulmonary veins.[75] Most cases of PVS present in infancy with a history of worsening respiratory distress and recurrent pneumonias. With disease progression, pulmonary hypertension develops and becomes progressive. Therefore PVS always should be excluded in young patients with unexplained pulmonary hypertension. Hemoptysis may occur, particularly in older patients.[74] Acquired PVS in pediatric patients typically occurs after anomalous pulmonary vein reimplantation surgery. In approximately 10% of these patients, substantial stenosis develops either at the anastomotic site or within the central portions of the pulmonary veins.[73,77,78]

***Imaging.*** Echocardiography usually can visualize all central pulmonary veins in neonates and infants. Turbulent flow on color Doppler with flow velocities greater than 1.6 m/s indicate hemodynamically significant pulmonary venous obstruction.[79] Findings on chest radiographs include patchy reticular opacities and thickened septa, reflecting the impaired venous drainage in the affected lung. CT shows pulmonary vein thickening and narrowing. Although it typically affects the pulmonary venous-left atrial junction, it may involve more central and peripheral segments, resulting in long-segment narrowing, particularly in cases of advanced disease[1] (Fig. 53.28). In advanced cases of PVS, lung and pleural findings may be indistinguishable from pulmonary venous atresia, with smooth septal thickening, reticular opacities, patchy ground-glass areas, and pleural thickening. MRI may show similar findings, but CT has better spatial resolution. However, MRI may provide additional useful physiologic information.[69]

***Treatment and Follow-up.*** PVS may be amenable to balloon dilatation occasionally followed by stent placement, although restenosis seems universal. Care should be taken, because stent placement before surgery may limit surgical approaches. The restenosis rate after surgery approaches 10%, despite advanced techniques reducing trauma to the veins to avoid any stimulus for regrowth of obstructive tissue. In severe cases with multiple vein involvement, lung transplantation may be necessary.[74]

## Combined Anomalies of the Pulmonary Artery and Vein

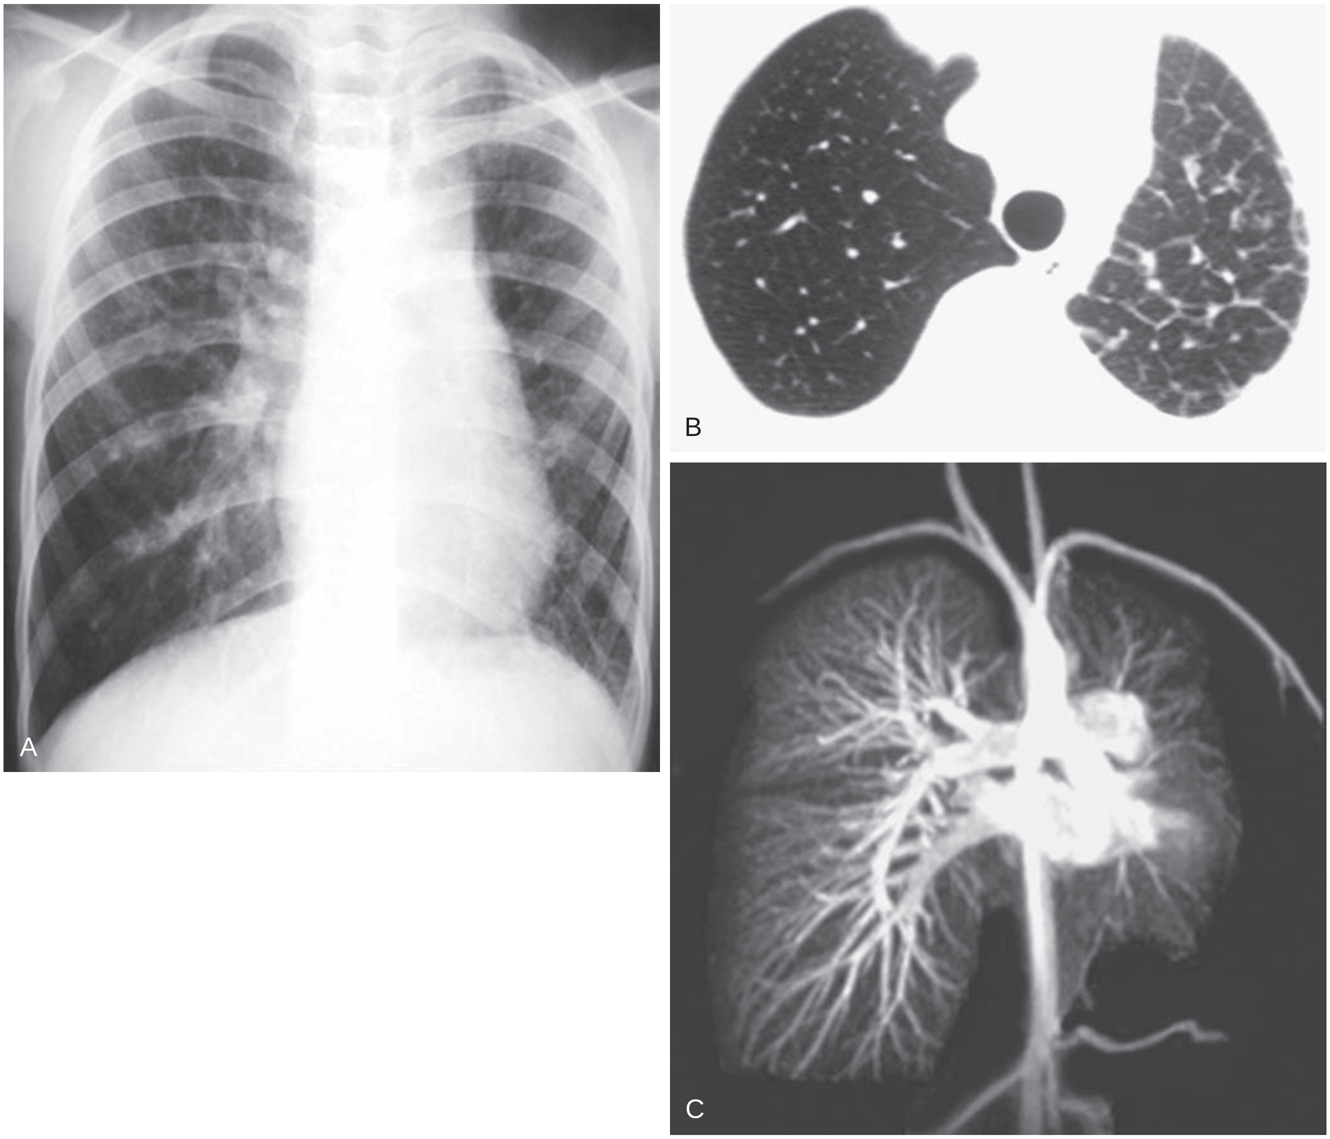
### Pulmonary Arteriovenous Malformation

***Etiology.*** Pulmonary AVM is a vascular malformation due to an underlying direct connection between the pulmonary arteries and veins without a normal intervening capillary network.[9] This bypass of the capillary network has two important physiologic consequences. First, the direct communication acts as a right-to-left shunt. Second, blood flowing through a pulmonary AVM circumvents the filter function of the normal pulmonary capillary bed, predisposing patients to paradoxical emboli.

Pulmonary AVMs can be congenital or acquired. Acquired pulmonary AVMs are usually seen in patients with a prior history of congenital heart disease surgeries, chronic liver disease, or infections such as tuberculosis or actinomycosis.[1,9] Congenital pulmonary AVMs may occur sporadically, although characteristically they are seen in 30% to 40% of family members with hereditary hemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome. HHT is an autosomal-dominant condition, which is diagnosed clinically on the basis of Curaçao criteria (cerebral, pulmonary, or hepatic AVMs; epistaxis; family history of HHT; and telangiectasias).[80]

Pediatric patients with small pulmonary AVMs often are asymptomatic. Typical clinical symptoms of patients with larger or multiple pulmonary AVMs include dyspnea on exertion, cyanosis, chest pain, palpitations, and hemoptysis.[9,81] Direct right-to-left shunting through larger or multiple pulmonary AVMs bypassing the pulmonary capillary bed can result in paradoxical emboli to the brain causing a stroke or brain abscess.

***Imaging.*** On chest radiographs, pulmonary AVM may appear as a well-circumscribed serpiginous or lobulated opacity. Occasionally, curvilinear opacities directed toward the hilum representing the feeding artery or draining vein may be observed. Most pulmonary AVMs are located within the lower lobes. Small pulmonary AVMs



**e-Figure 53.27. Unilateral left pulmonary vein atresia in an asymptomatic 13-year-old girl.** (A) Frontal chest radiograph shows a smaller volume of the left lung, with mediastinal shift to the left. (B) Axial CT image shows thickened interlobular septal lines. (C) Coronal MRA maximum intensity projection image of the chest demonstrates decreased left pulmonary vascularity; however, a left pulmonary artery is present. The left pulmonary veins are not visualized. Note the normal arborization of the right pulmonary vascular bed and the presence of the right pulmonary veins. *(Images reproduced with permission from Gasparetto TD, Daltro P, Marchiori E. Imaging findings of an asymptomatic child with pulmonary vein atresia.* Pediatr Radiol. *2010;40:1458–1459.)*

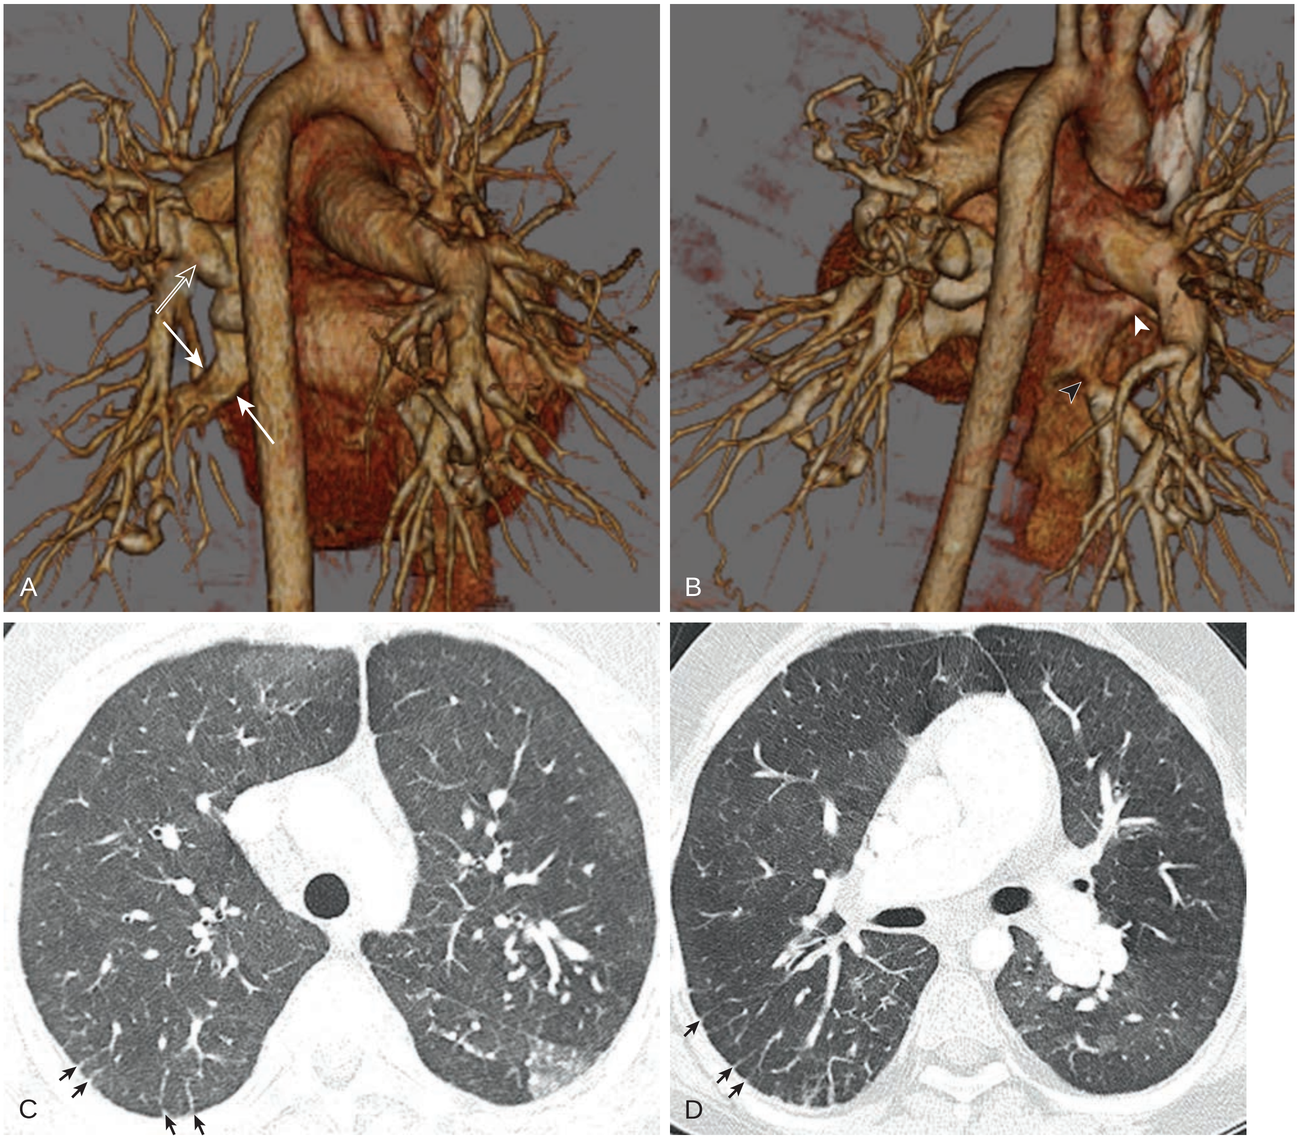


**Figure 53.28. Pulmonary vein stenosis in a 10-year-old boy.** Posterior oblique volume-rendered three-dimensional CT images (A and B) show severe right inferior pulmonary vein narrowing in the anteroposterior dimension resulting in flattening of the vein *(solid arrows)*. Compensatory variceal enlargement of the right superior pulmonary vein is present *(open arrow)*, likely because of the redirection of flow. The left inferior pulmonary vein shows approximately 50% stenosis *(black arrowhead)*, whereas the left superior pulmonary vein *(white arrowhead)* remains patent. Axial CT images in lung windows (C and D) show smooth interlobular septal thickening *(arrows)* and mild patchy areas of ground-glass opacity.

or lesions in areas obscured by normal structures, such as the retrocardiac area or the pulmonary hila, may easily be overlooked.

In the past, pulmonary AVM traditionally was evaluated with conventional pulmonary angiography. Multidetector CT is now the preferred imaging modality for a complete assessment of pulmonary AVMs and can clearly show the often complex angioarchitecture of the pulmonary AVM with its feeding artery and draining vein. This allows preinterventional planning before embolization, which is of outmost importance when managing large or complex lesions[1,81] (Fig. 53.29). Improvements in magnetic resonance angiography (MRA) make it increasingly useful for the assessment of pulmonary AVMs.[82]

Pulmonary AVMs may be simple or complex. Approximately 80% to 90% of pulmonary AVMs have simple angioarchitecture, consisting of single or multiple feeding arteries that all originate from one segmental artery and are connected directly to a single draining vein.[9] Typically, both the artery and vein are dilated and connected by the aneurysmal sac. The remaining 10% to 20% of cases involve complex architecture lesions, with two or more feeding arteries arising from at least two different segmental arteries and connecting with at least two draining veins.[9] Nearly 5% of patients with HHT have multiple pulmonary AVMs.[83]

***Treatment and Follow-up.*** As a general rule, treatment is offered for pulmonary AVMs with feeding arteries larger than 3 mm. However, symptomatic paradoxical emboli have been reported in patients with sub–3-mm feeding arteries. Consequently, many HHT centers currently are treating pulmonary AVMs with feeding arteries of less than 3 mm.[84] Less agreement exists regarding treatment of children who are asymptomatic and younger than 12 years of age[83,85] Developing lungs in this setting may be at

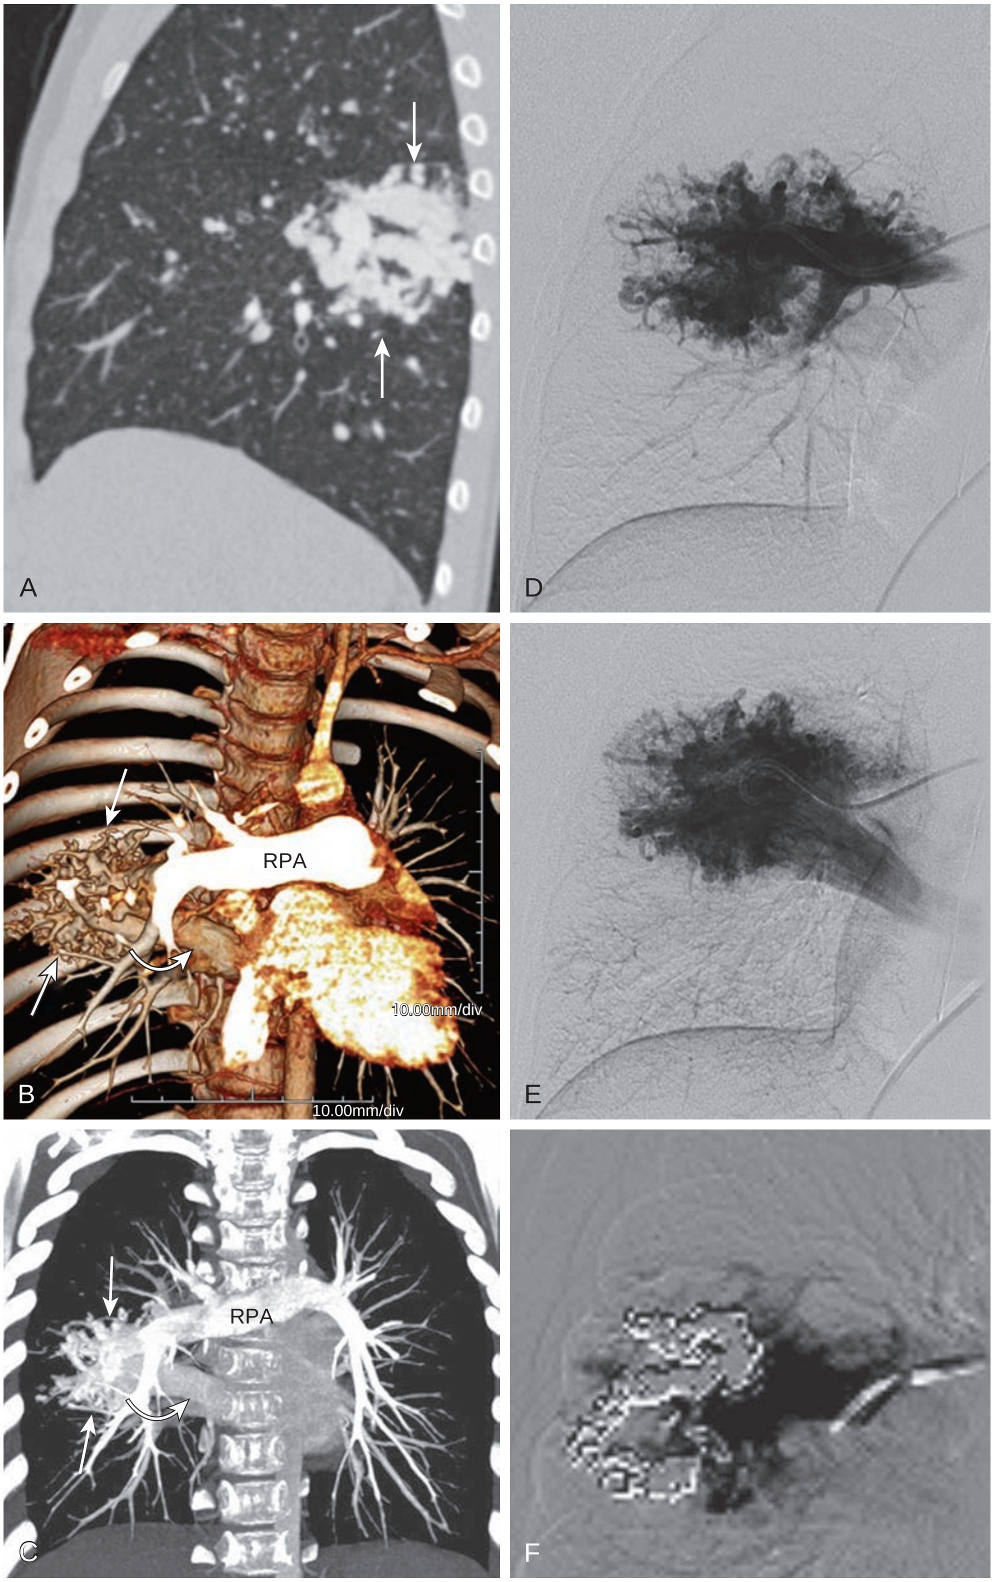

**Figure 53.29. Pulmonary arteriovenous malformation (AVM) in an 8-year-old with a family history of hereditary hemorrhagic telangiectasia and a positive echocardiogram.** (A) Contrast-enhanced sagittal reformatted CT image shows a large AVM *(arrows)* in the superior segment of the right lower lobe. Coronal-oblique volume-rendered (B) and coronal maximum intensity projection (C) CTA images show a large AVM *(straight arrows)* with a feeding artery from the right main pulmonary artery *(RPA)* and a large draining vein into an enlarged right inferior pulmonary vein *(curved arrow)*. Pulmonary angiogram images (D and E) demonstrate a large AVM that correlates well with the CT angiography findings. Postembolization image (F) with platinum coils shows partial obliteration of a large portion of the lesion.

increased risk for reperfusion via pulmonary collaterals, which are even more difficult to treat. Symptomatic pulmonary AVMs should be treated regardless of the age of patients.[81]

The current management choice for pulmonary AVM is transvenous transcatheter embolotherapy, which can be performed using a variety of devices including coils, detachable balloons, and, more recently, the Amplatzer vascular occluder (AGA Medical, Plymouth, MN).[81]

## KEY POINTS

- Congenital lung anomalies can be classified into three groups: predominantly parenchymal abnormalities, combined parenchymal and vascular abnormalities, and predominantly vascular abnormalities, based on morphologic-radiologic-pathologic classification.
- Lung anomalies vary widely in their clinical manifestations, imaging appearance, and pathology, but there is also considerable overlap. Despite advancements in pre- and postnatal imaging that have substantially enhanced our understanding of these lesions, controversy continues to exist regarding nomenclature, classification, pathogenesis, description, and management of congenital lung anomalies. Careful evaluation and thorough understanding of all imaging findings are more important for practical care than trying to categorize the lesions by pathologic terminology.
- Specific imaging findings of congenital lung anomalies that need to be evaluated include (1) location of lesions; (2) vascular supply and drainage of the lesions; (3) internal architecture, presence of cystic components, and degree of aeration; (4) airway abnormality; (5) exclusion of communication with the gastrointestinal tract; (6) integrity of the diaphragm; and (7) an assessment of associated anomalies, such as vertebral anomalies.
- Although radiographs play a role in the detection and initial postnatal imaging evaluation in clinically suspected congenital lung anomalies, cross-sectional imaging such as CT with 2D/3D evaluation often is required for confirmation of diagnosis, further characterization, and preoperative evaluation of surgical lesions.

# Pulmonary Infection

Sjirk J. Westra, Ali Yikilmaz, and Edward Y. Lee

Pneumonia and other pulmonary infections involving the lower respiratory tract continue to be the most common cause of illness in children, affecting over 150 million children under 5 years of age each year worldwide, with 20 million related US hospitalizations annually.[1-5] Despite the decrease in hospitalizations for pediatric pneumonia since the introduction of the pneumococcal conjugate vaccine in 2000, the rates of pneumonia presenting in the ambulatory care setting have not decreased.[6] Because clinical signs and symptoms are poor predictors of pediatric pulmonary infections, and the value of microbial studies is limited, chest radiography with the use of standardized reporting criteria continues to be the best available diagnostic standard.[1,3,7,8] Currently published definitions of pediatric pneumonia do not solely rely on radiographic criteria, but require several additional clinical features to be present.[9] The value of lateral radiographs in diagnosis continues to be debated, but the hyperinflation that is a radiographic hallmark of pulmonary infections in young children is more reliably detected on the lateral radiograph than on the frontal radiograph.[1,10,11]

In experienced hands, ultrasonography of the lung has proven able to diagnose pneumonia, validated in two recent meta-analysis studies.[12,13] In the ambulatory care setting, performing routine chest radiography has not been shown to improve the outcomes of pulmonary infections in young children, and it is not indicated in first-time wheezing episodes presumed to be viral or reactive in etiology.[14-17] The yield of radiography is greater in the presence of a high temperature and in the absence of a family history of asthma.[18] Radiography is most helpful when an inconsistency exists among the data from history, physical examination, and observation.[19] Negative chest radiography provides justification to withhold antibiotics in symptomatic children.[1] Newer evidence-based recommendations suggest that valid indications for chest radiography are severe disease requiring hospitalization, confirmation or exclusion of diagnosis in the presence of an atypical presentation, assessment of complications, and exclusion of other causes of respiratory distress.[20-26] Even in hospitalized individuals in intensive care, chest radiographs should be obtained based on clinical need rather than routine protocols.[27] However, compliance with these, as well as antibiotic use guidelines, is suboptimal.[6,20,24] Follow-up chest radiographs after 4 to 6 weeks are only recommended for children with recurrent pneumonia involving the same lobe, to look for underlying anatomic causes.[22]

Maternal antibodies protect newborns against viral pulmonary infections, and bacterial infections are most common in this age group, usually caused by pathogens acquired during labor and delivery. With dropping maternal antibodies, viral infections become more prevalent between ages 2 months and 2 years. After this, bacterial infections again become more common.[3] Tuberculosis, fungal infections, and parasitic infestations continue to add substantially to the disease burden of children who are immunocompromised or live in endemic areas.[2]

The spectrum of pulmonary infections in childhood is categorized in Table 54.1.[2,28] In young children, the lungs can only respond to insult in a limited number of ways, and this response is more age specific than antigen dependent.[29-33] Viral and bacterial infections frequently coexist, and radiographic criteria alone do not reliably distinguish between them.[34-36] This is compounded by a reported high interobserver variability for interpretation of chest radiographs.[37-41] Use of inexact terminology may hamper communication between radiologists and referring physicians, who agree with radiologists' interpretations in only 78% of cases, and antibiotics are frequently prescribed even when no bacterial agent can be proven.[7,42,43]

## PULMONARY INFECTIONS CAUSED BY VIRUSES

Viral pulmonary infections usually occur after the inhalation of infected air droplets.[2] The clinical presentation depends on the infectious agent, patient age, and immune response (mainly cellular, T-cell–mediated immunity). In young children, degrees of mucosal swelling within the small-caliber terminal airways, which would not compromise air exchange in older individuals with relatively larger-caliber airways, lead to diffuse alveolar air trapping (Fig. 54.1). In addition, more hypersecretion occurs in the inflamed airways in young children, contributing to mucous plugging of the airways; this leads to (sub)segmental atelectasis mimicking alveolar consolidations, which are frequently misinterpreted to represent bacterial pneumonia.[1,43-45]

***Etiology.*** The most common viral agents causing pulmonary infections in childhood are listed in Table 54.2.

*RNA Viruses.* Respiratory syncytial virus (RSV) is the most common cause of pulmonary infections in infants and young children. The disease can be virulent and is fatal in up to 1% of healthy infants, but those with chronic lung disease from prematurity and cardiovascular disease are at much higher risk.[46] Clinical signs range from mild coryza to severe respiratory distress with wheezing, tachypnea, cyanosis, dyspnea, and retractions. Hypoxemia, possibly caused by a ventilation-perfusion imbalance, may be profound and last for several weeks.[47] The diagnosis of RSV infection is made by examining the nasoepithelial cells by using direct fluorescent antibody detection.

Human metapneumovirus (HMV) is the second most common cause of viral pulmonary infections in young children after RSV.[48,49] It affects children who are slightly older than those infected by RSV, and the disease is less severe, except when seen as a coinfection. HMV has a worldwide distribution and causes a disease spectrum indistinguishable from influenza and RSV infection, with the same seasonal variation.

Parainfluenza virus is a common community-acquired virus. Types 1 and 2 fluctuate biannually, typically in the fall, with type 3 common in the late winter or early spring, unlike RSV.

The onset is often more abrupt and intense than that of RSV or parainfluenza. The Asian avian influenza virus (H1N1) spread rapidly over many parts of the world from 2003 to 2007.[48,50,51] Since 2009 a novel H1N1 infection resulting from antigenic shift of the virus has been reported to be associated with a higher rate of shock, acute respiratory distress syndrome (ARDS), and neurologic complications in children compared with seasonal (non-H1N1) infections.[52]

Severe acute respiratory distress syndrome (SARS) is caused by a coronavirus, which was recognized in 2003, and in the following year, it was diagnosed in over 8000 patients, primarily in China, Taiwan, Hong Kong, Vietnam, and Toronto.[48,53] After 2004 the outbreak appeared to have been contained; since then, SARS has only been sporadically reported. SARS typically has a brief prodrome of fever, with or without constitutional symptoms. This quickly progresses to severe respiratory symptoms by day 6 of the fever.[54] It has an overall mortality rate of 10%, but children have constituted only 5% of reported cases; they tend to have a milder

## Abstract:

This chapter reviews the imaging in pulmonary infections in children caused by viruses, bacteria (including mycobacteria), bacteria-like organisms, fungi and parasites. The value and limitations of chest radiography are discussed, supplemented with cross-sectional techniques (ultrasound, CT and MRI) when infections fail to respond to treatment, recur or occur in immunocompromised children. In young children, the imaging findings of viral and bacterial lung infections frequently overlap, making their differentiation difficult. Improved communication of the radiographic findings and their limitations can decrease over-prescription of antibiotics by referring physicians, when no bacterial cause can be proven. CT adds value to radiography only in pulmonary infections that are complicated, recurrent or occur in patients with an impaired immune system. Ultrasound is favored over CT to determine the need and feasibility of percutaneous drainage of parapneumonic effusions and empyemas in children.

course,[55] and no pediatric deaths have been reported.[48,53] Recently, newer coronaviruses (NL63 and HKU1), which cause milder forms of respiratory disease, have been discovered.[48]

Pneumonia as a complication of childhood measles is diminishing in frequency because of vaccination, but it is still occasionally seen in nonimmunized or immunosuppressed children. Atypical measles pneumonia followed exposure to measles or vaccination with the live vaccine and was characterized by a prodromal period of rash and flulike illness.

*DNA Viruses.* Adenovirus pneumonia is responsible for about 5% of respiratory tract disease in infants and children, with a peak age between 6 months and 5 years.[45] Adenovirus has also been associated with a pertussis-like syndrome. Although often relatively benign, adenoviral infection may be severe and even fatal in young infants, particularly when caused by the recently identified serotype Ad14.[48]

**TABLE 54.1** Classification of Pulmonary Infections in Childhood

| By Pathology, Clinical Presentation | By Primary Location | By Radiographic Feature |
|---|---|---|
| Acute focal | Trachea: tracheitis | Alveolar |
| Atypical | Large airways: bronchitis | Interstitial |
| Miliary or nodular | Small airways: bronchiolitis | Volume loss (atelectasis) |
| Progressive or fulminant | Small airways and parenchyma: bronchopneumonia | Pulmonary nodule(s) |
| Aspiration | Parenchyma | Necrosis, cavitation |
| "Pulmonary infiltrates with eosinophilia" | Alveoli ("alveolitis") | Lymphadenopathy |
| Chronic or recurrent | Interstitium | Pleural effusion |

*From Eslamy HK, Newman B. Pneumonia in normal and immunocompromised children: an overview and update.* Radiol Clin North Am. *2011;49:895–920.*

Cytomegalovirus (CMV) is a cause of congenital infection of the lungs, the liver, and the central nervous system, and causes hematologic changes of petechiae, purpura, hemolytic anemia, and atypical lymphocytes. These same systems are involved in acquired disease, but the disease is less severe. Children with a compromised immune status are at lifelong risk for CMV infection, and it is frequently seen in patients with acquired immunodeficiency syndrome (AIDS) and in children treated with cyclosporine.

Varicella (chickenpox) pneumonia is relatively rare, but immunocompromised children are at risk for progressive varicella and more severe pulmonary involvement, as well as for meningoencephalitis and hepatitis. These children are severely ill, with extensive rashes and high fever; chest pain and hemoptysis are frequent.

Epstein–Barr virus (EBV) infects B lymphocytes and pharyngeal and possibly pulmonary epithelial cells. It is associated with infectious mononucleosis, a common disease in older children and young adults, presenting with fever, pharyngitis, and adenopathy. The disease may be suspected if the tonsils and adenoid are markedly enlarged. EBV is frequently associated with posttransplantation lymphoproliferative disorder, lymphomas complicating immune deficiency disorders, and lymphocytic interstitial pneumonitis (with or without associated human immunodeficiency virus [HIV] infection).

***Imaging.*** Bilateral interstitial opacities with peribronchial thickening and hyperinflation (see Fig. 54.1), thought to represent viral bronchiolitis, are nonspecific and are, in fact, indicative of an acute pulmonary infection of any cause (viral or bacterial) in young children.[1,28] Pleural effusions are rare in purely viral lung infections. Radiologic abnormalities often clear slowly and lag behind clinical improvement. Complications are superimposed bacterial infection (often hospital acquired) and postinfectious bronchiolitis obliterans, bronchiectasis, or both.[2] These latter conditions, which frequently follow an adenovirus infection, are characterized by features of chronic air trapping and atelectasis resulting from bronchial dysfunction; mosaic perfusion abnormalities, peribronchial thickening, and bronchiectasis, best seen on

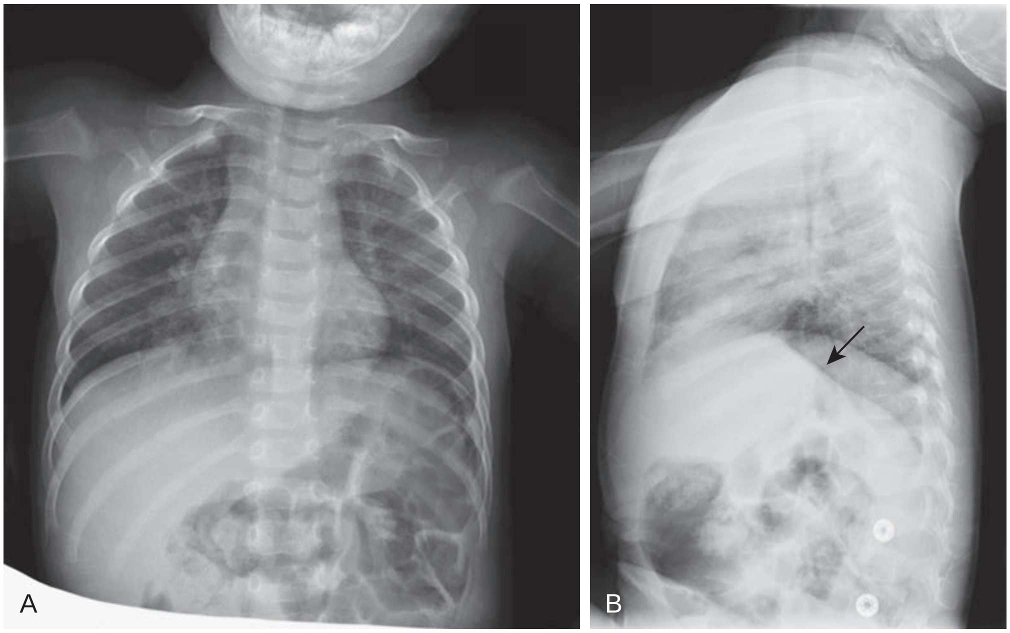

**Figure 54.1. Respiratory syncytial virus pneumonia in a 1.5-year-old boy.** (A) The frontal chest radiograph shows perihilar streaky lung opacities and peribronchial thickening, typical of viral infections, with more focal opacity medially in the right lung base, from superimposed atelectasis. This was mistaken for alveolar consolidation indicative of bacterial pneumonia, and antibiotic treatment was given unnecessarily. (B) The lateral chest radiograph better demonstrates air trapping in the right lung base, with flattening of the right hemidiaphragm *(arrow).*

**TABLE 54.2** Most Common Organisms Causing Pulmonary Infections in Childhood

| Organism | Characteristic Clinical Features | Typical Radiographic Findings and Sequelae |
|---|---|---|
| **VIRUSES** | | |
| **RNA Viruses** | | |
| RSV | Bronchiolitis (winter) | Interstitial pneumonia |
| HMV | Bronchiolitis (winter) | Interstitial pneumonia |
| Parainfluenza | Bronchiolitis (fall, spring) | Interstitial pneumonia |
| Influenza | "Bird flu," pandemic flu | Interstitial pneumonia |
| Corona | SARS | Interstitial pneumonia |
| Measles | Nonimmunized, opportunistic | Atypical pneumonia |
| **DNA Viruses** | | |
| Adenovirus | Necrotizing bronchopneumonia | Bronchiolitis obliterans |
| CMV | Congenital, opportunistic | Ground-glass opacity |
| Varicella | Opportunistic | Pulmonary calcifications |
| EBV | Infectious mononucleosis, PTLD | Lymphadenopathy |
| **BACTERIA** | | |
| **Aerobic/Facultative** | | |
| *Streptococcus pneumoniae* | De novo, postviral | Acute focal pneumonia |
| *Streptococcus* A | Pharyngitis | Bronchopneumonia |
| *Streptococcus* B | Prematurity, neonatal pneumonia | Confusion with hyaline membrane disease |
| *Staphyloccocus aureus* | Postviral, embolic | Bronchopneumonia |
| *Haemophilus influenzae* B | Epiglottitis, vaccination | Atypical pneumonia |
| *Bordetella pertussis* | Whooping cough | Atypical pneumonia, "shaggy heart" |
| *Pseudomonas* | Opportunistic (CF) | Findings of CF, bronchiectasis |
| *Legionella* | Opportunistic | Atypical pneumonia |
| *Anaerobic* | Aspiration, debilitated | Lung necrosis, abscess |
| **BACTERIA-LIKE** | | |
| *Chlamydia trachomatis* | Infancy, conjunctivitis | Interstitial pneumonia |
| *Chlamydia pneumoniae* | School age, bronchitis | Peribronchitis |
| *Mycoplasma* | School age, atypical pneumonia | Interstitial pneumonia, atypical |
| *Mycobacterium tuberculosis* | TB, opportunistic | Primary, miliary, postprimary |
| NTM | NTM disease, opportunistic | Mimics TB |
| **FUNGI** | | |
| *Aspergillus* | Aspergilloma, invasive disease | Halo, air crescent signs |
| *Histoplasma* | Histoplasmosis | Mimics TB, calcified granulomas |
| *Coccidioides* | Coccidioiodomycosis | Mimics TB |
| *Pneumocystis* | Opportunistic | Ground-glass opacities, interstitial pneumonia |
| *Candida* | Opportunistic, debilitated | Nodules |
| **PARASITES** | | |
| *Paragonimus* | Ingestion of uncooked crustaceans | Nodules, ring shadows |
| *Echinococcus* | Contact with infested dogs | Fluid-filled masses, with or without rupture |
| Others | Visceral larva migrans, Löffler syndrome | PIE |

computed tomography (CT).[2] Swyer–James–MacLeod syndrome, the result of bronchiolitis obliterans in the growing lung, is characterized by a unilateral small hyperlucent lung, which exhibits hypoperfusion and chronic bronchiectasis (e-Fig. 54.2).

In RSV infection, the lungs are often quite clear, or focal areas of superimposed atelectasis may be noted (see Fig. 54.1); when present, these predict a need for more prolonged mechanical ventilation.[56]

In mild influenza infection, initial chest radiographs are normal or may demonstrate nonspecific prominence of peribronchial markings and hyperinflation. In children with a more severe clinical course, bilateral symmetric and multifocal areas of consolidation, often associated with ground-glass opacities, are seen (e-Fig. 54.3).[57]

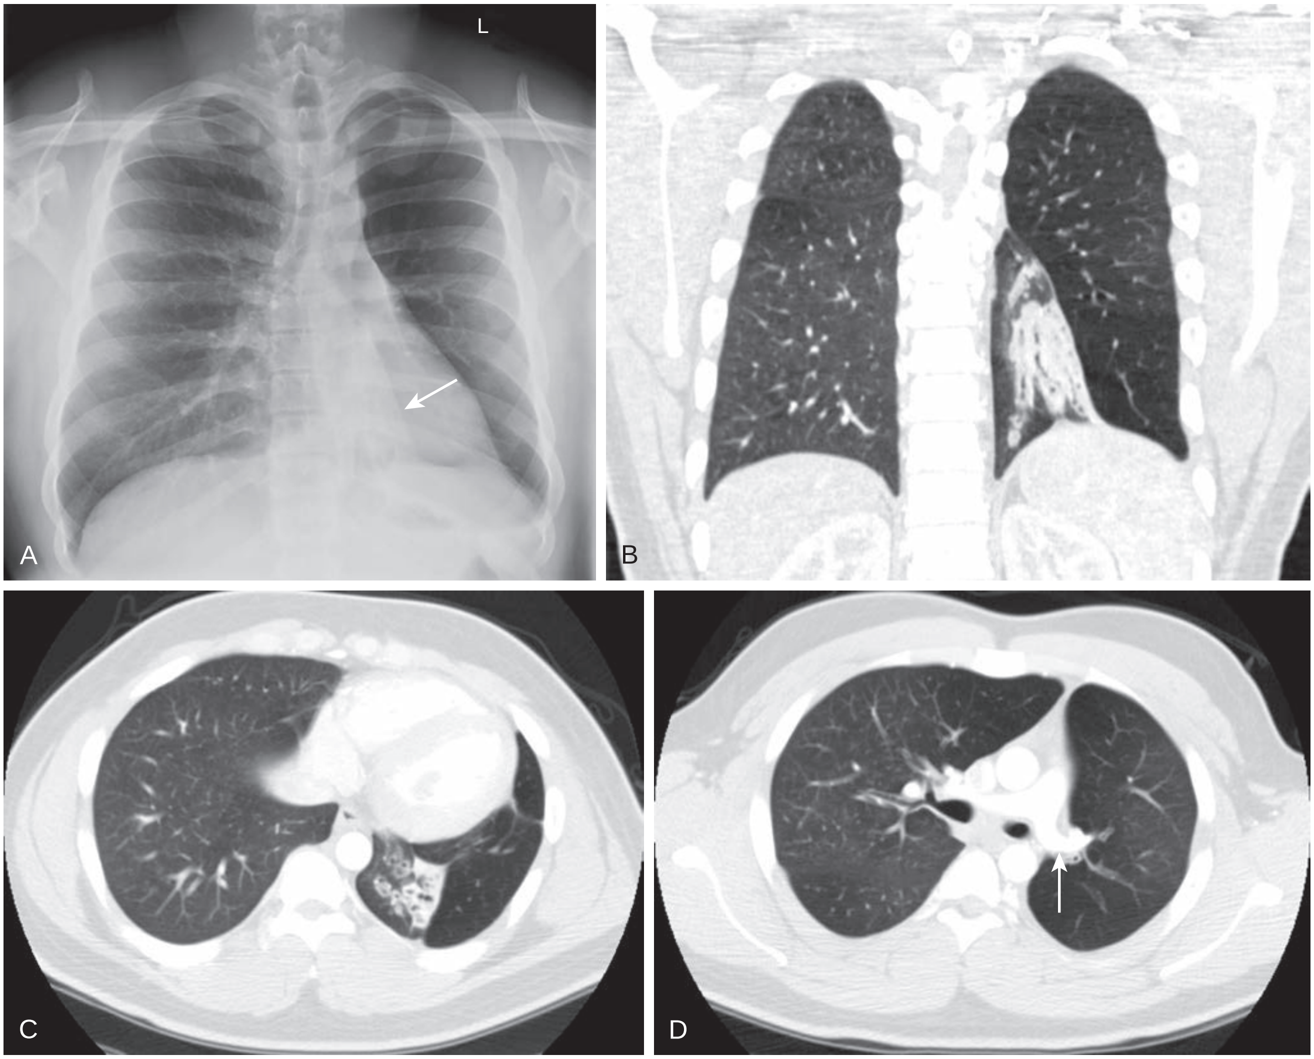
The radiographic manifestations of SARS are typically mild, with interstitial thickening, which may progress to focal consolidation.[58,59] In children, unlike in adults, no lymphadenopathy, pleural effusion, or cavitation is reported.[60] However, abnormalities may persist on thin-section CT in older children for up to 12 months after infection.[61]

Measles virus is thought to be the cause of giant cell pneumonia, which produces a diffuse reticulonodular bronchopneumonia-like radiographic pattern (e-Fig. 54.4), with hilar node enlargement and superimposed bacterial infection, usually affecting the lower lobes. Atypical measles pneumonia after vaccination with, or exposure to, live virus was characterized by extensive nonsegmental parenchymal consolidation, with pulmonary nodules, hilar lymph node enlargement, and pleural effusion being common.

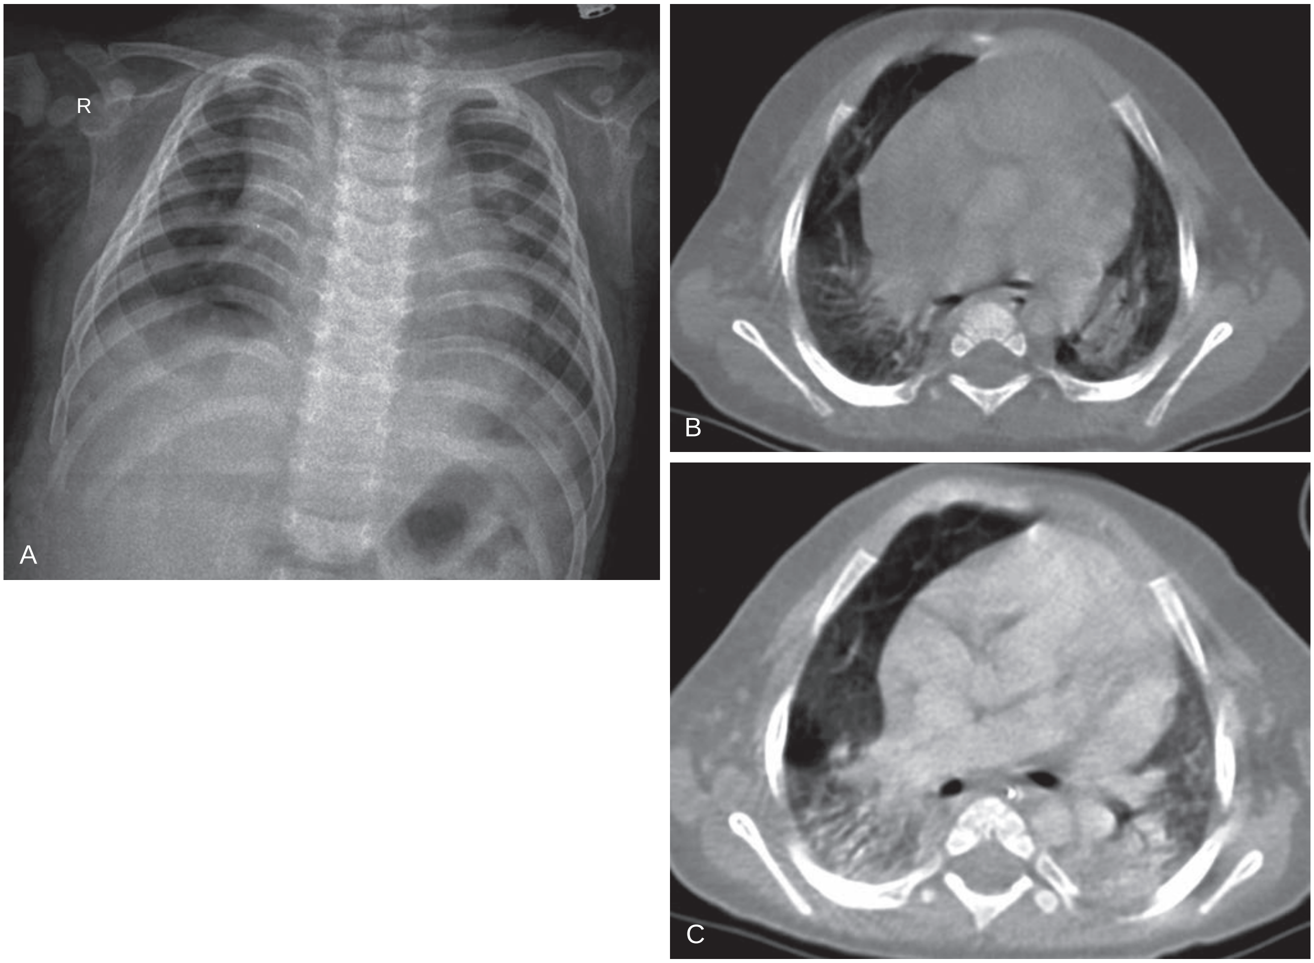
Adenovirus may cause necrotizing bronchopneumonia, bronchitis, or bronchiolitis. Radiographic features are nonspecific but usually include bronchial wall thickening, peribronchiolar densities, air trapping, and patchy or confluent consolidations.[44] Adenopathy is more common than in other viral pneumonias. Bronchiectasis or bronchiolitis obliterans may be a permanent sequel (see e-Fig. 54.2).[44,45,62]

In children infected with CMV, a progressive interstitial pneumonitis is seen (e-Fig. 54.5). CT findings are nonspecific, with ground-glass opacities and consolidations in 80% of the cases.[63] Gallium-67 scintigraphy may show abnormal uptake in the lungs of patients who have a normal chest CT.[64]

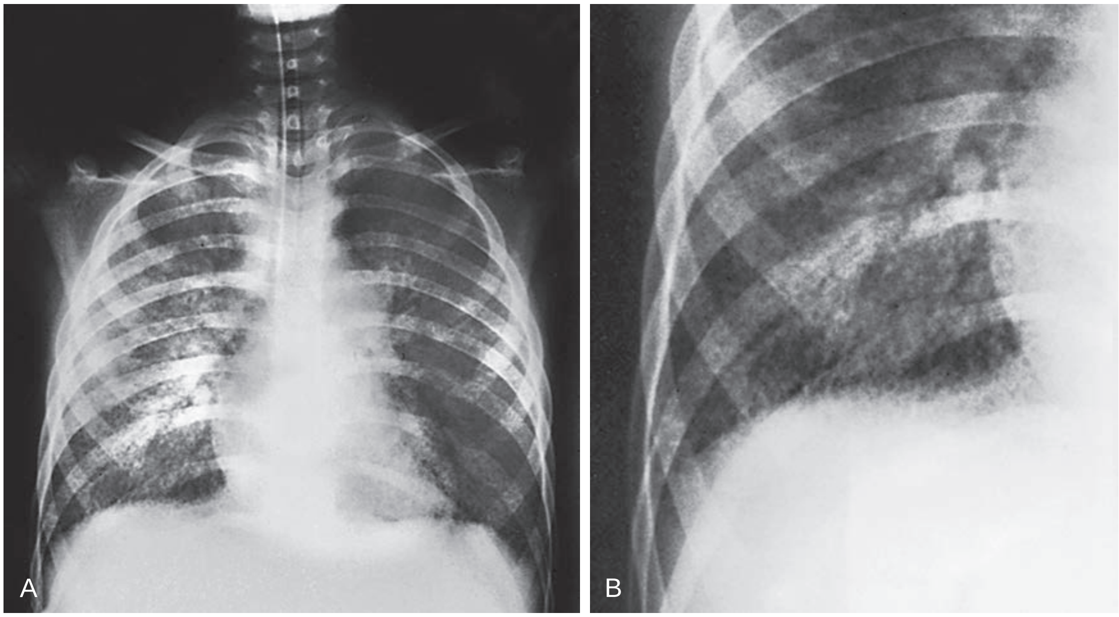
Findings in varicella are similar to those of measles pneumonia. Multiple focal calcifications frequently develop after severe chickenpox pneumonia (e-Fig. 54.6).



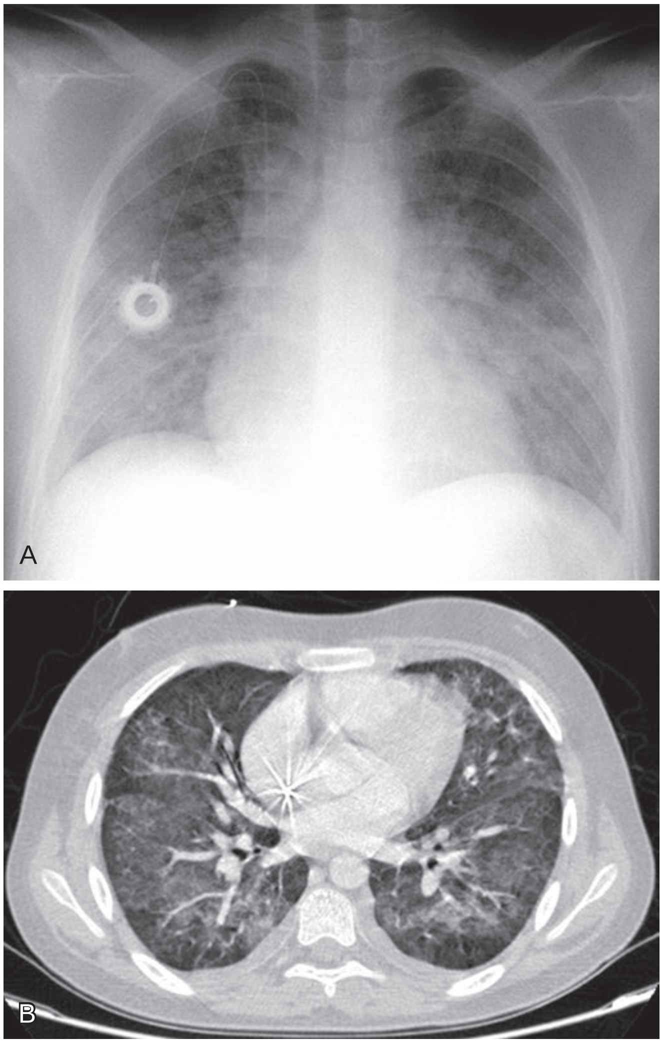
**e-Figure 54.2. Swyer–James–MacLeod syndrome in a 20-year-old man monitored since early childhood; he had chronic left lower lobe collapse and bronchiectasis secondary to bronchiolitis obliterans after an adenovirus infection.** (A) The radiograph shows left lower lobe collapse *(arrow)* and hyperlucency of the left upper lobe. (B–D) Computed tomography images demonstrate a hyperlucent, smaller left lung, cylindric bronchiectasis in the collapsed left lower lobe, and a relatively small left pulmonary artery (*arrow* in D).



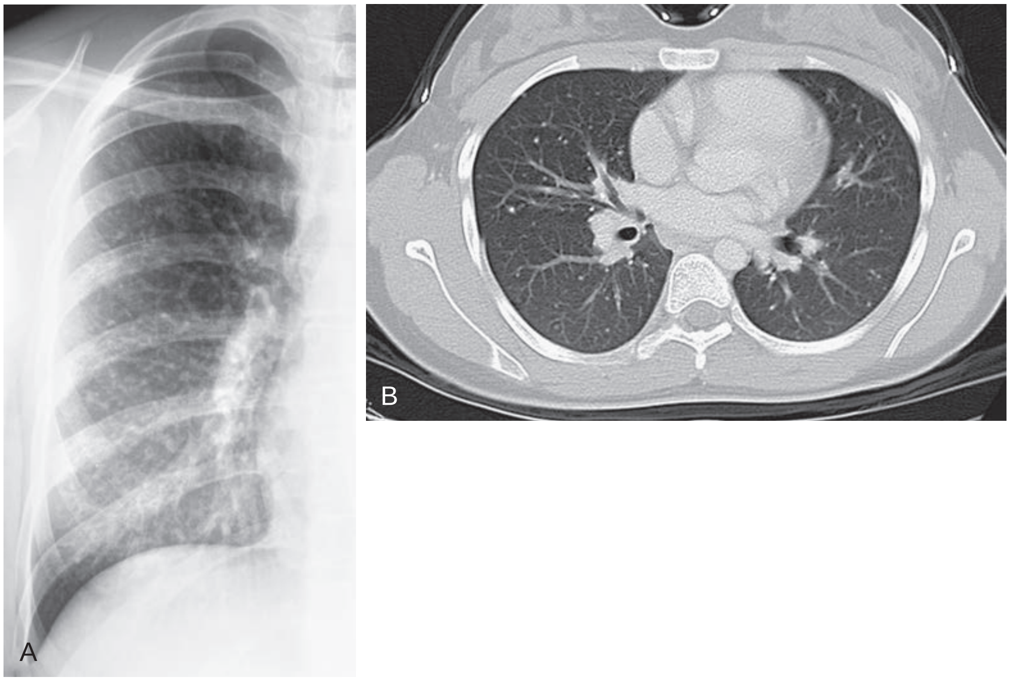
**e-Figure 54.3. Lethal H1N1 influenza in an 8-month-old boy who presented with shortness of breath and fever during an outbreak of epidemic flu.** (A) The radiograph shows nonspecific increased perivascular markings and somewhat low lung volumes. (B) The contrast-enhanced computed tomography (CT) scan demonstrates consolidation in both lower lobes. (C) The follow-up CT scan after 1 month showed progression of the consolidations. Soon after this scan was obtained, the baby died from cardiopulmonary failure.



**e-Figure 54.4. A 12-year-old girl with leukemia and measles pneumonia.** (A) Initial radiographic examination showing a diffuse bilateral reticulonodular infiltrate, reflecting the interstitial distribution of the disease. (B) Close-up of the right lower lobe showing the reticulonodular pattern to better advantage.



**e-Figure 54.5. Cytomegalic virus infection in a 14-year-old boy with acute lymphoblastic leukemia and immunodeficiency, presenting with dyspnea, fever, cough, and decreased white blood cell counts.** (A) The radiograph shows bilateral ill-defined pulmonary vasculature, more prominent in the lower lung zones. (B) The contrast-enhanced computed tomography scan demonstrates bilateral ground-glass opacities with relative sparing of the peripheral parenchyma.



**e-Figure 54.6. Chickenpox pneumonia in a teenager.** (A) The detail from a frontal chest radiograph early in the disease reveals diffuse nodules throughout the right lung. (B) A computed tomography scan done for clarification reveals nodules ranging from 2 to 4 mm, and many are densely calcified.

In EBV infection, hilar and mediastinal lymph node enlargement may be seen (e-Fig. 54.7). Pulmonary involvement is uncommon but is characterized by bilateral reticular perihilar infitrates.[65]

***Treatment and Follow-up.*** Effective antiviral therapies have not been established, and treatment of viral pulmonary infections is mainly supportive. Experimental treatments to correct the acquired surfactant deficiency and dysfunction that occurs in critically ill infants with viral pulmonary infections are actively being investigated.[52] With a few exceptions, the use of extracorporeal membrane oxygenation to treat severe respiratory failure from ARDS, which frequently complicates severe infections, has not led to better outcomes than those of optimal less invasive supportive care.[52] Certain high-risk infants may qualify for prophylactic injection of monoclonal antibodies against the F-glycoprotein of RSV. Because the most important complication of viral pulmonary infection is a superimposed bacterial infection, this should be actively looked for and treated with antibiotics when confirmed.[2]

## PULMONARY INFECTIONS CAUSED BY BACTERIA AND BACTERIA-LIKE ORGANISMS

Bacterial pulmonary infections are acquired through inhalation, aspiration, hematogenously, or rarely by direct extension of chest wall or extrathoracic sites. Their course is determined by the balance between the virulence of the organism and the host immune response (mainly humoral, B-cell–mediated immunity, and macrophageal activity). They are characterized by alveolar airspace consolidation, visible as one or more focal lung opacities that exhibit air bronchograms and obliterate normal air–soft tissue interfaces (the silhouette sign). Pleural effusions are common. The most common bacteria and bacteria-like agents causing pulmonary infections in children are listed in Table 54.2.

In young children, the classic segmental or lobar airspace consolidation is rarely present, and it is nearly absent in neonates. This is reflected by the reported low 30% positive predictive value of radiographic criteria for a bacterial cause of pneumonia, accounting for a widespread overprescription of antibiotics and development of antibiotic-resistant bacteria.[1,34] On the other hand, the high 92% negative predictive value of radiographic criteria for bacterial pneumonia is helpful, allowing clinicians to withhold antibiotics in symptomatic children with a negative chest radiograph and to focus on other potential sources of the fever.[1,34] It is therefore important not to overcall pediatric chest radiographs for the presence of a pulmonary infection, which is the most common interpretation error made by radiologists unfamiliar with pediatric imaging.[66,67]

Clinically occult pneumonia may be diagnosed with radiography in up to 19% of children less than 5 years old with fever of unknown origin and leukocytosis, although a more recent study found a lower incidence (5.3%) and a low utility of radiography when cough was not one of the presenting symptoms in this setting.[68,69]

### Aerobic and Facultative Organisms

#### *Streptococcus pneumoniae*

***Etiology.*** *Streptococcus pneumoniae* is the most common cause of bacterial pneumonia in children less than 5 years of age. It is a gram-positive diplococcus that infects healthy patients but also commonly attacks those with underlying illness, including the hospitalized and immunocompromised, and children with sickle cell anemia.[70] A strong association with a preceding viral infection, in particular influenza, is seen.[71] The virally activated respiratory epithelium has an increased expression of receptors for pneumococcal attachment.[72] In the usual case of an infected but otherwise healthy child, the onset is acute with fever, headache, and abdominal or chest pain with respiratory symptoms and signs. Rapid clinical resolution usually occurs within 24 to 48 hours after treatment with antibiotics in patients with uncomplicated infections. However, a rapid increase has been seen in the incidence of partially or fully penicillin-resistant strains of *S. pneumoniae*.[73] After the institution of conjugate pneumococcal vaccination, the proportion of children younger than 5 years with suspected occult pneumococcal pneumonia confirmed by radiography decreased from 15% to 9%.[74]

***Imaging.*** Pneumococcal pneumonia is usually confined to one lobe, but only rarely is the entire lobe consolidated. A pattern of homogeneous airspace consolidation is usual but not invariable, especially in the presence of underlying lung disease. This pneumonia may initially have a strikingly round appearance in children younger than 8 years (Fig. 54.8), simulating an intrapulmonary mass or abscess, until it spreads further to reach a normal anatomic boundary such as a fissure.[1,75,76] Large pleural effusion, empyema, and lung necrosis are infrequent complications, seen in less than 30% of patients. Resolution on radiographs is usually complete by 6 to 8 weeks.

#### *Streptococcus pyogenes* (Group A Streptococci) and *agalactiae* (Group B Streptococci)

***Etiology.*** Group A streptococcus usually produces tonsillitis or pharyngitis. In the 1990s, *S. pyogenes* pneumonia, often associated with the toxic shock syndrome, was increasingly reported in childhood. It may occur de novo in a healthy child or follow a viral infection. In neonates, group B streptococcus is a leading cause of sepsis, including pneumonia and meningitis.

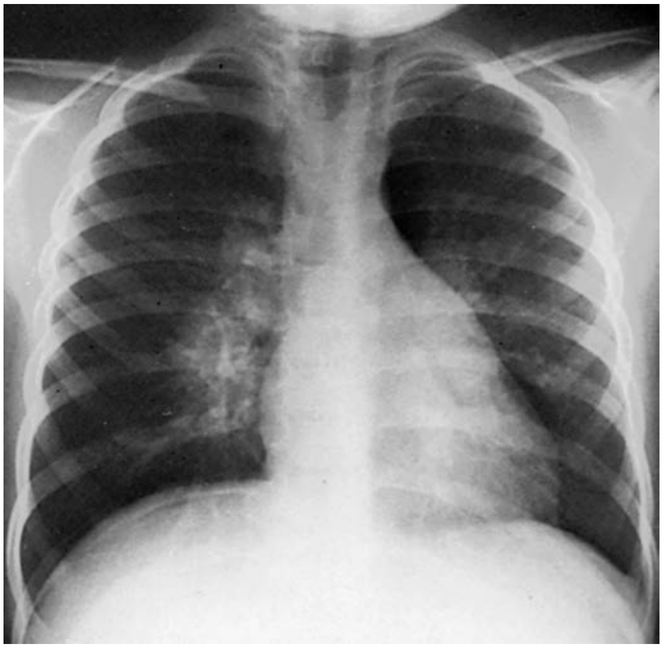
***Imaging.*** Group A *Streptococcus* produces a bronchopneumonia in a segmental configuration with either homogeneous or patchy consolidation, which frequently affects a lower lobe. It may be bilateral. Pleural effusion and empyema are common in untreated cases. Lung abscess may be a complication. Clinically and on imaging studies, this pneumonia is very similar to staphylococcal pneumonia, although pneumatoceles are less commonly seen. Group B *Streptococcus* may accompany or mimic hyaline membrane disease in neonates and is radiographically difficult to distinguish from it, although the presence of pleural effusion favors (concomitant) infection.

#### *Staphylococcus aureus*

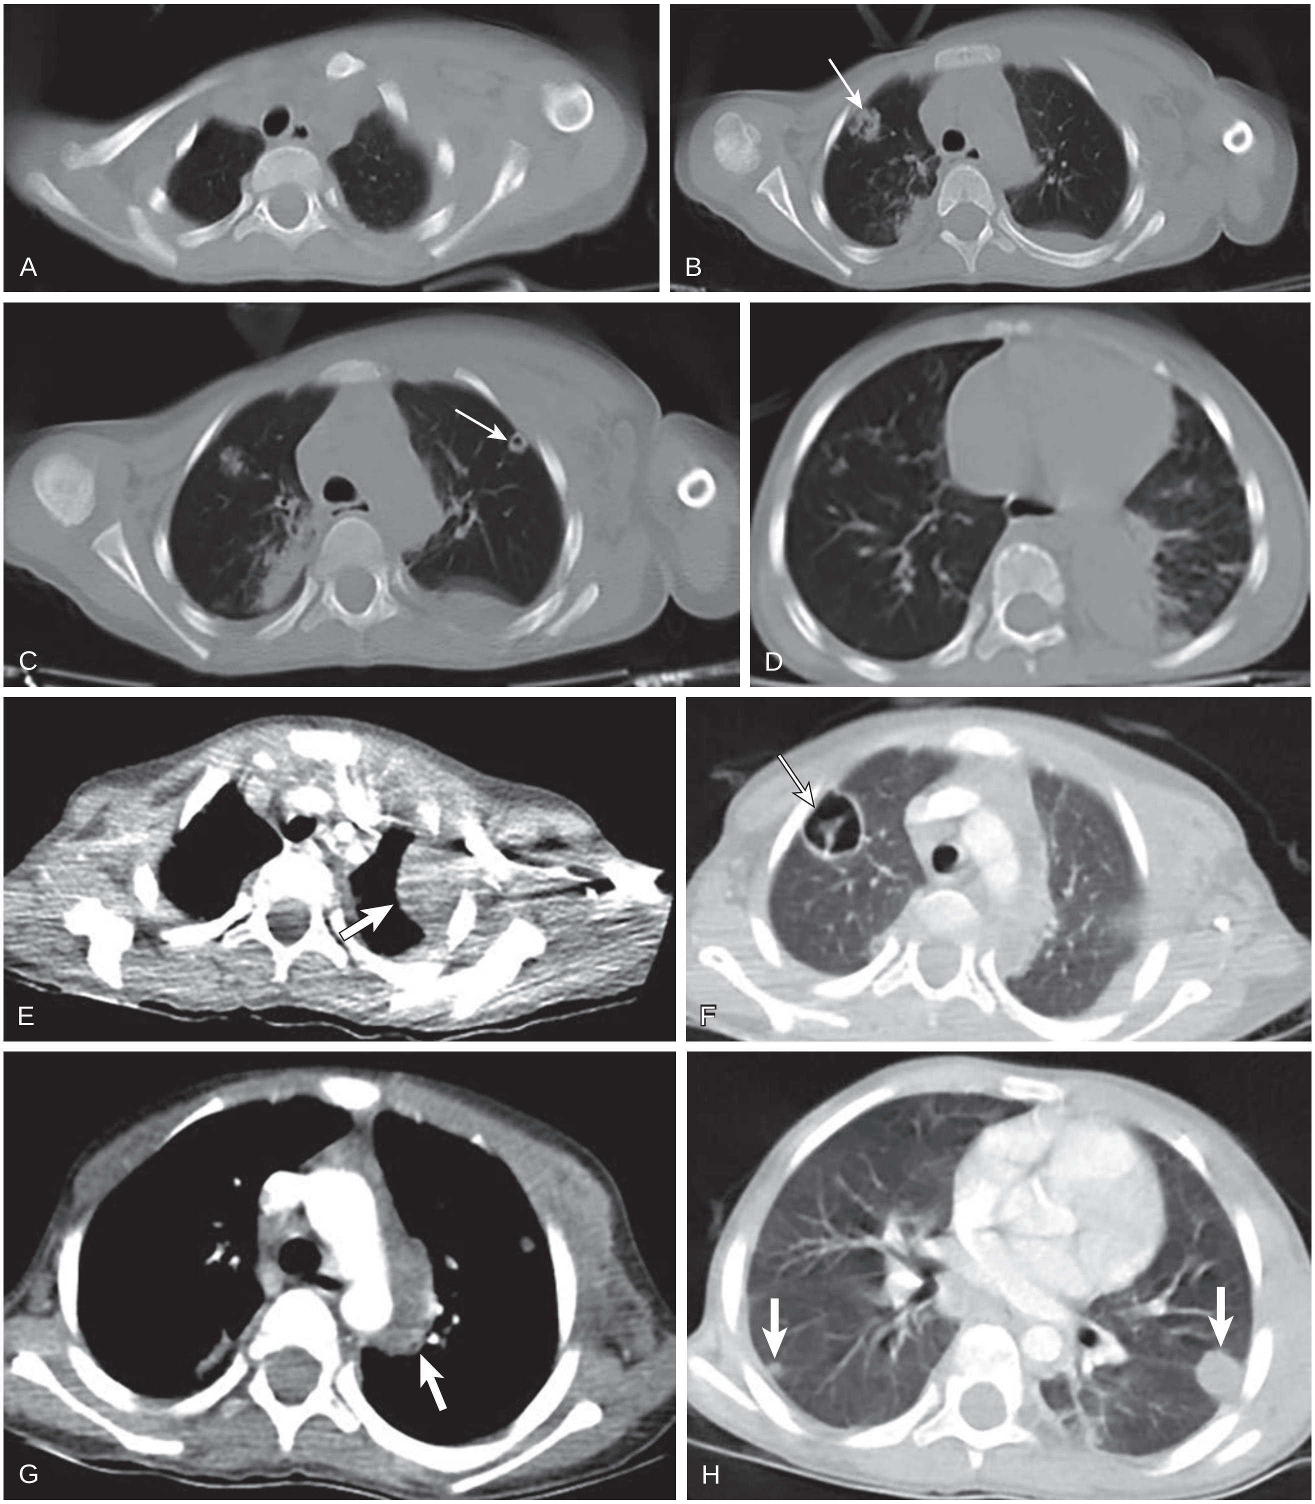
***Etiology.*** This gram-positive, catalase-positive coccus primarily affects infants under 1 year of age (70%). The incidence of "primary" staphylococcal pneumonia has decreased markedly since the early 1950s. However, staphylococcal pneumonia secondary to septicemia rather than inhalation of organisms is increasing and occurs in older children. This form of "embolic" disease may present with multiple nodular masses or abscesses (e-Fig. 54.9). This evolving pulmonary pattern in a child with sepsis should initiate a search for a distant source of infection, often in bones, joints, or skin.[77] Despite extensive pulmonary disease, if recovery occurs it is usually without sequelae. In comparison with methicillin-sensitive strains, methicillin-resistant strains of community-acquired *S. aureus* cause more serious pneumonias in younger children.[78,79]

The more invasive and virulent strains of *S. aureus*, which carry the genetic marker Penton-Valentin leucocydin (PVL), are responsible for the most serious primary or metastatic infections of the lungs that are acquired in community settings.[80]

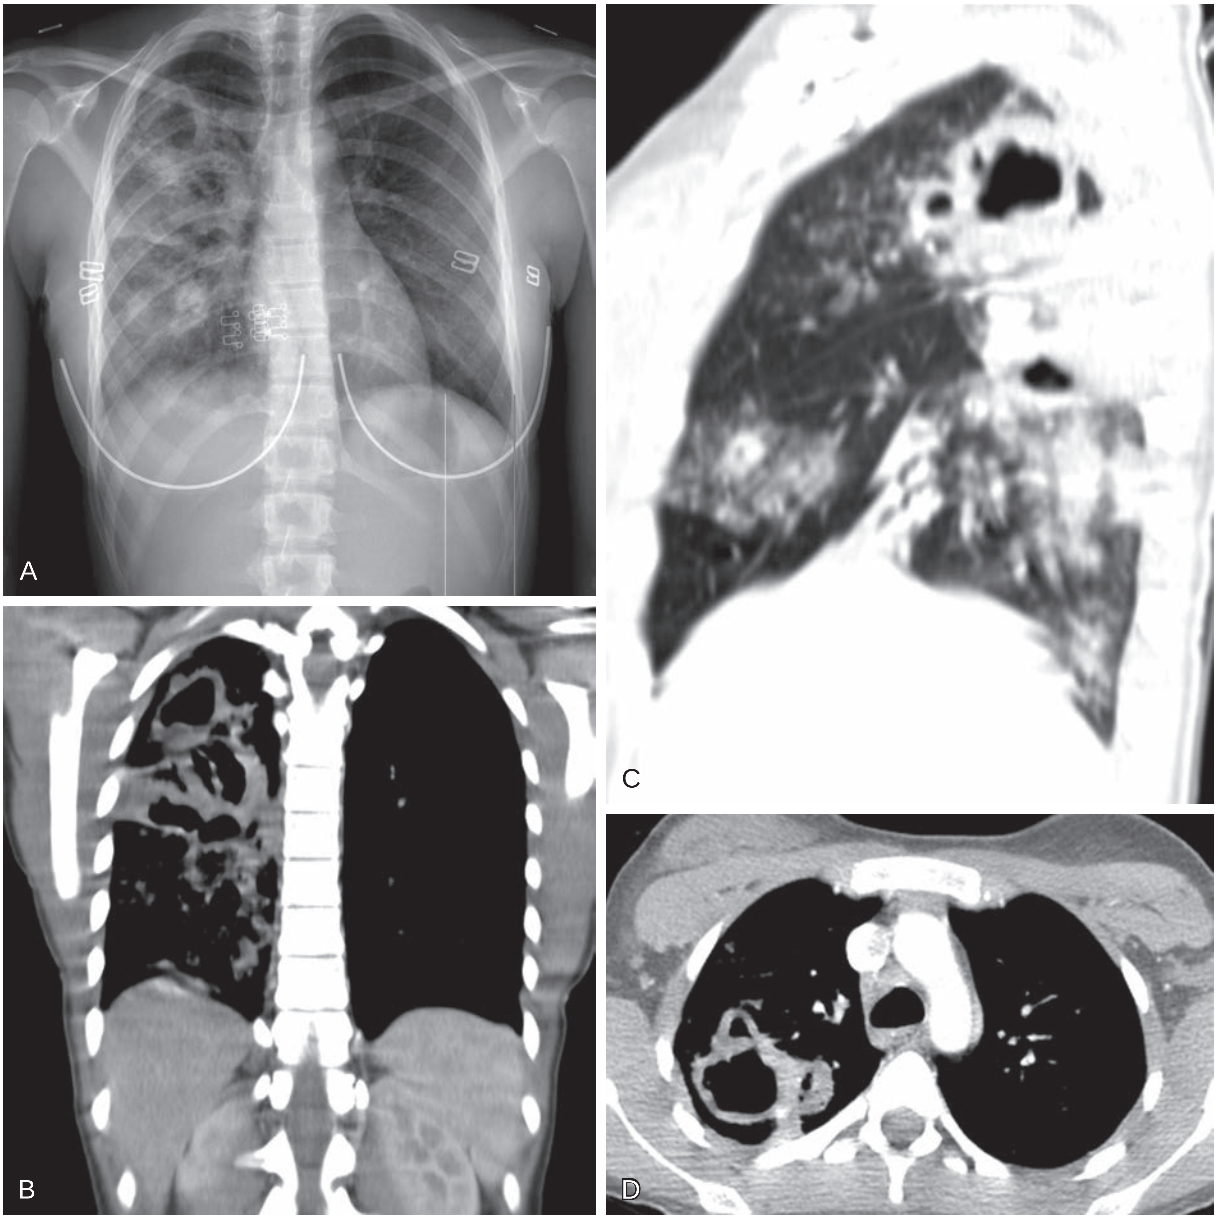
***Imaging.*** In contrast to pneumococcal pneumonia, staphylococcal pneumonia is a lobular or bronchopneumonia, which begins in the airways rather than in the alveoli (e-Fig. 54.10). Consolidation of peribronchiolar acinar units occurs initially in a segmental distribution. This infectious agent is very virulent, and severe hemorrhagic pulmonary edema may develop rapidly. Pneumatoceles are more common than in any other type (also reported in



**e-Figure 54.7. Mononucleosis in a teenager with hepatosplenomegaly and lymphadenopathy.** The chest radiograph reveals marked bilateral hilar adenopathy. Lymphoma was considered, but infectious mononucleosis was diagnosed. *(Courtesy of Dr. Jack Sty, Milwaukee, WI.)*



**e-Figure 54.9.** ***Staphylococcus aureus*** **septicemia in 4-year-old male Syrian refugee, who presented with loss of consciousness, dyspnea, fever, and swelling in the left axilla and right forehead. The swelling in the right forehead was punctured and a purulent discharge was observed.** (A–D) A noncontrast enhanced computed tomography (CT) demonstrates soft tissue swelling in the left axilla that extends into the soft tissues along the left hemithorax. There are also multifocal airspace opacities and multiple cavitating nodules involving both lungs. Based on the CT findings *Staphylococcus* sepsis was suspected, and the diagnosis was confirmed by blood cultures and cultures from the wounds. (E–H) Follow-up CT after 16 days demonstrates improvement of the inflammatory soft tissue changes and airspace opacities; however, some parenchymal nodules show progression and cavitation associated with occurrence of new nodules.



**e-Figure 54.10.** ***Staphylococcus aureus*** **pneumonia in a 15-year-old girl who presented with a 3-day history of fever, cough, fatigue, and vomiting.** (A) Radiograph shows patchy air space opacities and multiple cavitary lesions involving the right lung. (B–D) Contrast-enhanced computed tomography demonstrates diffuse patchy airspace opacities and multiple cavities with thick walls in the right lung. Blood cultures yielded *S. aureus.*

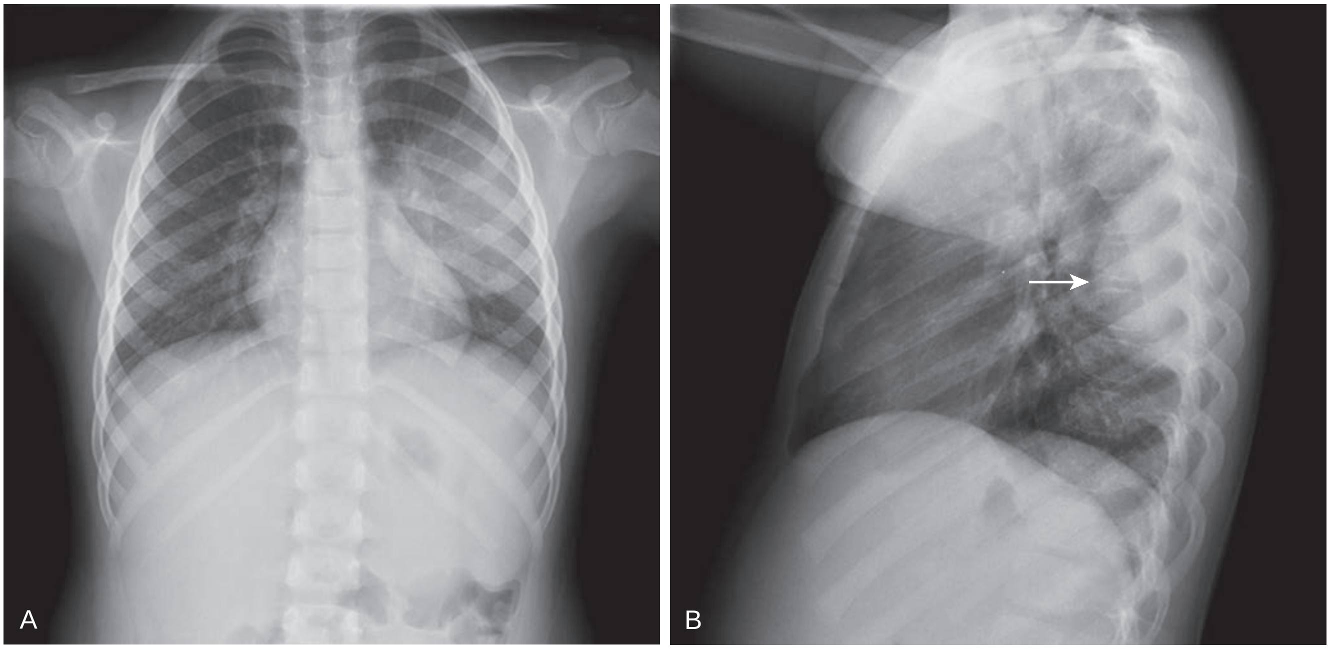


**Figure 54.8. Streptococcal round pneumonia in a 5.5-year-old girl presenting with fever and left-sided back and rib pain.** Frontal (A) and lateral (B) radiographs show alveolar consolidation in the superior segment of the left lower lobe with a rounded appearance (*arrow* in B). Note in (A) the visibility of the left hilar shadow, which is superimposed on the posteriorly located pulmonary pseudomass (hilar overlay sign).

*S. pneumoniae*, *H. influenzae*, and *Escherichia coli* pneumonia) and occur in 40% to 60% of patients.[78,81,82] Ten percent of children with staphylococcal pneumonia have a pneumothorax, which may result from the rupture of a pneumatocele.[78,81,82] Pleural effusion and empyema are also very frequent, occurring in more than 90% of children (Fig. 54.11).[82]

### *Haemophilus influenzae* Type B

***Etiology.*** *Haemophilus influenzae* is a gram-negative, rod-shaped bacterium, which was first discovered in 1892 during an influenza pandemic. In infants and young children, it causes bacteremia, pneumonia, cellulitis, epiglottitis, and meningitis. Since 1990, vaccination has markedly reduced the incidence of this pneumonia (<95%).

***Imaging.*** The radiographic appearance of pneumonia due to *H. influenzae* is nonspecific: pulmonary opacities that often begin as a segmental, interstitial-appearing process progresses to airspace consolidation.[83] Approximately two-thirds of cases have unilateral involvement, but more than one lobe is involved 25% of the time.[83] Empyema is a common complication, occurring in about 40%.[83]

### *Bordetella pertussis*

***Etiology.*** *Bordetella pertussis* is a gram-negative, aerobic, capsulated coccobacillus. The incidence of pertussis (whooping cough) has decreased significantly with immunization, but it is still seen in young infants, particularly in the unimmunized. This agent is spread by airborne droplets. A characteristic clinical sign is the paroxysmal cough (whoop). Even after convalescence, the patient's cough may persist for weeks or months. In China the disease has been called "the cough of 100 days."

***Imaging.*** Abnormal but nonspecific findings are present in most patients with pertussis. Because this is an airways-centered disease, it may mimic viral airways disease and pneumonia. The classic appearance is that of the "shaggy heart" (e-Fig. 54.12). However, nonspecific findings such as hyperaeration, atelectasis, segmental consolidations, and hilar lymphadenopathy are seen more commonly. Bronchiectasis may be a long-term complication.

### *Pseudomonas aeruginosa*

***Etiology.*** *Pseudomonas aeruginosa* is a gram-negative, aerobic, rod-shaped bacterium, which is an opportunistic pathogen in humans. Lungs, urinary tract, and kidneys are the common sites of infection. *P. aeruginosa* usually occurs as a nosocomial infection and is a major problem for patients with cystic fibrosis, in which thick layers of lung mucus and alginate produced by the bacteria may limit the diffusion of oxygen. Diagnosis of this infection depends on the Gram stain of sputum or other bacteriologic specimens (e.g., lung tissue, bronchoscopic aspiration, and bronchoalveolar lavage fluid).

***Imaging.*** When the patient is infected by airway contamination, the process tends to involve both lung bases, with extensive bilateral parenchymal consolidation, patchy areas of disease with small abscess formation, or small regions of lobular emphysema. In the bacteremic form, widespread patchy or nodular shadows may be found throughout both lungs. Lung necrosis may also occur.

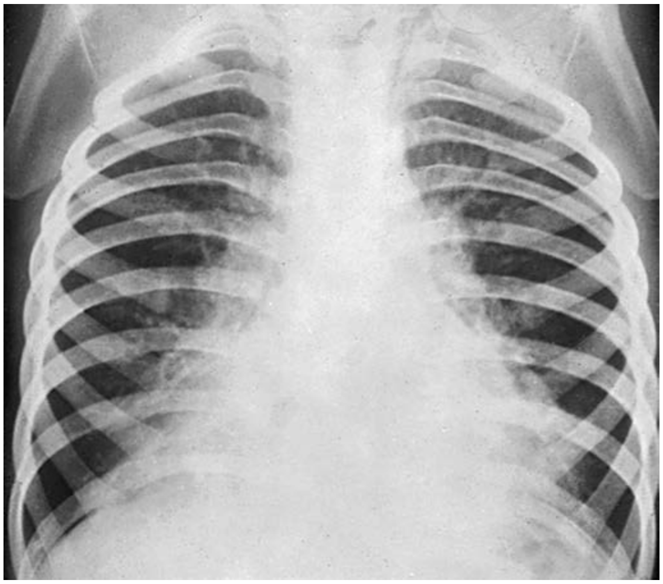
### *Legionella pneumophila*

***Etiology.*** *Legionella pneumophila* is an aerobic, pleomorphic, flagellated, gram-negative bacterium. It is the cause of legionnaires' disease, is mainly seen in immunocompromised patients, and is rare in children.[84,85]

***Imaging.*** Typically, initial radiographs show poorly marginated opacities that progress to more widespread consolidation, often accompanied by pleural effusion. Presentation as multiple pulmonary nodules has been reported but is less common.[85] Cavitation and abscess formation are complications.

## Anaerobic Organisms

***Etiology.*** Anaerobic bacteria are uncommonly responsible for pneumonia and lung abscess.[86] Aspiration is the most common



**e-Figure 54.12. Pertussis bronchopneumonia.** Bilateral basilar bronchopneumonia during the active phase of whooping cough. The heart contours are irregular ("shaggy heart").

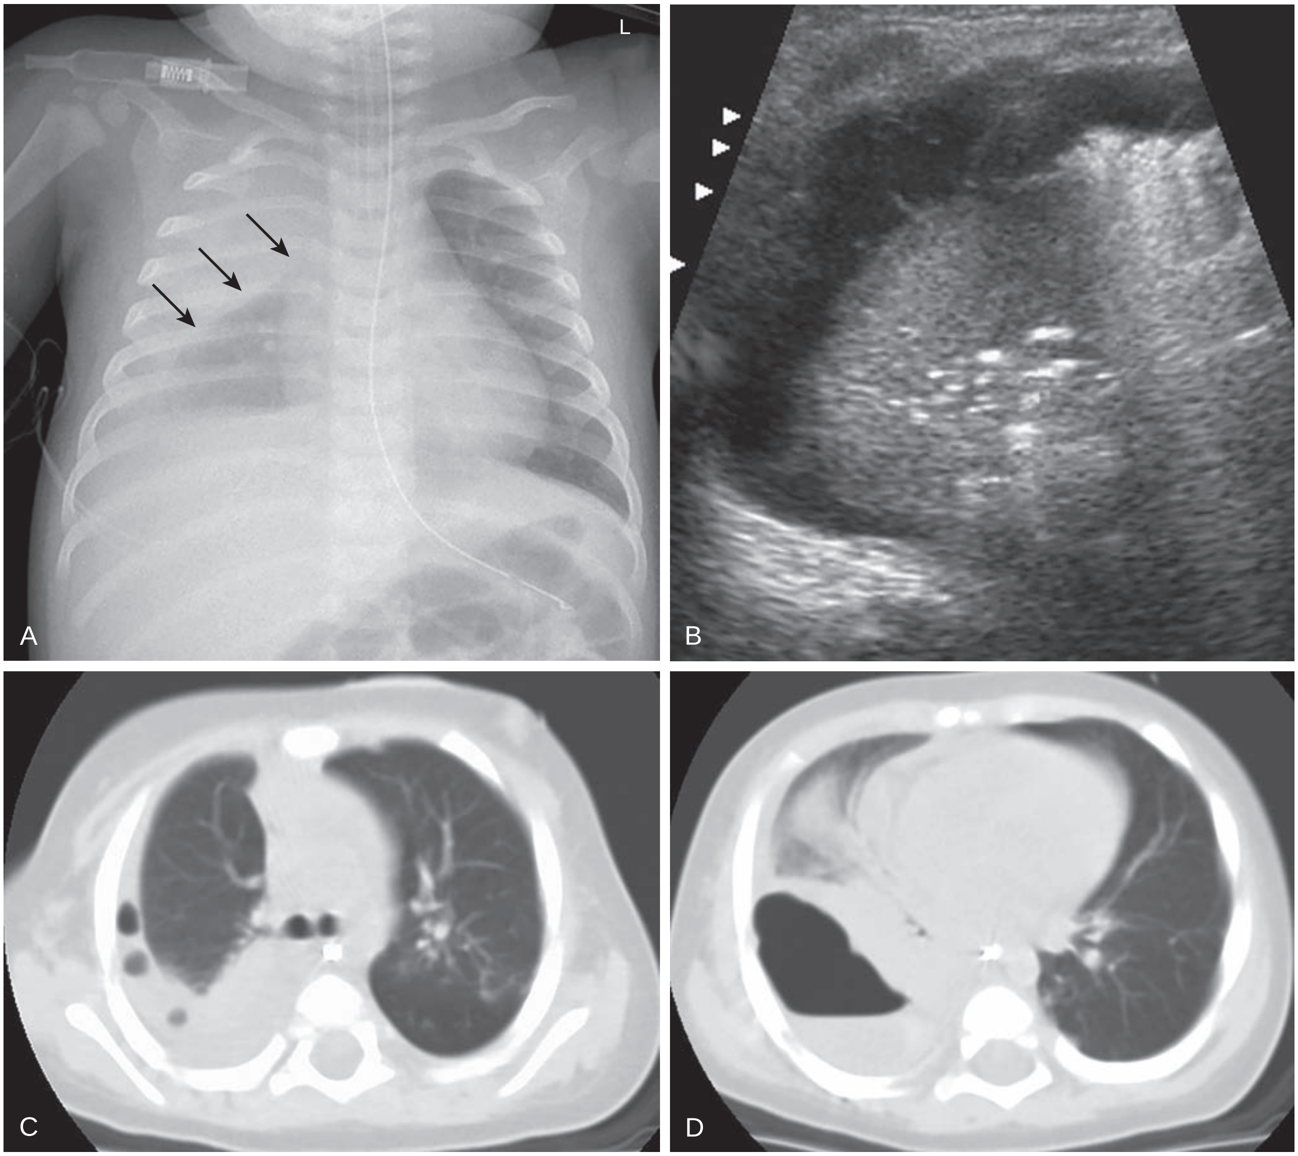


**Figure 54.11. Role of cross-sectional imaging in a 7-month-old girl with staphylococcal pneumonia and empyema.** (A) The radiograph demonstrates right pleural thickening, which has a convex margin toward the lung *(arrows).* (B) The transverse ultrasound image of the right chest shows a complex pleural effusion, containing thin septations. (C and D) Computed tomography confirmed the presence of loculated pleural fluid collections, containing trapped gas bubbles (C) and, more inferiorly, an air-fluid level (D). *(Reprinted with permission granted by Springer-Verlag of Westra SJ, Choy G. What imaging should be performed for the diagnosis and management of pulmonary infections?* Pediatr Radiol. *2009;39[suppl 2]:S178–S183 [Fig. 1, page S179].)*

route of exposure, and *Fusobacterium* species, *Bacteroides* species, *Peptococcus*, and *Peptostreptococcus* may be cultured from the abscess or the pleural fluid.

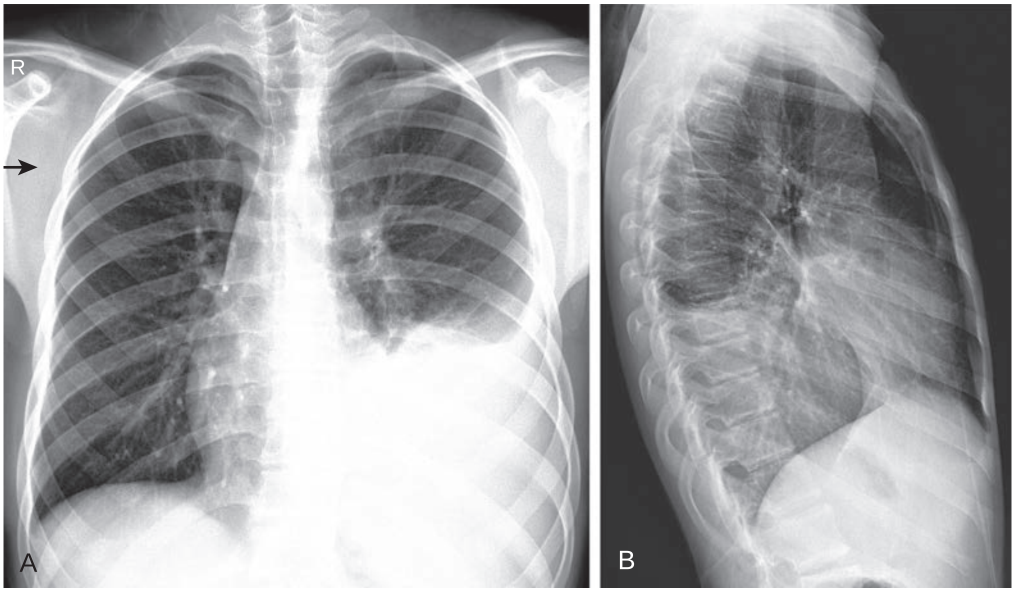
***Imaging.*** Usually, consolidation occurs in the lower respiratory tract, and the clinical course is slowly progressive (e-Fig. 54.13). Lung abscess (e-Fig. 54.14) and fulminant necrotizing pneumonia may eventually develop.

## Bacteria-like Organisms

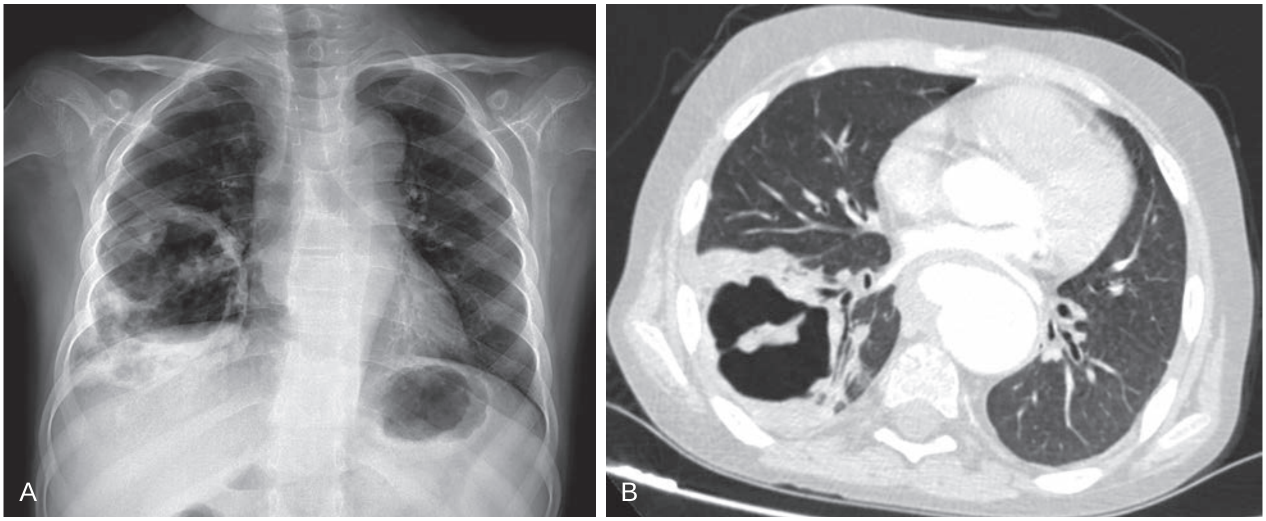
### *Chlamydophila trachomatis* and *pneumoniae*

***Etiology.*** *Chlamydia trachomatis* is an intracellular bacterium commonly found in the genital tract, where it causes urethritis in men and cervicitis in women. In neonates, it causes conjunctivitis, which is contracted during passage through an infected birth canal. *Chlamydia* is a common cause of pneumonia in infants between 2 and 14 weeks of age.[87] The infant is affected by a staccato-like cough and may have conjunctivitis and eosinophilia, although these are not invariable findings. Usually, the patient is afebrile, with a radiographic appearance suggesting an illness more severe than the clinical findings indicate. Recently *C. pneumoniae* has been recognized as a common agent causing community-acquired bronchitis and mild atypical pneumonia in school-age children.[3] The clinical response to appropriate therapy is usually rapid.

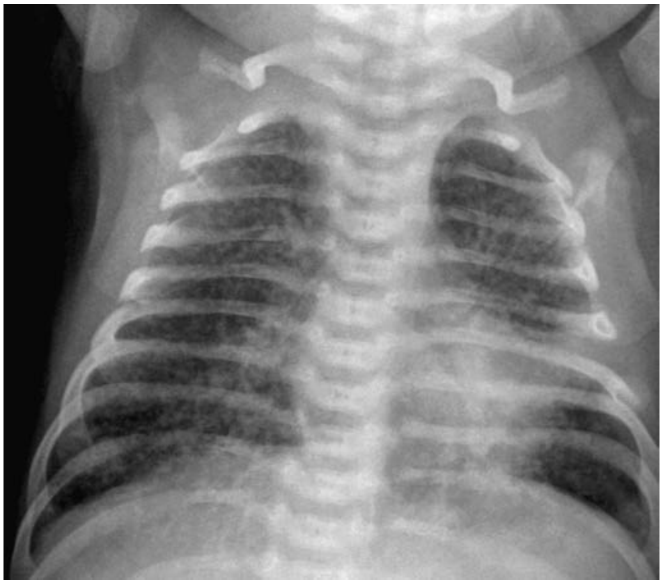
***Imaging.*** The radiographic findings of *C. trachomatis* infections are nonspecific (e-Fig. 54.15), but when they are analyzed in conjunction with clinical findings, the disease may be suspected. Bilateral involvement is usual.[88] The lungs are usually hyperaerated



**e-Figure 54.13. Anaerobic pulmonary infection in a 15-year-old boy who presented with chronic cough and chest pain without fever.** Frontal (A) and lateral (B) radiographs show a large opacity in the left lower thorax that obscures the diaphragm, consistent with consolidation with pleural fluid. Polymerase chain reaction on the drainage fluid from the pleural cavity was consistent with *Fusobacterium* infection.



**e-Figure 54.14. Anaerobic pulmonary infection in a 12-year-old boy with Wiskott-Aldrich syndrome presenting with multiple cerebral abscesses, septicemia, cough, and fever.** (A) The radiograph shows a thick-walled air cavity in the right lower lung zone. (B) Contrast-enhanced computed tomography depicts the pulmonary abscess. There is also a pseudoaneurysm in the descending thoracic aorta. Polymerase chain reaction test of the cerebral abscess was consistent with *Peptostreptococcus* infection.



**e-Figure 54.15. Chlamydial pneumonia in a 6-week-old boy with wheezing and a low-grade fever.** The frontal radiograph shows diffuse interstitial infiltrates with hyperinflation. Polymerase chain reaction results confirmed the diagnosis.

with increased linear density and patchy areas of consolidation, probably representing subsegmental atelectasis. Lobar consolidation is rare.[88]

## Mycoplasma pneumoniae

***Etiology.*** *Mycoplasma pneumoniae* is one of the most common causes of pulmonary infection in childhood, accounting for 10% to 30% of pediatric pneumonias.[89] It is most often seen in school-age children and is uncommon in children less than 3 years of age. It is acquired by droplet inhalation, and it is most commonly noted in families, in schools, and among military recruits. The disease is usually mild, with low-grade malaise, headache, fever, and cough. Stevens–Johnson syndrome (erythema multiforme) may complicate the disease. The diagnosis is established by culturing the organisms from sputum or by demonstration of rising specific *Mycoplasma* titers. A rise in the titer of cold agglutinins is seen in about 50% of cases but is nonspecific; of greater diagnostic value are immunofluorescent and complement fixation tests for specific antibodies and the recently developed molecular probes.[90]

***Imaging.*** This classic "atypical pneumonia" has a radiographic appearance that frequently mimics viral pulmonary infection (Fig. 54.16).[1] In early cases, a fine reticular pattern suggestive of interstitial inflammation may be seen.[91] This tends to be in a segmental distribution and in some cases progresses to airspace consolidation suggestive of bacterial pulmonary infection.[92,93] Small pleural effusions are seen in up to 20% of patients. Hilar adenopathy is common. Bilateral involvement occurs in approximately one-third of cases. The radiographic changes are frequently more severe compared with the patient's clinical condition. Resolution is often slow and lags behind clinical improvement.

## Treatment and Follow-up

Treatment of bacterial pulmonary infections is with antibiotics and other chemotherapeutic agents, focused on the causative agent, either presumed (empirical treatment) or preferably directed by the results of culture or immunoassay. Complications of bacterial pulmonary infections are lung necrosis, abscess, empyema, and bronchopleural fistula.[2] Ultrasonography is the most effective initial cross-sectional modality when pleural complications are suspected,[94-96] whereas CT is the preferred modality to diagnose parenchymal complications.[97-103] A review of the diagnostic performance of CT versus radiography confirms the expected higher sensitivity of CT.[99,104-111] CT is more sensitive than radiography to determine the cause of a delayed response to medical and percutaneous treatment of pediatric chest infections, but it is unclear whether this affects the eventual outcomes of treatment.[99,110] An initial trial of image-guided fibrinolytic treatment of empyemas has better outcomes that primary video-assisted thorascopic surgery (VATS).[94] Failure of this regimen and the eventual need for surgery may be expected in those in whom more virulent and antibiotic-resistant bacteria are isolated.[112] Cavitary lung necrosis is demonstrated well by CT.[111] However, most of the affected children recover without permanent sequelae on clinical and imaging follow-up.[1] For this reason, documentation of complete resolution of pneumonia in children who are otherwise healthy is not indicated.[1,35,113] CT and, potentially, magnetic resonance imaging (MRI) are helpful, however, to fully investigate any underlying focal anatomic cause such as anomalous bronchi, bronchogenic cysts, sequestrations, or bronchial atresia (Fig. 54.17), which may underlie recurrent or chronic pneumonia.[1,114-116] Conversely, the value of CT to monitor diffuse processes that predispose to repeated pulmonary infections such as chronic granulomatous disease of childhood and cystic fibrosis remains controversial.[117,118] Children with these chronic conditions will accumulate a substantial radiation burden from repeated examinations during their lifetime, and the theoretical risks of these procedures with regard to the induction of cancer will have to be balanced against the immediate clinical benefits, which remain unproven.[119] MRI has promise as a nonradiating cross-sectional imaging alternative for examination of these conditions.[114,120-122]

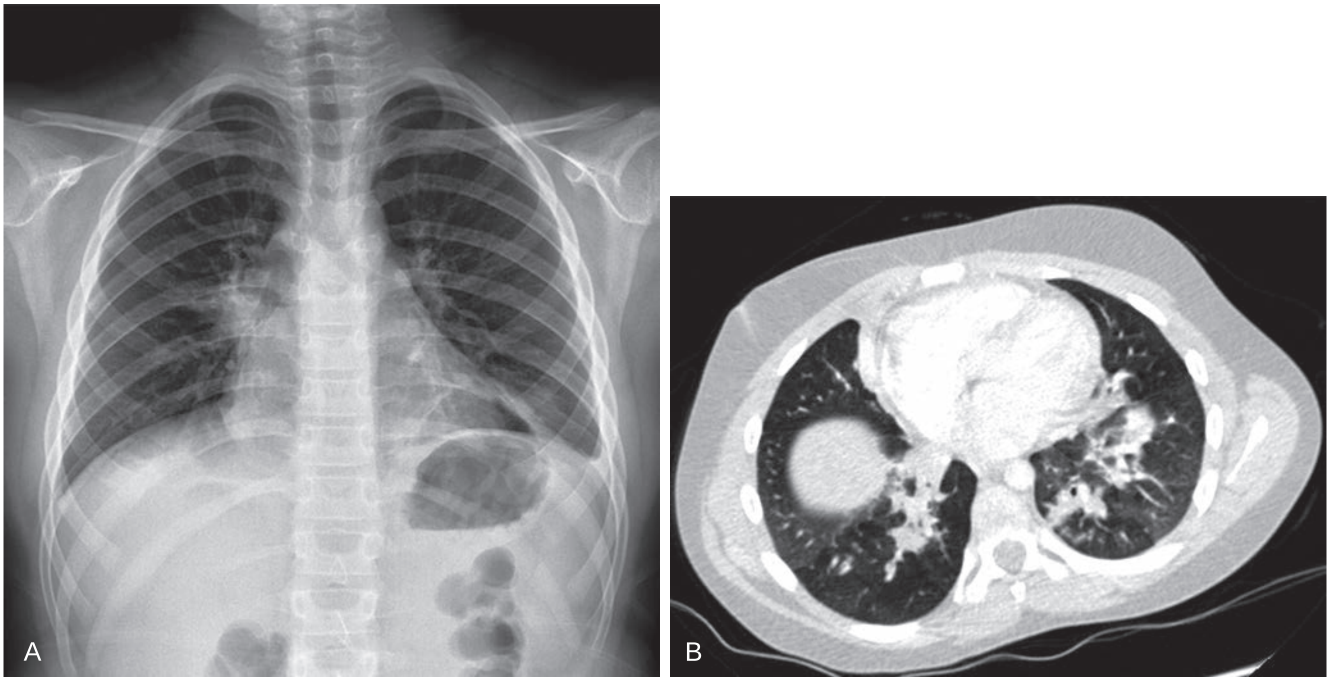


**Figure 54.16. Mycoplasma atypical pneumonia in an 8-year-old girl who presented with fatigue, low-grade fever, and cough.** (A) The chest radiograph shows irregularity of the right hilum and bibasilar infiltration. (B) Contrast-enhanced computed tomography demonstrates bilateral bronchopneumonia in the lower lobes. A direct fluorescent antibody test from nasopharyngeal aspirate confirmed the diagnosis.

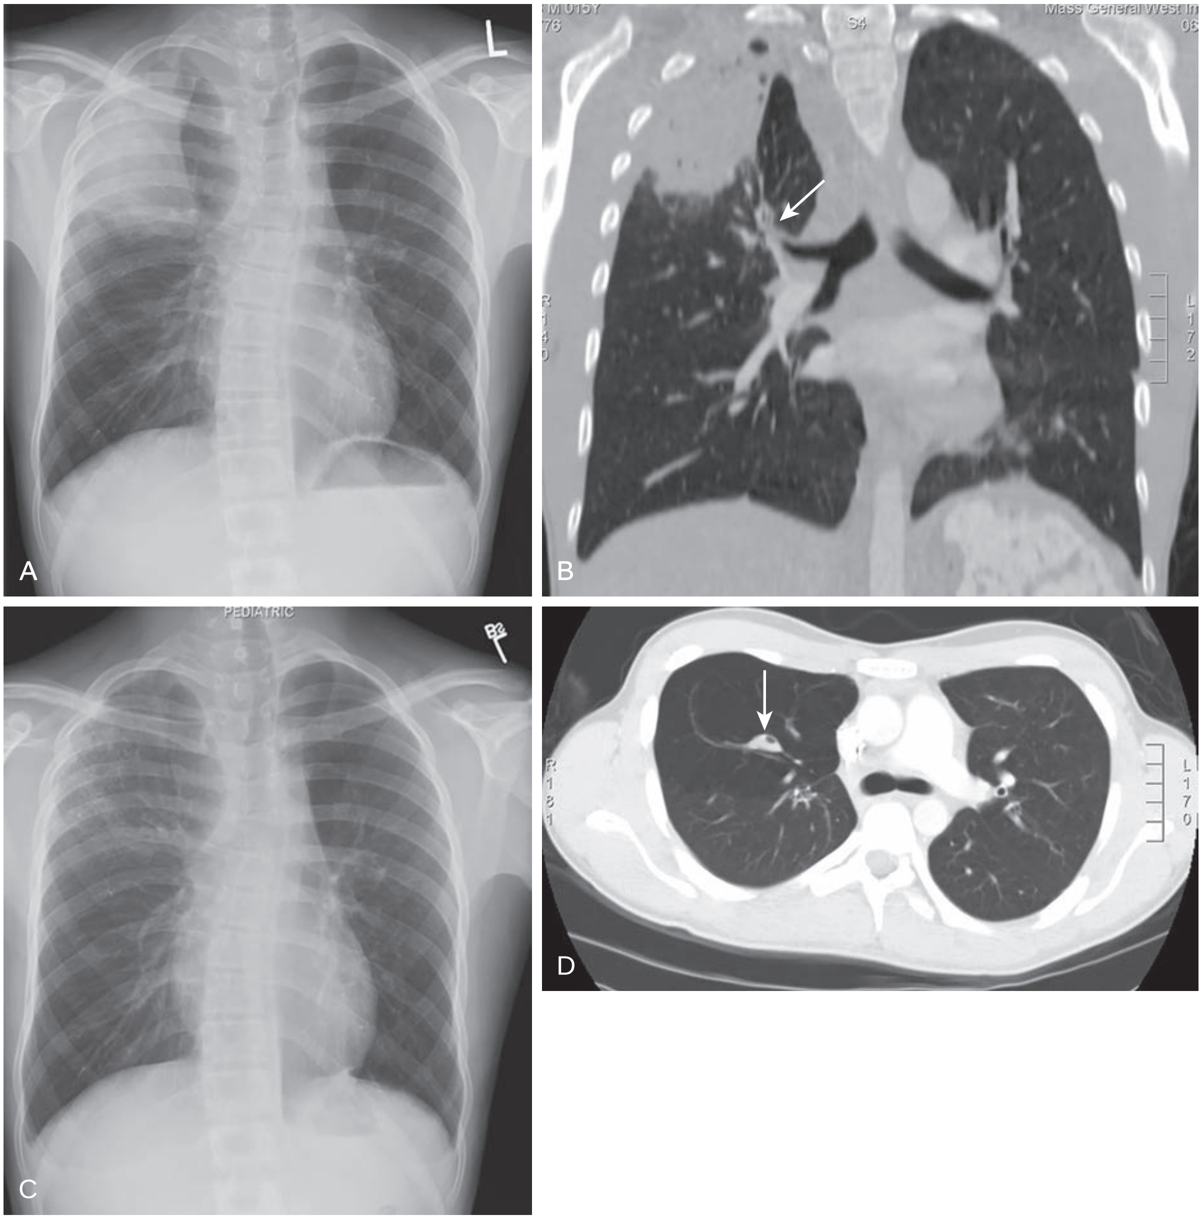

**Figure 54.17. Role of computed tomography (CT) in recurrent pneumonia in a 15-year-old boy with bronchogenic cyst and bronchial atresia.** (A) The chest radiograph shows consolidation in the right upper lobe and right upper mediastinal widening. (B) The CT scan shows atresia in the apical bronchus of the right upper lobe *(arrow)* and right mediastinal widening caused by a bronchogenic cyst. (C and D) The follow-up chest radiograph (C) and CT scan (D) show near-complete resolution of the pneumonia, with persistent architectural distortion of the right upper lobe. The atretic bronchus contains inspissated mucus (*arrow* in D). Right upper lobectomy and resection of the bronchogenic cyst was performed.

## Mycobacterial Infection—Pulmonary Tuberculosis

***Etiology.*** TB is caused by *Mycobacterium tuberculosis*, an aerobic, nonmotile, non–spore-forming rod. Although the resurgence of TB noted in the United States in the 1980s and 1990s has declined, in 2003, 15,000 new cases were reported, and the rate of decline appears to be slowing.[123] A significant number of new cases are diagnosed in foreign-born children, as well as immunocompromised patients (especially HIV).[124-127]

Inhalation of the tubercle bacillus is the most common route of infection in children. Congenital infection is extremely rare and is most often secondary to hematogenous spread across the placenta during pregnancy or from contaminated amniotic fluid. Pulmonary TB infection may be categorized into three groups: (1) primary infection; (2) miliary infection; and (3) reactive or postprimary infection.

The length of the incubation period of TB depends on the size of the initial inhaled inoculum and varies from 2 to 10 weeks; it ends when the patient becomes sensitized (i.e., has a positive skin test). Annual skin testing in high-risk groups is recommended. In the low-risk child, skin testing at 12 to 15 months, at 4 to 6 years, and in adolescence is a reasonable approach.[128] In asymptomatic primary tuberculosis, the disease is detected because of a routine skin test, and chest radiography is most often normal. In endemic areas, radiographs may demonstrate hilar lymphadenopathy only.[129-131] Because children produce little sputum, they do not

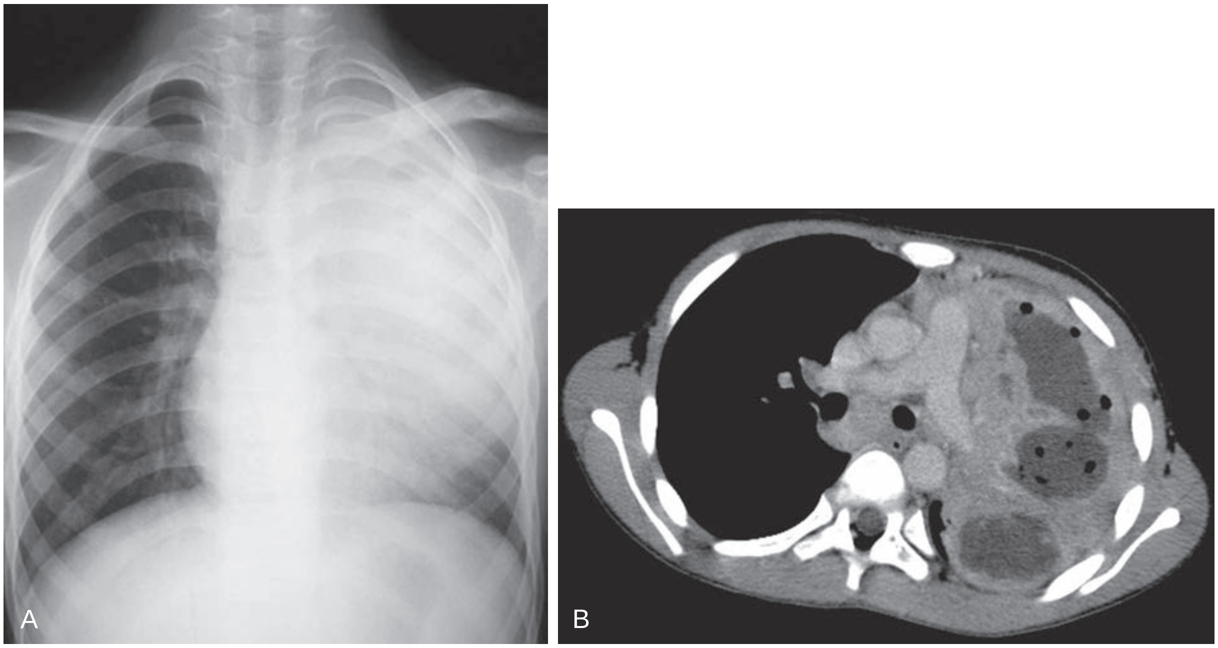

**Figure 54.22. Progressive primary tuberculosis in an older child.** (A) The radiograph shows dense consolidation with expansion in the left upper lobe, which contains an air-filled cavity. (B) Contrast-enhanced computed tomography demonstrates extensive liquefactive parenchymal disease *(Courtesy of Bernard Laya, MD.)*

transmit the disease to one another, and a search for the infected adult must be undertaken. The index child is always treated with antibiotics.

If radiographs are positive, usually a single small primary focus is present (70%), located in the subpleural region. From there, the bacilli spread through the lymphatics to regional hilar and mediastinal lymph nodes (primary complex, e-Fig. 54.18). In postobstructive tuberculosis, large lymph nodes may cause extrinsic bronchial compression, and granuloma formation may cause endobronchial obstruction, leading to segmental air trapping, atelectasis (e-Fig. 54.19), or both. Chronic obstruction may lead to bronchiectasis. Calcification occurs after caseation of the primary lesion and is seen earlier in infants (6 months after infection, e-Fig. 54.20) than in older children (2–3 years after infection, e-Fig. 54.21).

Progressive primary pulmonary tuberculosis is a serious but rare complication.[132] Progressive enlargement of the primary complex occurs, with caseation of the lesion followed by liquefaction (Fig. 54.22). The lesion may rupture into a bronchus, establishing new foci of disease (Fig. 54.23). Affected children are usually quite ill, with weight loss, dyspnea, anorexia, and failure to thrive. Pleural involvement in TB is usually noted in children older than 2 years, who present with fever, chest pain, and symptoms of pneumonia.[133]

The host response to lymphohematogenous spread is varied, with immunosuppressed patients being at greatest risk. A few children present with high spiking fevers, hepatomegaly, and positive blood culture (chronic tuberculous bacteremia, e-Fig. 54.24). Miliary tuberculosis usually occurs within 6 months of the primary infection and results from lymphohematogenous dissemination of *M. tuberculosis* from the primary complex.

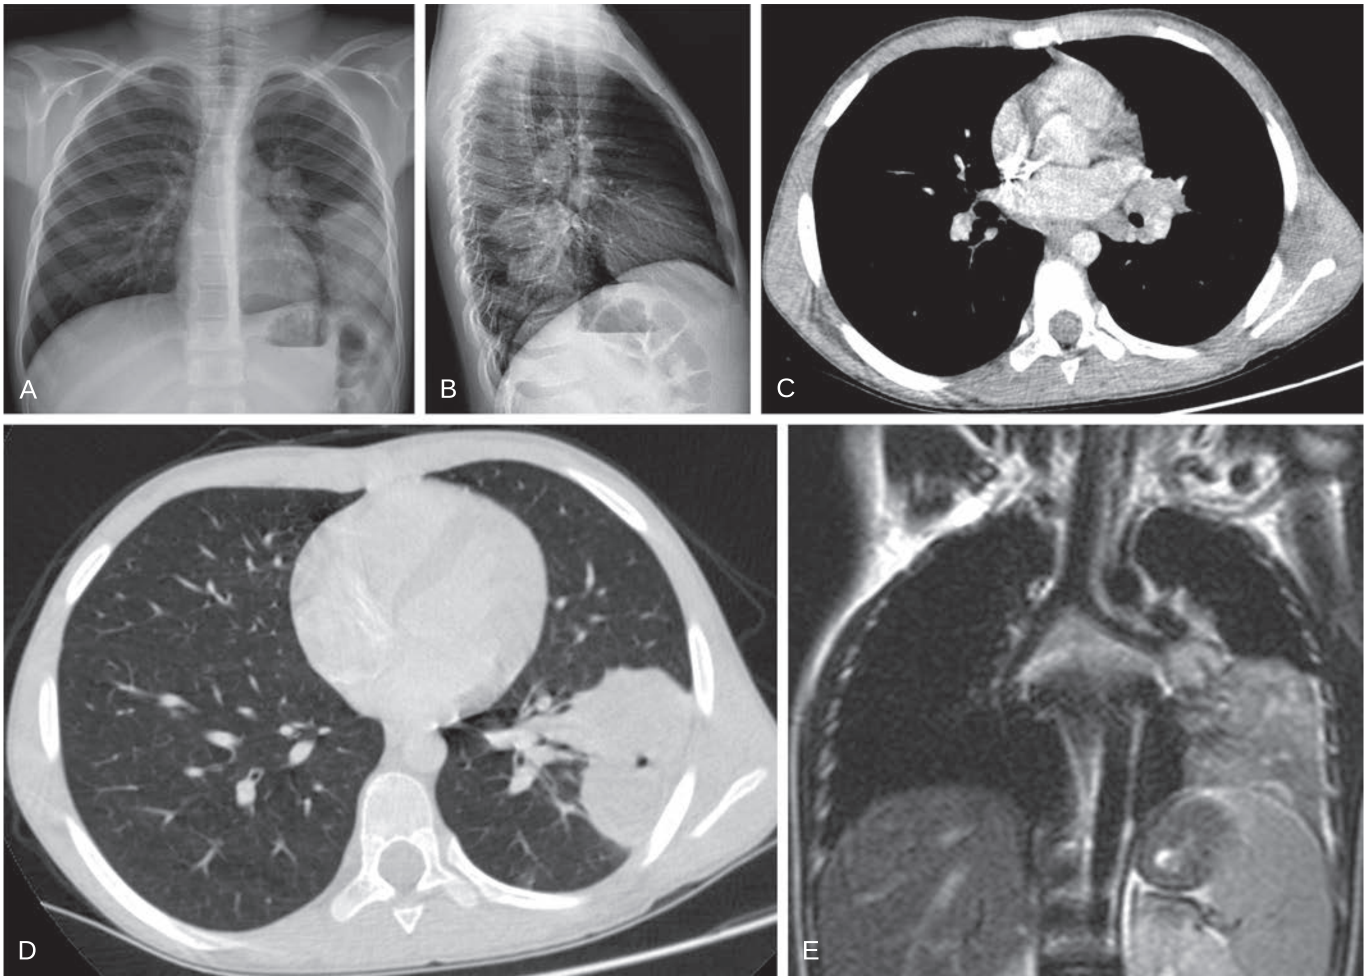
Reactivation or postprimary TB infection is the classic adult or adolescent form of the disease. It is the result of growth of previously dormant bacilli in the apices of the lung. Reactivation of tuberculosis is rare in children who were infected with primary tuberculosis before age 2 years. It is much more frequent in children whose primary infection occurred after age 7 years, particularly if they were initially infected near puberty.[123]

***Imaging.*** Primary TB infection of the lung falls under the subcategory of subacute dense focal (atypical) pneumonia (see e-Fig. 54.18).[28,134-136] Chest radiography is insensitive to primary infection.[137,138] With a positive skin test, screening with a frontal radiograph is often sufficient; however, in endemic areas the addition of the lateral radiograph improves detection of hilar lymphadenopathy.[129,139] Almost half (43%) of children diagnosed with tuberculous meningitis have normal chest radiographs.[140] CT typically shows a subtle parenchymal opacity with associated lymph node enlargement. When initial chest radiography is positive, hilar and peritracheal lymphadenopathy is the most common finding, present in 92% of the cases.[124,126] CT studies confirm that infected patients frequently have adenopathy that tends to be low density with rim enhancement and later calcification (see e-Figs. 54.18–54.20), but 50% may not have nodes larger than 1 cm and they may be contralateral to the parenchymal disease.[141] Miliary TB infection (see e-Fig. 54.24) produces a “snowstorm” pattern in the lung, liver, and spleen.[142] Occasionally this may be present before there is overt clinical manifestation of the disease; as expected, CT is more sensitive than chest radiography.[143,144] Regression of abnormalities is slow and may require from 6 months to 2 years to resolve on radiography and up to 15 months on CT evaluation (see e-Fig. 54.20).[126,145]

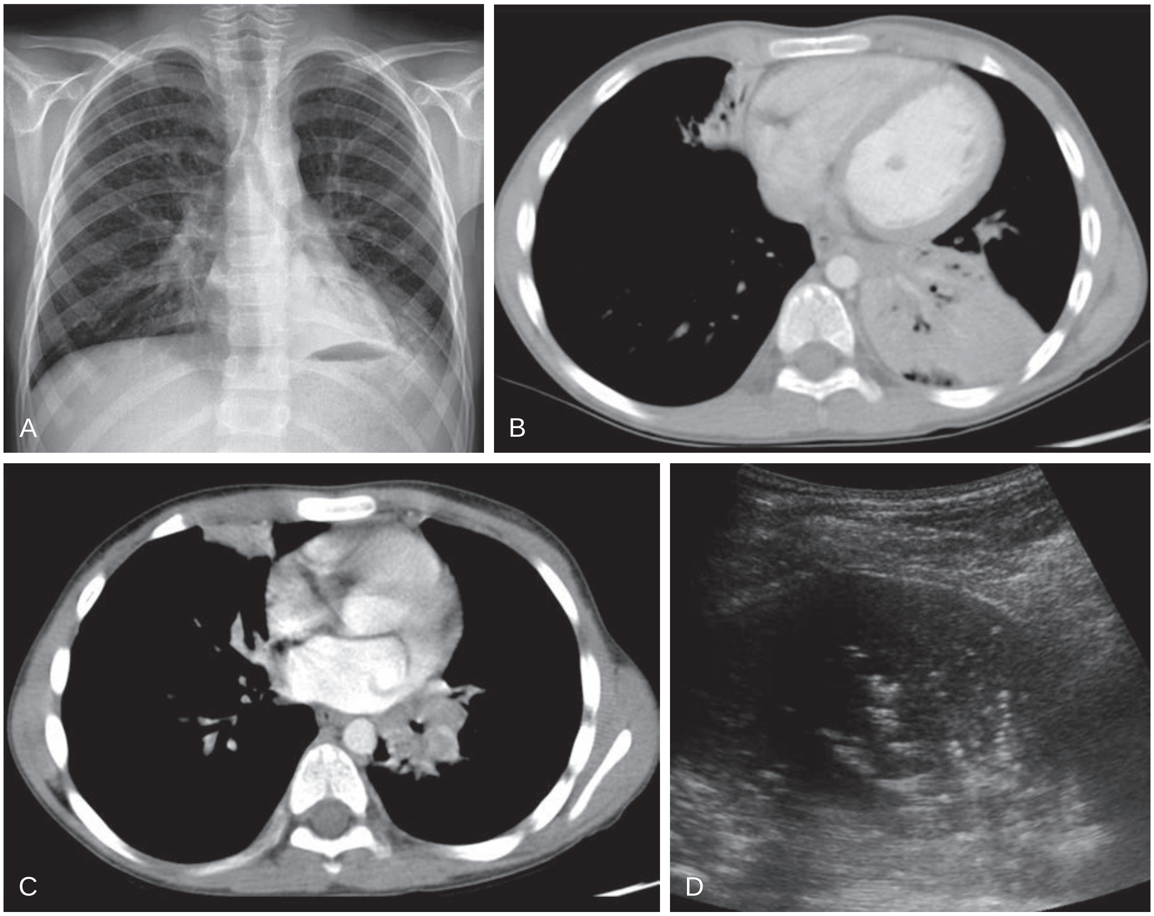
***Treatment and Follow-up.*** TB is treated with a combination of antibiotics and chemotherapeutic agents to which the organism is sensitive.[146] Multidrug resistance to the regimens is an increasing problem worldwide, but strategies for effective treatment and reinforcing patient adherence have proven successful, even in the developing world.[146] Because of the limited sensitivity of radiography, cross-sectional imaging with CT, when locally available, is frequently helpful for patient management (see e-Figs. 54.18 and 54.20, Figs. 54.22 and 54.23, and e-Fig. 54.24).[125,132,133,142,144,147]

## Nontuberculous Mycobacterial Pulmonary Infection

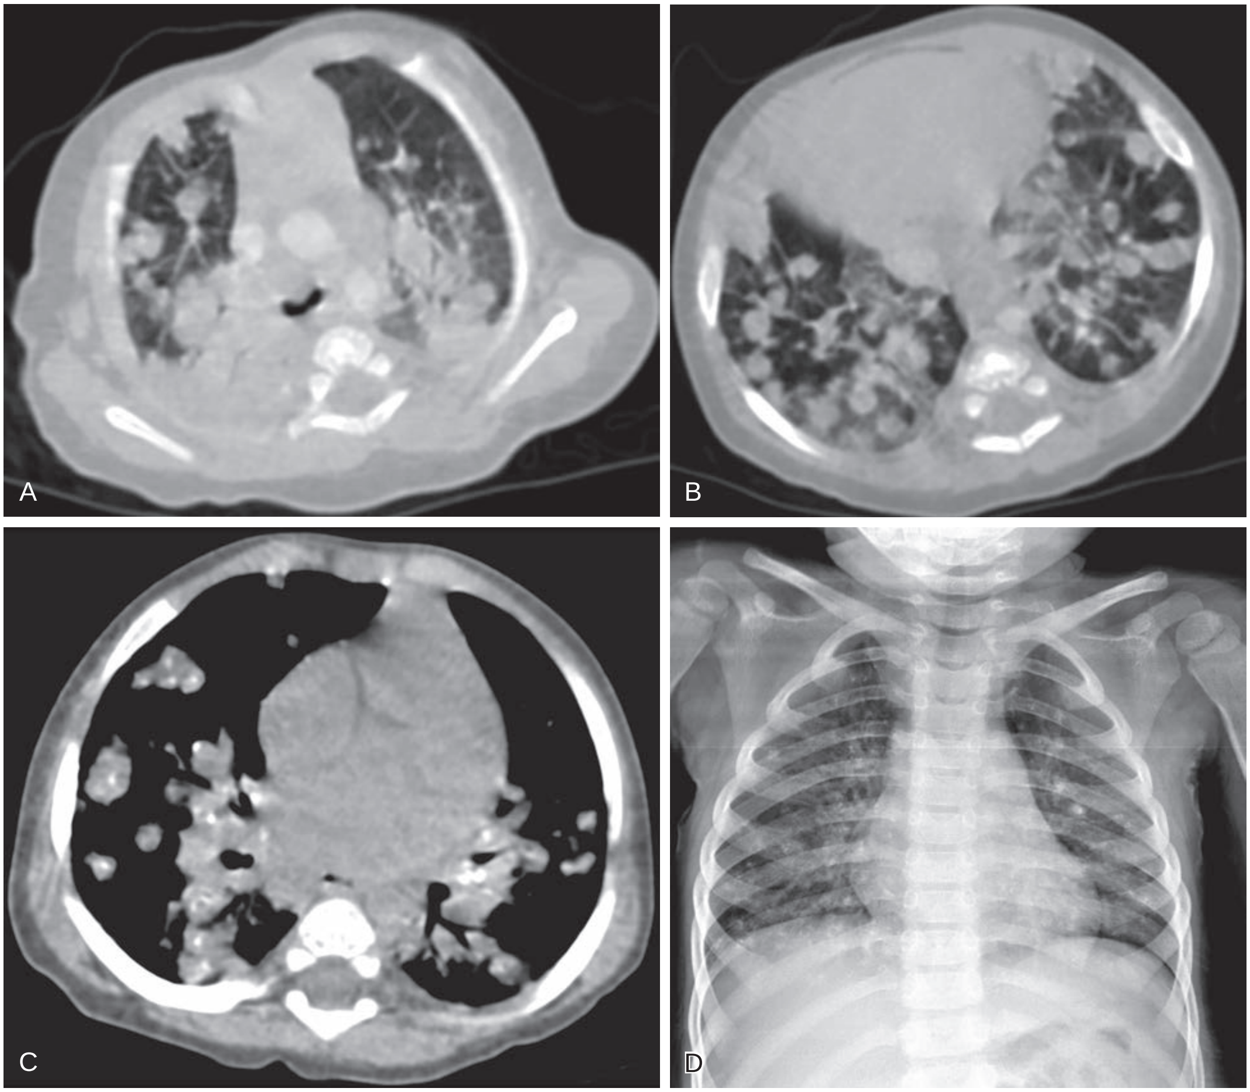
***Etiology.*** Nontuberculous mycobacteria (NTM) are widely distributed in the environment and may produce infection in patients with normal immunity, although infection is significantly



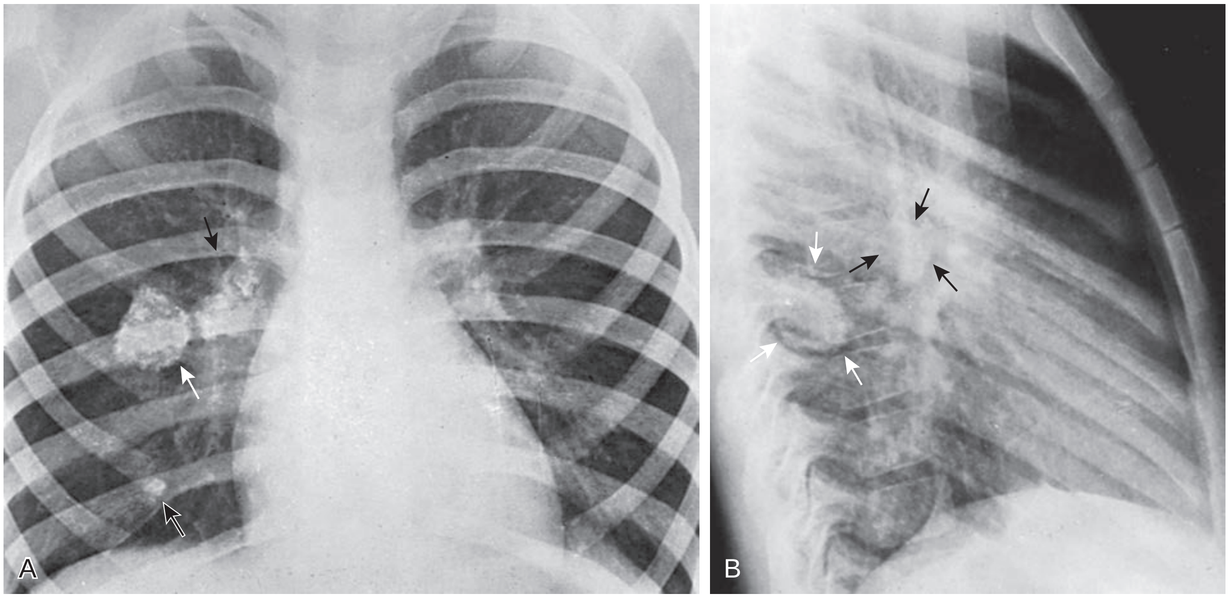
**e-Figure 54.18. Primary tuberculosis (TB) in an 8-year-old boy who presented with cough, abdominal pain, and fatigue.** (A and B) Radiographs show nodular consolidation in the left lower lung zone and an enlarged left hilum. (C and D) Contrast-enhanced computed tomography demonstrates a peripheral consolidation in the left lower lobe, associated with enlarged left hilar lymph nodes. (E) On coronal T2-weighted magnetic resonance imaging, the consolidation and lymph nodes exhibit high signal intensity. The parenchymal consolidation and associated ipsilateral lymph nodes constitute the primary Ghon complex in TB. Culture of bronchial lavage fluid confirmed the diagnosis.



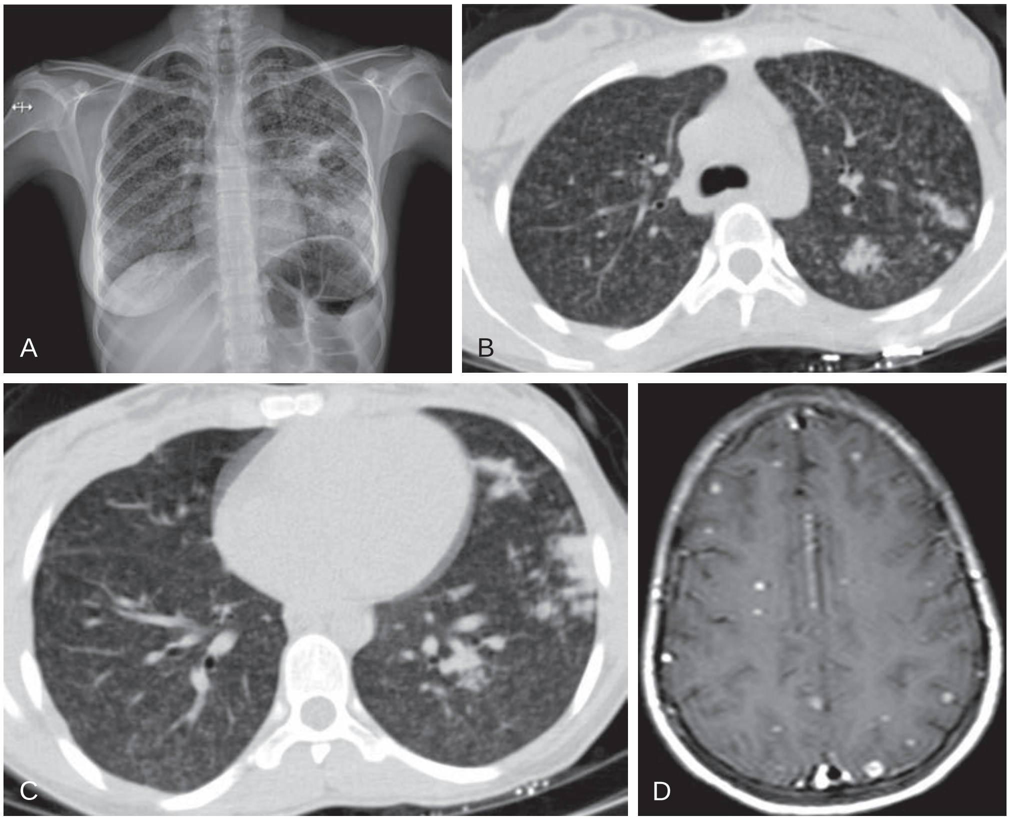
**e-Figure 54.19. Consolidation with atelectasis from pulmonary tuberculosis (TB) in an 8-year-old boy with a history of recurrent lung infections presenting with cough.** (A) The radiograph shows an enlarged left hilum and consolidation in the left retrocardiac area. (B and C) Contrast-enhanced computed tomography demonstrates consolidation with volume loss in the left lower lobe and right middle lobe, with adenopathy in the left pulmonary hilum leading to bronchial compression. (D) Ultrasonography scan shows sonographic air bronchograms within the consolidated left lower lobe. The diagnosis of TB was made on the basis of clinical and radiologic findings, although the organism could not be cultured. The patient responded well to anti-TB treatment.



**e-Figure 54.20. Disseminated tuberculosis (TB) in an infant who presented with fever, cough, tachypnea, and intercostal retractions. Her father had TB.** (A and B) Initial contrast-enhanced computed tomography shows multiple bilateral pulmonary nodules (granulomas). Enlarged lymph nodes are present in the mediastinum and hila. (C) After 6 months of anti-TB treatment, the nodules and lymph nodes have decreased in number and size, and several show central calcification. (D) On 2-year follow-up, the nodules and lymph nodes have resolved, leaving calcified foci in the lung, mediastinum, and hila. The diagnosis of TB was made on the basis of clinical and radiologic findings; the microorganism could not be cultured.



**e-Figure 54.21. Calcified lesions of tuberculosis.** (A) A large calcified primary tuberculous focus in the right lower lobe that dwarfs the rest of the complex in an asymptomatic 6-year-old girl. The healing and calcification of this huge necrotic focus *(white arrow)* without manifest clinical disease at any time shows the often benign clinical aspects of severe structural tuberculous disease. The *black arrow* shows calcified hilar adenopathy. In the frontal projection, the large calcifying focus appears to be perihilar. (B) In the lateral projection, this focus lies posterior to right hilar nodes *(black arrows)* in the apical segment of the right lower lobe *(white arrows)* near the dorsal pleura.



**e-Figure 54.24. Progressive tuberculosis (TB) with tuberculous bacteremia in a 14-year-old girl who presented with a convulsion while on treatment.** (A) The radiograph shows multiple patchy nodules in both lungs and parenchymal consolidations in the left middle and lower lung zones. (B and C) Contrast-enhanced computed tomography shows multiple nodules with a diameter of 1 to 3 mm (miliary) throughout both lungs. (D) Contrast-enhanced T1-weighted cranial magnetic resonance imaging depicts enhancing lesions consistent with TB granulomas. The diagnosis was made on the basis of clinical and radiologic findings, although the organism could not be cultured. The patient responded well to tuberculostatic drug treatment.

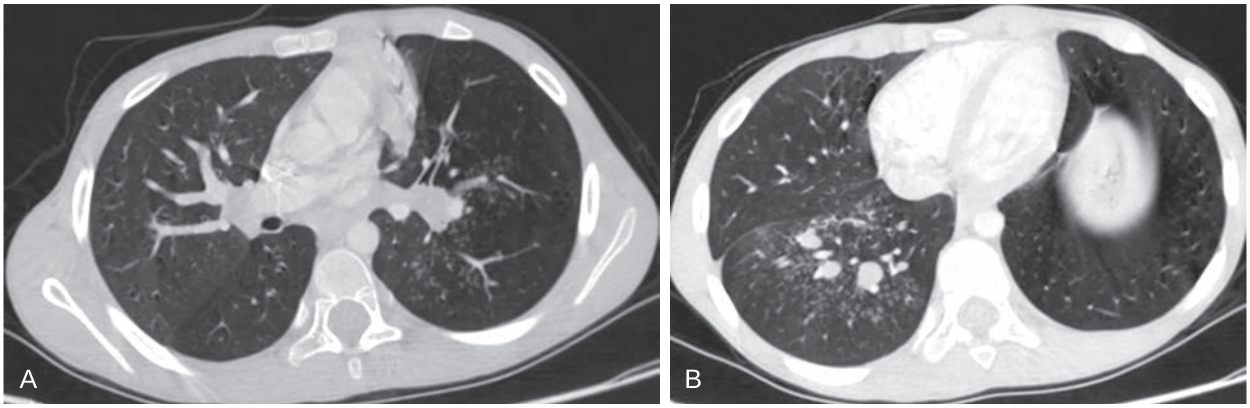


**Figure 54.23. Active pulmonary tuberculosis in a 9-year-old boy who presented with cough and fever.** (A and B) Contrast-enhanced computed tomography demonstrates centrilobular nodules and branching linear opacities ("tree-in-bud" pattern) in both lower lobes. Dilated fluid-filled bronchi are adjacent to areas of parenchymal abnormality. Atelectasis is also present in the paramediastinal parenchyma of the left lung. Culture of bronchial lavage fluid confirmed the diagnosis.

more frequent in patients with immunodeficiencies (particularly HIV infection[26]) or with altered local defenses (e.g., in cystic fibrosis or ciliary dyskinesia). Although the signs and symptoms of NTM pulmonary infection are variable and nonspecific, affected pediatric patients usually present with chronic cough, fever, chills, night sweats, dyspnea on exertion, and weight loss. The diagnosis is based on clinical, radiographic, and bacteriologic criteria.

***Imaging.*** Although the radiologic findings of pulmonary NTM disease are variable, depending on the presence or absence of underlying disease, typical findings include multiple nodules, consolidation, and cavitation. Mediastinal or hilar adenopathy similar to that of TB may be present (e-Fig. 54.25). NTM may also complicate or cause bronchiectasis.

***Treatment and Follow-up.*** Successful treatment depends on tailoring drug treatment to the type of NTM cultured. Because NTM pulmonary infection could be indolent, long-term clinical and radiologic study follow-up (months to years) may be required at relatively short intervals.

## PULMONARY INFECTIONS CAUSED BY FUNGI

Fungal infections of the lung predominantly affect children with a suppressed immune system, mainly those with defective T-cell immunity and granulocyte function, either congenital (DiGeorge syndrome, chronic granulomatous disease of childhood) or acquired (AIDS,[26] those undergoing chemotherapy for malignancies, post-transplant). In immunocompromised children, CT may add both sensitivity and specificity to radiography and should be performed with a low threshold.[105,109] The imaging appearance of fungal infections is typically within the miliary or nodular pneumonia category.[28] The nodules may be surrounded in the acute phase by a ground-glass halo, indicating the angioinvasiveness of the organism, and may eventually calcify.[2,28] Hilar and mediastinal lymphadenopathy is frequently seen, and the lymph nodes often calcify, as in TB. The most common fungal agents causing pulmonary infections in children are listed in Table 54.2.

### Aspergillosis

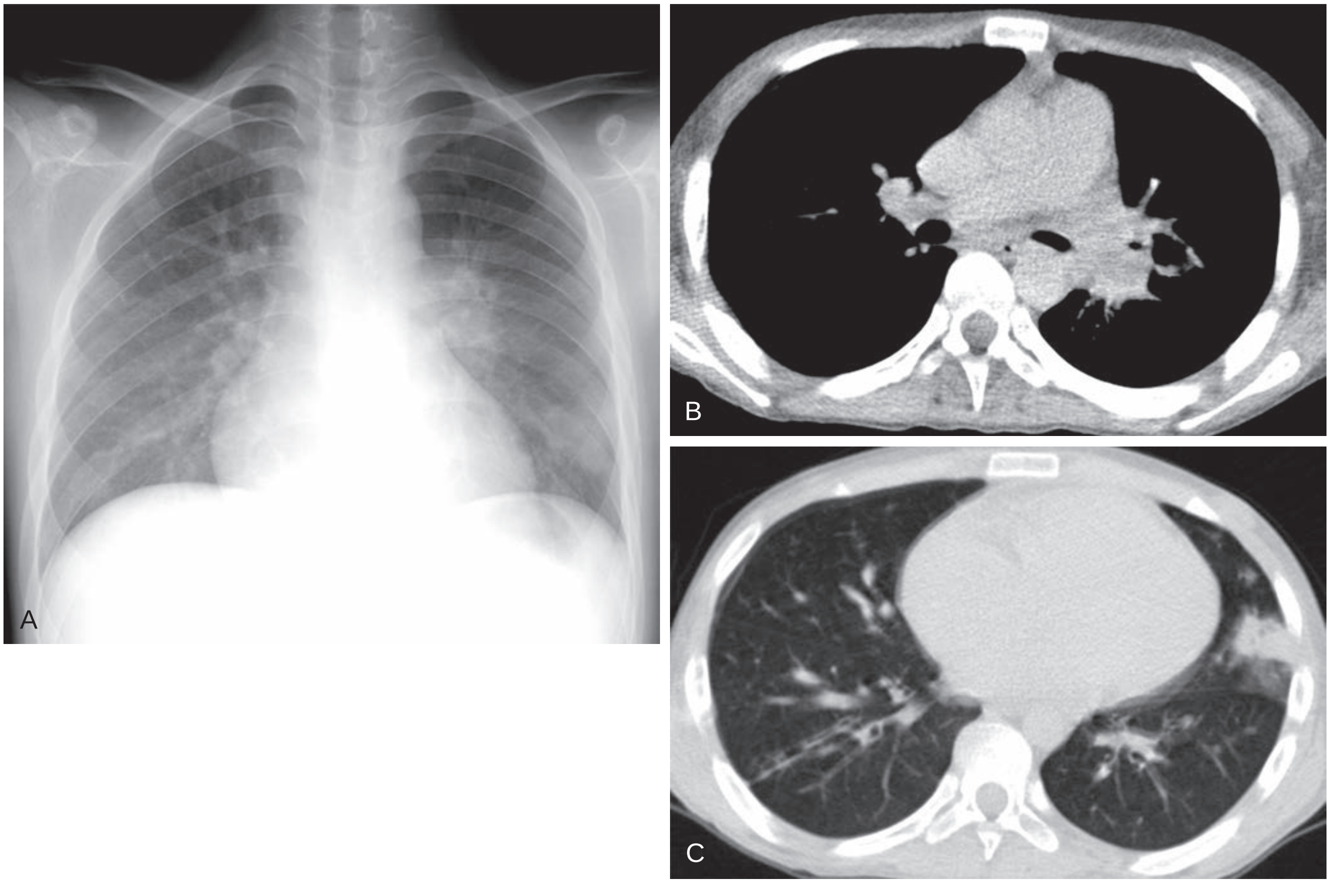
***Etiology.*** *Aspergillus* species are a group of ubiquitous molds within the environment that may be cultured from a wide variety of soils, water sources, and decaying organic matter. Pulmonary infection is most often caused by *Aspergillus fumigatus*. Although pulmonary infection with *Aspergillus* species may take a variety of clinical courses and imaging appearances, mainly dependent on the affected patients' immune status, it can be grouped into three main categories: (1) fungal ball, (2) allergic bronchopulmonary aspergillosis (ABPA), and (3) invasive aspergillosis.[148] A fungal ball or mycetoma typically grows saprophytically in immunocompetent children with a preexisting cavity, often related to cystic fibrosis or postprimary TB. ABPA, characterized by a hypersensitivity response to *Aspergillus* antigens, typically develops in children with cystic fibrosis or asthma.[149] Invasive aspergillosis almost exclusively occurs in immunocompromised children with underlying neutropenia.[148] The organism may produce a bronchocentric or angiocentric lesion and is associated with a high morbidity and mortality.[150] A semi-invasive, less aggressive form of *Aspergillus* infection may be seen in patients with underlying lung disease or in mildly immunocompromised patients.[151]

***Imaging.*** A fungal ball typically appears on chest radiographs as an intracavitary mass within a thick-walled cavity usually located in an upper lobe, especially the apical segment (e-Fig. 54.26). CT shows a round or oval-shaped cavity containing a freely mobile soft tissue mass surrounded by a crescent of air (Monad sign).[152] The most common features of ABPA are mucoid impaction within bronchiectasis and segmental and lobar atelectasis. Such dilated bronchi filled with inspissated mucus often cause a homogeneous branching opacity referred to as the *finger-in-glove sign*. Invasive aspergillosis characteristically appears as one or a few nodular opacities randomly distributed throughout the lungs. Distinctive but nonspecific characteristics include the halo sign and the air crescent sign. The *halo sign* refers to an irregular ground-glass opacity surrounding a nodule of infection (Fig. 54.27). The indistinct halo probably represents hemorrhage in lung adjacent to the nodule, resulting from vascular invasion. The *air crescent sign* is an air collection that partially outlines a masslike lesion that represents a contracting nodule.[152] This sign is noted in well-established *Aspergillus* infections when the host's defense mechanisms have partially recovered.

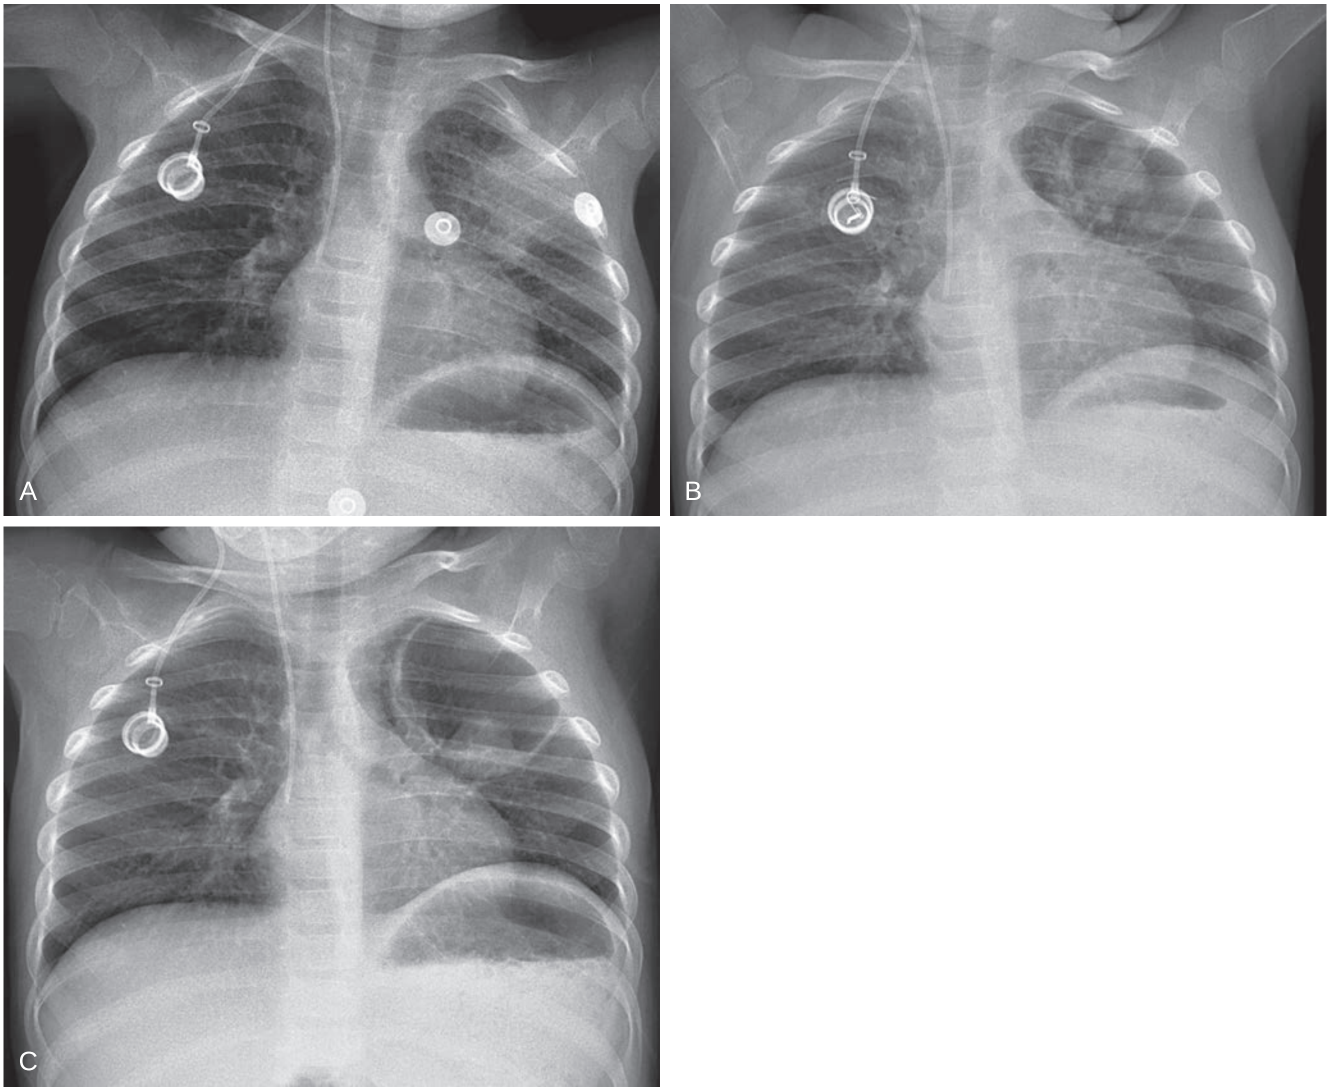
***Treatment and Follow-up.*** The main treatment goal in children with pulmonary aspergillosis is to correct any underlying immune deficiency and to control the infection with antifungal medications.

### Histoplasmosis

***Etiology.*** Histoplasmosis, caused by *Histoplasma capsulatum*, is common in many parts of the United States. Initial infection is similar to that of the primary tuberculous complex except that in histoplasmosis, large numbers of pulmonary foci are the rule. Histoplasmosis may be categorized into three phases: (1) acute



**e-Figure 54.25. Nontuberculous mycobacterial infection in a 15-year-old boy with aplastic anemia who was hospitalized for bone marrow transplantation.** (A) The radiograph shows consolidation in the left lower zone and left hilar lymphadenopathy. (B and C) Noncontrast computed tomography demonstrates consolidation in the inferior lingular segment and lymphadenopathy in the left hilum. Culture of fluid from the pericardial cavity was consistent with nontuberculous mycobacterial infection.



**e-Figure 54.26. Invasive pulmonary aspergillosis in a 30-month-old girl with acute leukemia who presented with neutropenia and fever.** (A) The initial radiograph shows a round consolidation in the left upper lung zone. (B) The follow-up radiograph on day 9 demonstrates cavitation of the consolidation, with an eccentric “fungus ball” attached to the left cavity wall. (C) The radiograph on day 17 shows expansion in the cavity and downward displacement of the “fungus ball,” indicative of its free movement.

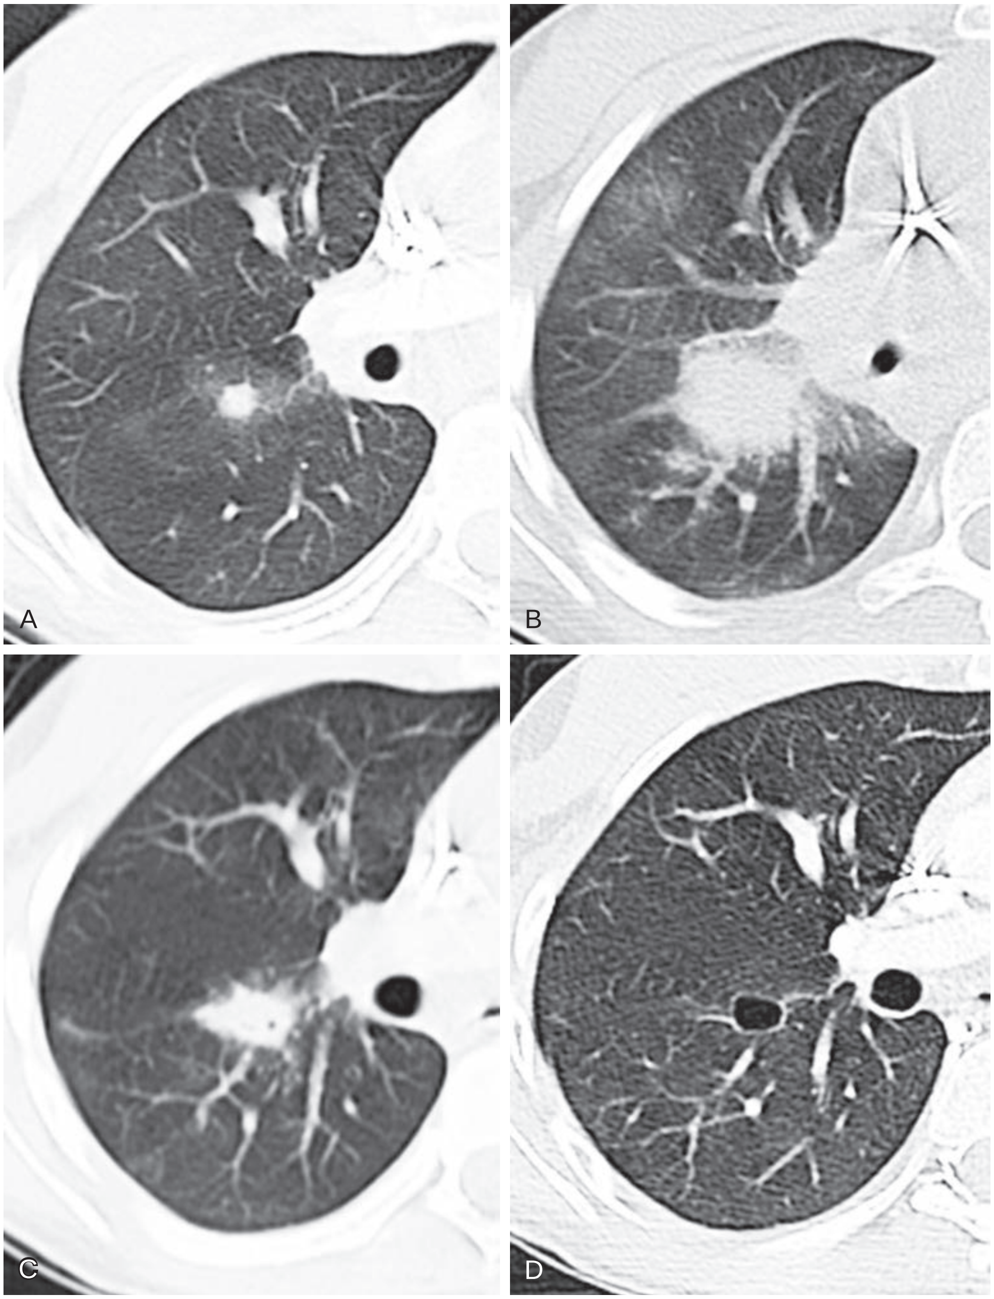


**Figure 54.27. Invasive pulmonary aspergillosis in a 14-year-old girl with non-Hodgkin lymphoma, who presented with fever after chemotherapy. The chest radiograph was normal.** (A–D) Computed tomography scans on days 1, 5, 35, and 75 demonstrate the evolution of the largest nodule after intravenous antifungal therapy. The nodule has spiculated contours surrounded by ground-glass opacity ("halo sign") at presentation, and shows complete resolution with a residual pneumatocele.

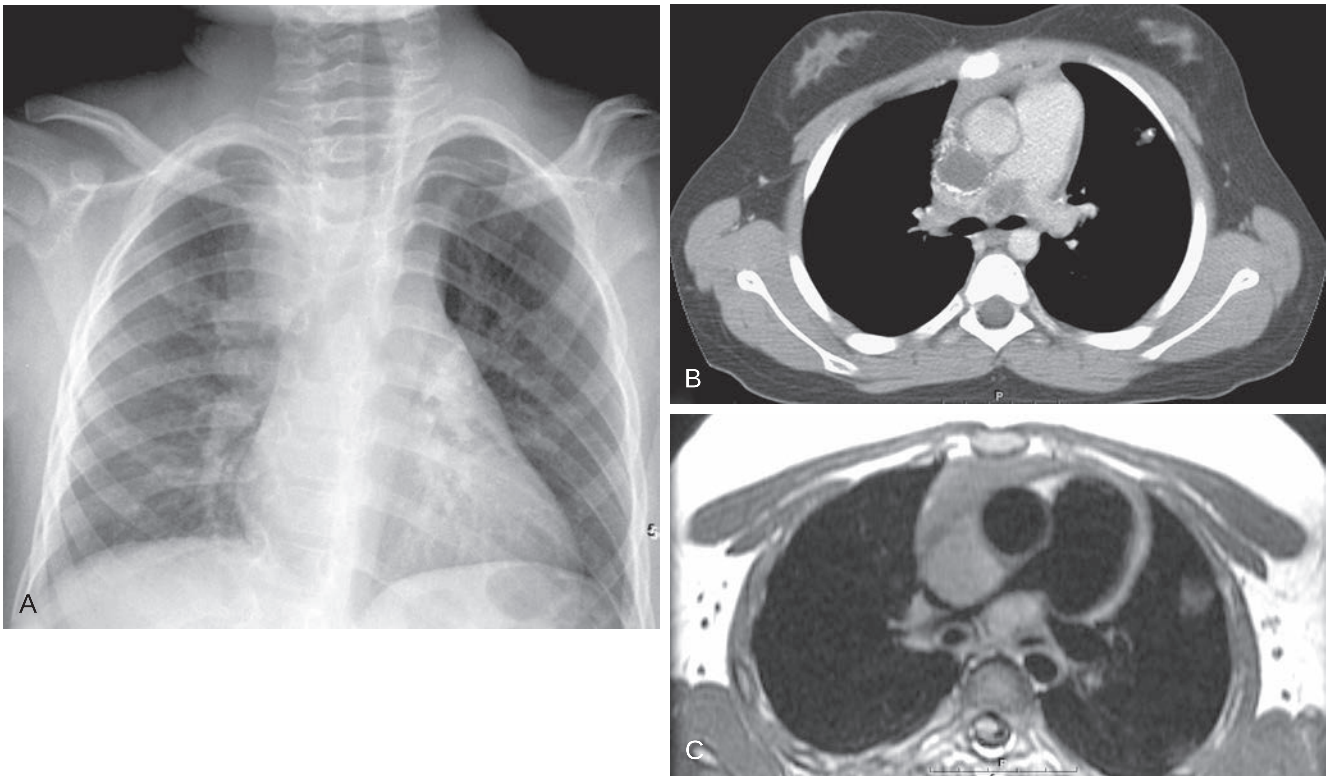
infection, characterized by nonspecific respiratory symptoms that usually develop 12 to 14 days after initial exposure; (2) chronic infection, which may resemble TB; and (3) disseminated infection. The diagnosis of pulmonary histoplasmosis rests on the identification of antigen and the demonstration of *Histoplasma*-specific antibodies. Rapid diagnosis may be obtained from biopsy of the granulomas with special fungal stains. *Histoplasma* may be cultured from lavage or blood specimens, but cultures take a long time to grow and have a low sensitivity.

***Imaging.*** Radiographic findings are similar to TB in all phases of these diseases, and in some cases they resemble those in coccidioidomycosis (e-Fig. 54.28).[153] The first phase of the infection is characterized by single or multiple pulmonary nodules that are 1 to 3 cm in size, as well as mediastinal and hilar lymphadenopathy. Pulmonary nodules that have been present for more than a few months usually show central or dystrophic calcification. Calcified mediastinal and hilar lymph nodes are often seen in patients with calcified pulmonary nodules. Sarcoidosis may exhibit similar adenopathy. Because treatment of sarcoidosis involves immunosuppression, histoplasmosis must be excluded, particularly in endemic areas. In children with chronic histoplasmosis, upper lobe consolidations simulating TB infection, sometimes associated with cavitation, may be present. Disseminated histoplasmosis has been observed in infancy, and the imaging findings are similar to those in miliary



**e-Figure 54.28. Histoplasmosis in a 9-year-old girl who presented with shortness of breath.** (A) The radiograph shows mediastinal adenopathy, particularly in the right paratracheal and right hilar regions. Note the shift of the trachea to the left side. (B) Computed tomography shows a small calcified nodule in the left upper lobe with extensive adenopathy. The mediastinal nodes are centrally low in density, as would be seen in tuberculosis, and are calcifying peripherally. (C) A gated magnetic resonance image shows the marked compression of the right pulmonary artery.

TB. Massive hepatosplenomegaly is common in disseminated cases. Granulomatous or calcified foci in the spleen are a frequent incidental finding in endemic regions and are almost diagnostic of disease exposure in an otherwise healthy patient. A rare but devastating result of chronic pulmonary histoplasmosis is mediastinal fibrosis, which may lead to pulmonary artery compression (see e-Fig. 54.28). It may also result in compression of the superior vena cava, pulmonary veins, esophagus, trachea, and bronchi.

***Treatment and Follow-up.*** Treatment is merely supportive in asymptomatic and mild cases, but when disseminated histoplasmosis is present, a combination therapy of antifungal agents is given.

### Coccidioidomycosis

***Etiology.*** Coccidioidomycosis, caused by *Coccidioides immitis* or *C. posadasi*, is acquired by inhalation. Endemic areas in the United States include the semiarid regions of California, Arizona, New Mexico, and western Texas. The infection is usually self-limiting, and affected children present with mild flulike illness, with fever, cough, headaches, rash, and myalgia. However, severe pulmonary infection may develop in immunocompromised children (particularly those with HIV infection). The diagnosis may be made by positive reaction to the coccidioidin skin test or by positive culture of the sputum or gastric washings.

***Imaging.*** Radiographic examination during the early stages of disease usually shows lobar or segmental airspace consolidation and enlargement of the regional lymph nodes.[154] The pulmonary opacity of primary coccidioidomycosis is similar to that in primary tuberculosis (e-Fig. 54.29). It usually clears after a few weeks—its duration is usually much shorter than in TB—and residual calcified foci appear later within both the lung and lymph nodes. Small localized or large free pleural effusions may be visualized early.[155] Although small, sharply defined, thin-walled pulmonary cavities are commonly noted in adults, they are uncommon in children.

***Treatment and Follow-up.*** Affected children with mild symptoms often do not require treatment. However, immunocompromised children with progressive or disseminated disease are treated with a combination of antifungal agents.

### Pneumocystis jiroveci

***Etiology.*** *Pneumocystis carinii*, a unicellular organism that infects humans, was recently renamed *Pneumocystis jiroveci*. Originally considered a parasite, it is currently categorized as a fungus on the basis of molecular similarities to fungal RNA. This potentially life-threatening opportunistic infection most often affects immunodeficient children, particularly those who are infected with HIV[26] and have CD4 counts of less than 100 cells/mm.[3] The clinical onset is variable but often abrupt, with tachypnea, cough, and cyanosis. A marked decrease in the arterial oxygen saturation is seen, with a normal carbon dioxide level.

***Imaging.*** The characteristic radiographic findings of *P. jiroveci* pneumonia are symmetric bilateral ground-glass opacities (Fig. 54.30). Such opacities may be diffuse but tend to involve predominately the perihilar regions or middle and lower lung zones.[39,156,157] Disease progression may result in more confluent, mainly perihilar or diffuse, bilateral airspace consolidation. Associated interstitial edema or cellular infiltration may present on CT as septal thickening, intralobular thickening, or both.[158] The combination of such interstitial thickening and ground-glass opacities may produce a CT pattern known as “crazy paving.”[159] Terminally, massive consolidation may occur, often complicated by pneumothorax and pneumomediastinum.[160] Pleural effusions are rare.[161]

In 10% to 30% of patient with AIDS who received prophylaxis with aerosolized pentamidine and trimethoprim-sulfamethoxazole, a cystic form of the disease may evolve, characterized by either unilateral or bilateral upper lobe predominant thin-walled cysts.[39,158] Such pulmonary cysts are associated with pneumothoraces.[162] In recent years, in spite of the advances in the prevention and treatment of *P. jiroveci* infection, several atypical presentations have emerged, including multiple pulmonary nodules, mass lesions, pleural effusion, and lymph node enlargement.[163-166]

***Treatment and Follow-up.*** Although imaging findings are not specific for *P. jiroveci* infection, the presence of bilateral ground-glass opacities in immunocompromised children should lead to this diagnosis.[167] Tracheal washings or lung biopsy, when performed, may show the organisms on microscopic examination after silver methenamine staining.

### Candidiasis

***Etiology.*** Pulmonary candidiasis is almost always encountered in immunocompromised children, those with indwelling catheters, those who are undergoing prolonged antibiotic therapy, or those who are on steroids. The organism regularly colonizes the upper respiratory tract and then spreads to the lungs. Pulmonary candidiasis may be either a primary infection (limited to the lungs) or a secondary infection (caused by hematogenous dissemination from other sites of infection).

***Imaging.*** Although radiographs are often normal in the earliest stages of infection, nonspecific features of bronchopneumonia and lung nodules may be noted (e-Fig. 54.31).[168,169] Those nodules may cavitate, and unilateral or bilateral lobar or segmental opacities may also be seen.

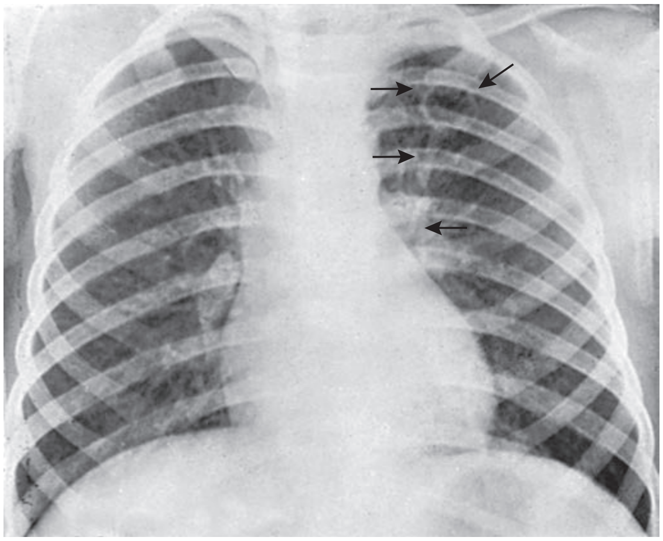
***Treatment and Follow-up.*** Children who are severely ill with pulmonary candidiasis receive appropriate antifungal therapy.

## PULMONARY MANIFESTATIONS OF PARASITIC INFESTATIONS

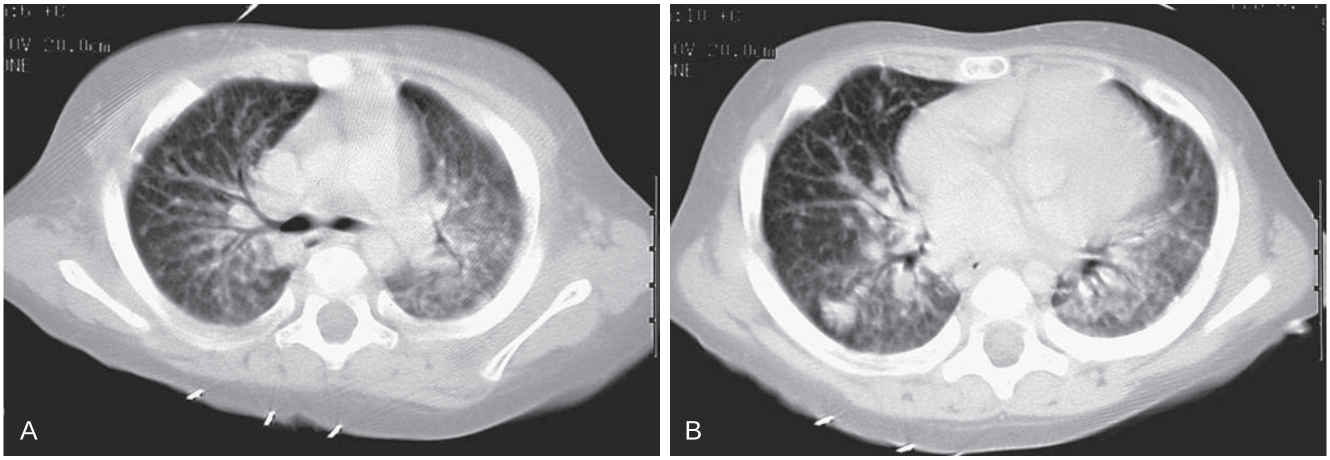
Pulmonary manifestations of parasitic infestations are predominantly encountered in the developing world, in those who have recently traveled to or from these regions, or in immunocompromised patients. A variety of imaging findings are seen, predominantly in the multinodular pneumonia category, as in paragonimiasis and echinococcus (hydatid) disease. However, several types of parasitic infestation may produce clinical and radiographic signs as a consequence of the passage of larval forms through the lung in the course of the parasite’s life cycle. These include *Ascaris lumbricoides*, *Necator americanus*, *Ancylostoma duodenale* (hookworms), *Strongyloides stercoralis*, and *Toxocara cati* and *canis*.[170] *T. cati* and *T. canis* may produce a localized granulomatous reaction, termed *visceral larva migrans*, with resultant opacities in the lungs. The first four mentioned species, as well as a number of rarer parasites, may be associated with Löffler syndrome (acute allergic eosinophilic pneumonia).[2] The most common parasitic agents with pulmonary involvement are listed in Table 54.2.

### Pulmonary Paragonimiasis

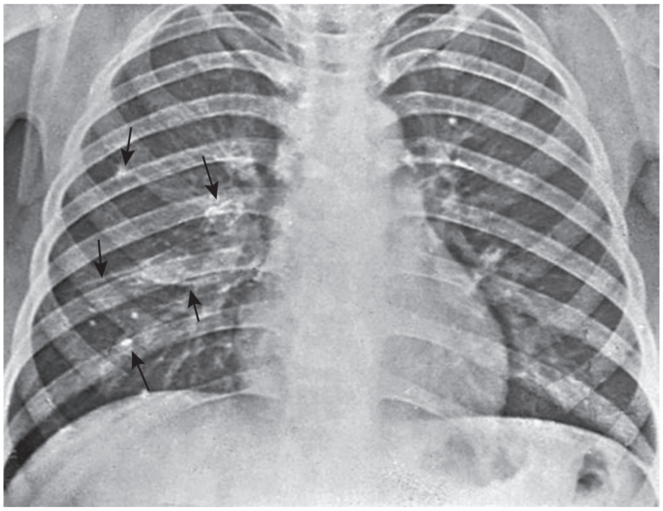
***Etiology.*** The lung fluke *Paragonimus westermani* is endemic in parts of Southeast Asia, South America, and Western Africa. In the United States, pulmonary paragonimiasis has affected refugee Indochinese children and Latin American immigrants.[171,172] Children are usually infected after ingestion of undercooked crustaceans, including crabs or crayfish, or by drinking contaminated water. In Southeast Asia, infestation of the lungs by *P. westermani* is said to be a common cause of pediatric lung necrosis and calcification, but it is difficult to differentiate from TB and fungal diseases on the basis of radiographic criteria alone (e-Fig. 54.32). Affected children usually present with fever, pleuritic chest pain, and respiratory symptoms such as chronic cough or hemoptysis. The diagnosis depends on a combination of findings, including history,



**e-Figure 54.29. Coccidioidomycosis of the lung.** A primary complex in a 4-year-old girl whose skin reaction was positive to coccidioidin. The primary pulmonary focus is excavated into a thin-walled cavity—one of the most distinctive radiologic changes in this disease *(upper arrows).* The strands of increased density between the pulmonary focus and the hilar nodes represent lymphangitis *(lower arrows).* The regional hilar nodes are enlarged. *(Courtesy of Dr. Hugh C. Thompson, Tucson, AZ.).*



**e-Figure 54.31. Candidiasis in a 10-month-old with acute myelogenous leukemia and fever and hazy opacities in left lung on chest radiograph (not shown).** (A and B) Helical computed tomography (CT) sections at the middle (A) and lower (B) zones show a bilateral pattern of ill-defined nodules and more confluent opacity in the left lung posteriorly.



**e-Figure 54.32. Calcifying paragonimiasis in the lungs of a 12-year-old Korean boy, whose sputum had contained *Paragonimus westermani* for 4 years.** The multiple calciferous foci in the right lung and hilum *(arrows)* are identical to the findings in some cases of primary tuberculosis. The clinician found radiographic signs of calcifying paragonimiasis in 60 of 1,000 Korean refugee children examined by him in Poland. *(Courtesy of Dr. Roman Marciniak, Warsaw, Poland.)*

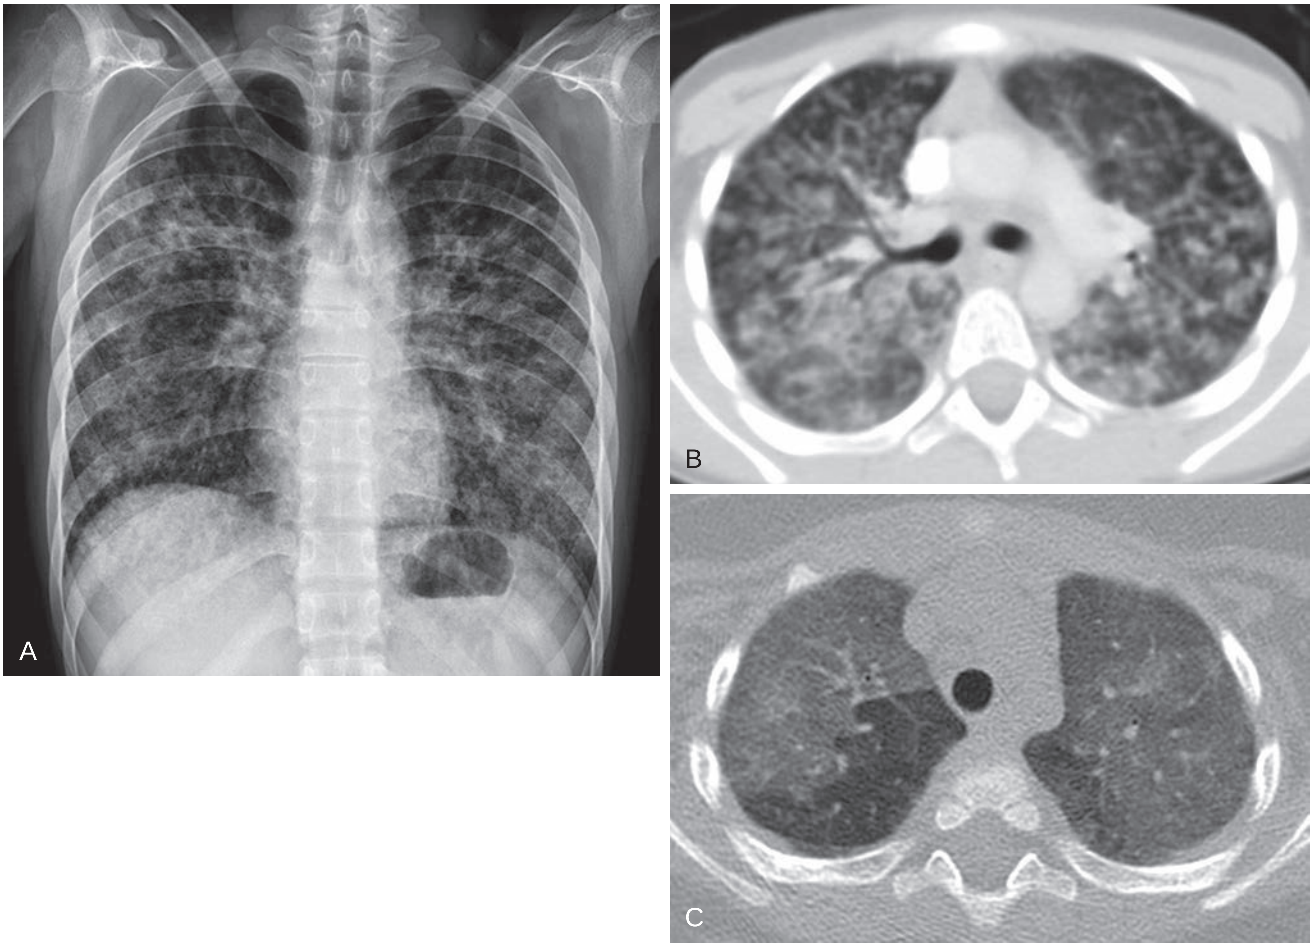


**Figure 54.30.** ***Pneumocystis jiroveci*** **infection in a 17-year-old boy with acute lymphoblastic leukemia and immunodeficiency, who presented with dyspnea, fever, nonproductive cough, and decreased white blood cell counts.** (A) The radiograph shows diffuse bilateral interstitial opacity throughout the lungs. (B) Contrast-enhanced computed tomography (CT) confirms the bilateral patchy and ground-glass opacities in both lungs. The diagnosis was confirmed by a positive polymerase chain reaction test from bronchial lavage fluid. (C) CT in a different patient demonstrates a typical "crazy paving" pattern in both upper lobes.

peripheral blood eosinophilia, identification of ova in the stool or the sputum, and a positive enzyme-linked immunosorbent assay (ELISA) test result.

***Imaging.*** Imaging findings depend on the stage of the disease. The early stage is characterized by (1) linear opacities, which are 2 to 4 mm thick and 3 to 7 cm long, extending inward from the pleura representing the migration of juvenile worms; (2) focal airspace consolidation, representing exudative or hemorrhagic pneumonia caused by the migrating worm; (3) pneumothorax; or (4) hydropneumothorax. Features of the late stage of infection include nodules, thin-walled crescent-shaped worm cysts (the "signet ring" sign), dense masslike consolidation, or bronchiectasis. As the flukes move from the abdomen to the chest, they penetrate the diaphragm and pleural layers, and thus pleural effusions and thickening are commonly noted.

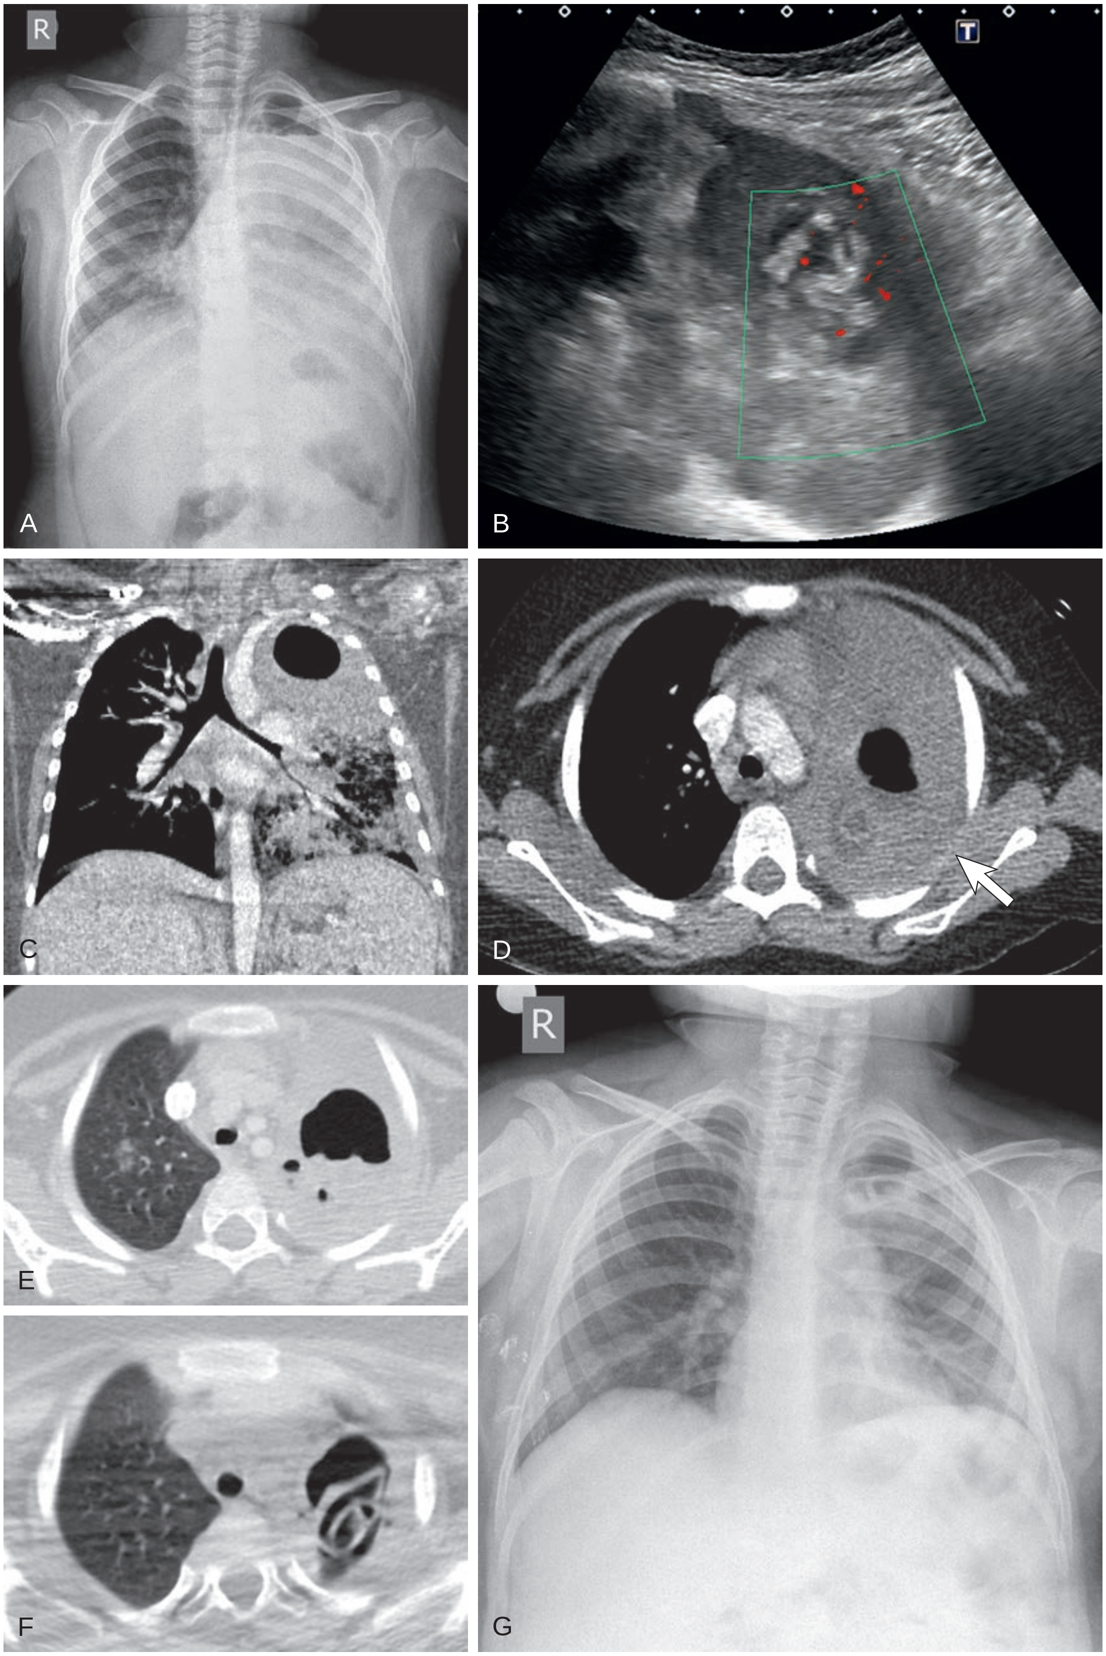
***Treatment and Follow-up.*** Pulmonary paragonimiasis is treated with antiparasitics.

## *Echinococcus Disease of the Lung*

***Etiology.*** Echinococcosis or hydatid disease in humans is caused by infestation with *Echinococcus granulosus* (dog tapeworm). Humans are infected by direct contact with definite hosts (e.g., dogs) or by ingestion of eggs present in infected water, food, or soil. The eggs of *E. granulosus* hatch into larvae in the duodenum and are typically trapped within the liver (approximately 75%) or lungs (approximately 5%–15%). They pass through the portal system in the liver or pulmonary alveolar capillaries, respectively. These larvae eventually develop into round or oval-shaped cysts within the liver or lungs (e-Fig. 54.33). Although most children with pulmonary involvement by hydatid disease are asymptomatic, they may present with fever, shortness of breath, cough, and chest pain, which is usually a sign of cyst rupture. Diagnosis of hydatid disease depends on the combination of imaging and serology.

***Imaging.*** The radiologic findings are characterized by single or multiple (approximately 25%), round or oval-shaped, cystic nodules or masses (1–20 cm in diameter) with well-defined walls, surrounded by normal lung parenchyma (see e-Fig. 54.33). Other findings include an air-crescent sign, when a cyst communicates with a bronchus, or the water-lily sign (Fig. 54.34), when a cyst membrane floats in residual fluid after cyst rupture.[160,161] Pericystic emphysema may be a sign of impending rupture. After rupture of the cysts, cavitation or abscess formation and bronchiectasis may occur.

***Treatment and Follow-up.*** Traditionally, surgical removal of the pulmonary cysts, often with supplemental medication, has been performed. Despite the risk of anaphylactic reactions after



**e-Figure 54.33. Ruptured hydatid disease in a 5-year-old girl, who presented with sudden-onset persistent cough that started 3 days before her admission.** (A) The radiograph shows white-out left lung associated with air-fluid level in the apex. (B) Transverse ultrasonography image obtained by anterior approach through the apex of the left lung demonstrates a nonvascular cyst with internal detached germinative membranes surrounded by consolidated lung. (C–E) Contrast-enhanced computed tomography (CT) on the same day demonstrates a cavity with air-fluid level and floating membranes surrounded by consolidation in the left lung apex. There are also patchy air space opacities in the rest of the lung. (F) Follow-up CT after 12 days shows resolution of the fluid and detached germinative membranes within the cavity. (G) Follow-up radiography on the second month shows marked improvement. Indirect hemagglutination test was positive for echinococcosis.

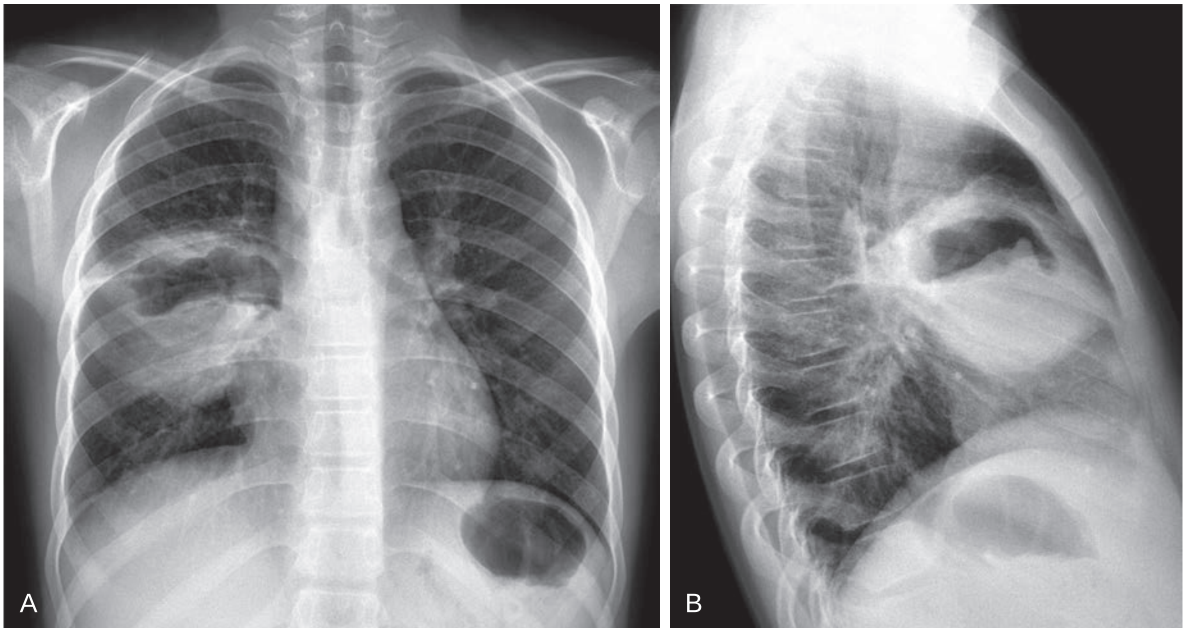


**Figure 54.34. Hydatid disease in a 12-year-old boy who presented with cough.** (A and B) Radiographs show a cavitary lesion with an irregular air-fluid level in the right middle lobe. The floating germinative membranes account for the classic "water lily" sign. Histopathologic diagnosis after surgical resection was consistent with hydatid infection.

cyst aspiration, careful image-guided percutaneous techniques appear to be sufficiently safe.[173]

## KEY POINTS

- Imaging studies have limited value in the differentiation between viral and bacterial pulmonary infections in young children, and these infectious agents frequently coexist.
- Ultrasonography is used as the initial modality to detect and characterize complex effusions from pulmonary infection.
- CT or MRI should be considered when cross-sectional chest imaging is needed for diagnosing unusual pulmonary infections with complications.
- Children who recently tested positive to tuberculin skin testing need to be evaluated with chest radiography for possible acute or chronic pulmonary TB infection.
- CT may improve the diagnosis and management of symptomatic pulmonary TB, fungal infection, and parasite infestation, particularly if an associated immune deficiency exists.

# 55

# Neoplasia

Winnie C. W. Chu, Monica Epelman, and Edward Y. Lee

Pulmonary neoplasm is much less common in children than in adults. Affected children may present clinically with respiratory symptoms, or a pulmonary neoplasm may be detected incidentally on a chest radiograph in an asymptomatic child.[1] In a recent series of 204 pediatric lung tumors, the ratio of primary benign to primary malignant to secondary malignant pulmonary neoplasms (i.e., metastases) is 1.4 : 1 : 11.6.[2] Primary lung tumors represent only 0.19% of all pediatric neoplasms.

## PRIMARY BENIGN PULMONARY NEOPLASMS

Primary benign pulmonary neoplasms are uncommon in children.[3,4] Their imaging characteristics are summarized in Table 55.1.

### Hamartoma

***Etiology.*** Pulmonary hamartoma, originally thought to represent a congenital lesion, is now considered a benign mesenchymal neoplasm. It is slow growing and contains predominantly cartilage, fat, and fibrous tissue. Occasionally, pulmonary hamartoma may also have smooth muscle, bone, and entrapped respiratory epithelium.[5] Pulmonary hamartoma is rare in children; however, it is the most common primary benign pulmonary neoplasm, accounting for 7% to 14% of all solitary pulmonary nodules in children. Ninety percent of pulmonary hamartomas are parenchymal in location. They usually present as incidental findings.

***Imaging.*** The typical radiographic appearance of pulmonary hamartoma is a smooth or slightly lobulated, solitary pulmonary nodule or mass, usually located in the peripheral lung. Characteristic punctate or popcorn-like calcifications may be seen in approximately 10%. On computed tomography (CT), it is typically a well-circumscribed pulmonary nodule that is less than 2.5 cm in diameter and often contains fat or calcification, which, in a solitary pulmonary nodule, is considered diagnostic (Fig. 55.1).[6]

***Treatment and Follow-up.*** No treatment is required unless the lesion grows rapidly or symptoms such as recurrent pneumonia or atelectasis are caused by mass effect from the tumor.[7] In such situations, surgical resection is usually curative.

### Chondroma

***Etiology.*** Pulmonary chondroma is a benign tumor composed of a well-differentiated cartilage with lack of bronchial epithelium.[8] Pulmonary chondroma is associated with the Carney triad,[8,9] which is a rare multitumoral syndrome of unknown etiology affecting the stomach, lungs (pulmonary chondroma), paraganglionic system, adrenal cortex, and esophagus. The syndrome is usually only partially expressed. Seventy-six percent of patients with the Carney triad have one or more pulmonary chondromas.

***Imaging.*** Pulmonary chondroma may be single (51%), multiple unilateral (32%), or bilateral (17%) without predilection for specific lobe or side of lung.[8] Chest radiography usually shows one or more well-demarcated lung masses with central or popcorn-like calcification (Fig. 55.2A). When calcified (45%), the appearance of chondroma is indistinguishable from that of pulmonary hamartoma on imaging studies (Fig. 55.2B).

***Treatment and Follow-up.*** Although surgical resection is sometimes performed, pulmonary chondroma may be left in situ because it is benign and usually indolent. Periodic screening of patients is currently recommended for metachronous development of paragangliomas or gastrointestinal stromal tumors.

### Recurrent Respiratory Papillomatosis

***Etiology.*** Recurrent respiratory papillomatosis (RRP) is characterized by ingrowths of a squamous cell–lined fibrovascular core in the lumen of airways. It is related to human papillomavirus (HPV) infection, most often acquired at birth. The majority of cases are uncomplicated, with lesions remaining localized to the laryngeal and subglottic region.[9] Lung lesions are seen in 1.8% of affected patients, especially if surgical or laser therapy had been provided earlier.[10] The ultimate prognosis is poor when pulmonary involvement occurs. Malignant transformation into squamous cell carcinoma may occur.[11]

***Imaging.*** On chest radiography, RRP typically presents as bilateral, multiple nodular and cystic lesions of varying size containing air or debris. Postobstructive atelectasis, bronchiectasis, or secondary infection presenting as consolidation may also be seen.[12] On CT, scattered nodules are seen in the lungs (e-Fig. 55.3), and these nodules may enlarge, become air-filled cysts, or form large cavities with thin or thick walls.[13] CT virtual bronchoscopy may be useful to evaluate mural nodules within the central airways.

***Treatment and Follow-up.*** A combined concurrent adjunctive therapy including microlaryngeal surgery, pulsed dye laser, and intralesional cidofovir injection is promising as a cure for RRP and restoration of vocal function after treatment.[14-16] It is hoped that the use of HPV vaccination will largely prevent this disease.[17]

### Lymphatic Malformation

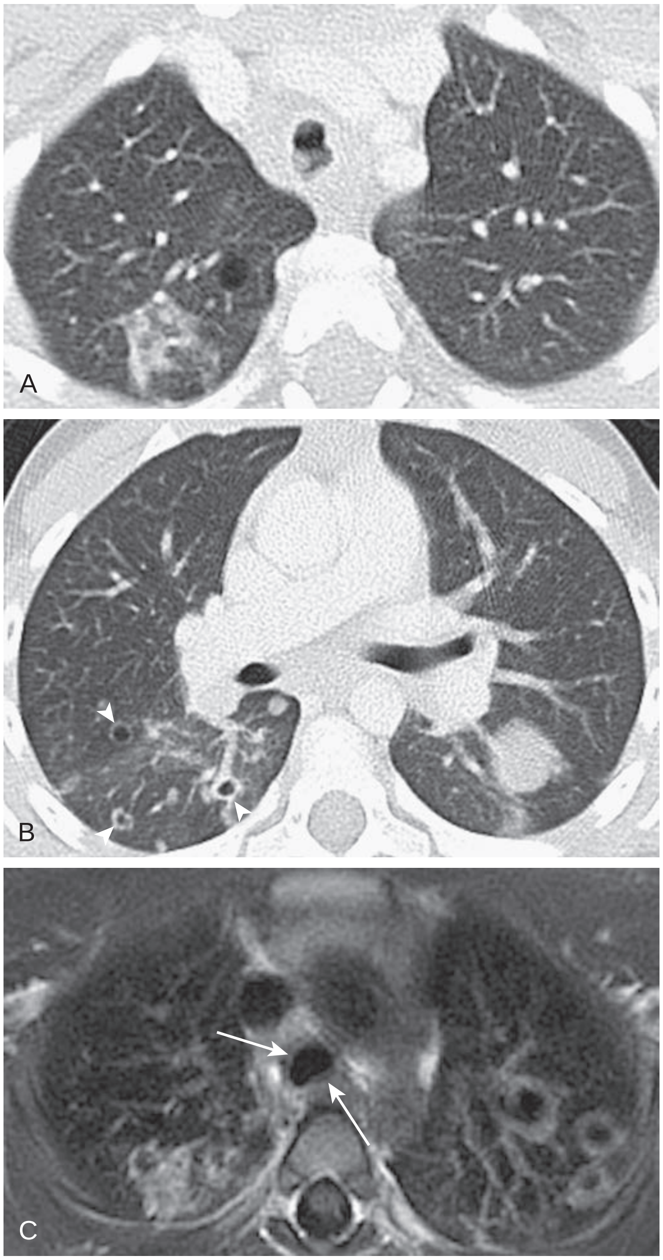
***Etiology.*** Lymphatic malformation, previously referred to as lymphangioma,[18,19] is characterized by a benign proliferation of nonfunctional lymphatic tissue that may involve nearly every organ of the body. Only 1% of lymphatic malformations remain confined to the chest. Primary pulmonary lymphatic malformation is even less common.[20] Affected persons are often asymptomatic. Younger patients tend to have lesions that affect the lung.[21,22]

***Imaging.*** On chest radiography, lymphatic malformation typically presents as a masslike opacity. The most common CT finding is a smooth, well-marginated, nonenhancing, cystic mass. In neonates and infants, this may simulate congenital pulmonary airway malformation (CPAM) or diaphragmatic hernia. Older children may have a solid, low-attenuation, masslike lesion that may mimic pneumonia or tumors (e-Fig. 55.4).

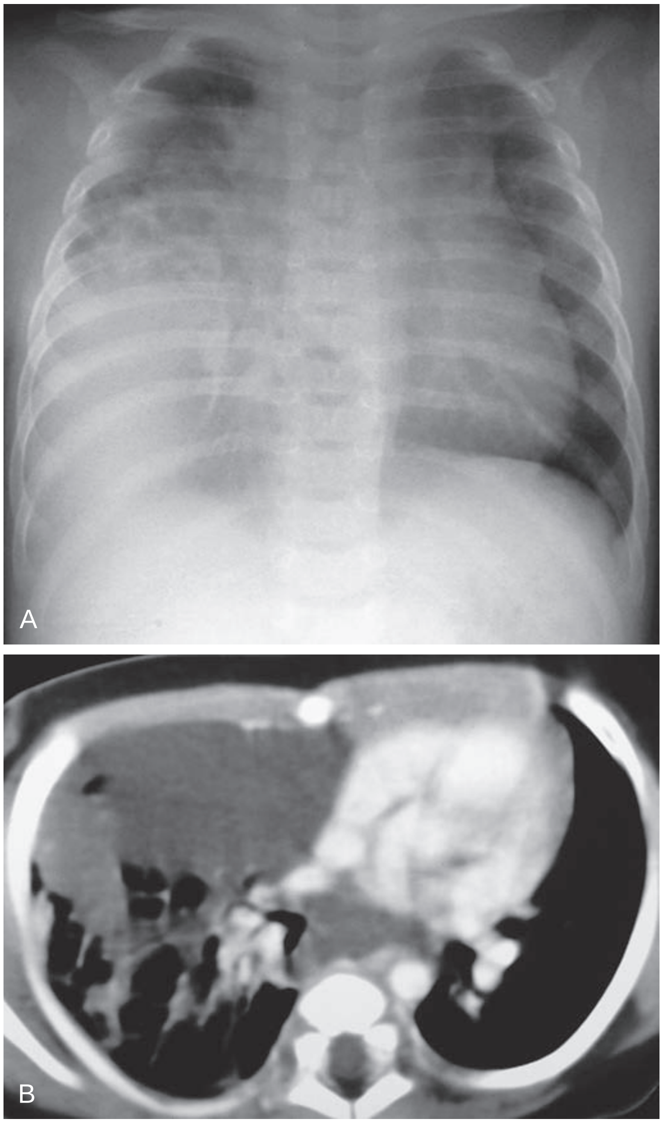
***Treatment and Follow-up.*** Early surgical removal or sclerotherapy of lymphatic malformation is currently recommended to prevent local growth and the resultant compression of vital structures.[23]

## BENIGN REACTIVE LYMPHOPROLIFERATIVE DISORDER

Pulmonary lymphoproliferative disorders (LPDs) are characterized by abnormal infiltration of lung parenchyma by lymphoid cells. They encompass a wide spectrum of focal or diffuse abnormalities, which may be classified as reactive or neoplastic (primary or secondary) on the basis of cellular morphology and clonality.[24,25] The



**e-Figure 55.3. Recurrent respiratory papillomatosis.** (A) Axial lung window CT image obtained in a 5-year-old girl with recurrent respiratory papillomatosis shows multiple intratracheal soft tissue nodules. (B) Multiple parenchymal papillomas are also present, some of which show cavitation *(arrowheads).* (C) Axial T1-weighted MRI shows cavitating lesions in both lungs and mildly thickened tracheal walls *(arrows).*



**e-Figure 55.4. Lymphatic malformation.** Biopsy-proven lymphatic malformation in a 4-year-old boy. (A) Chest radiograph demonstrates a mass in the right hemithorax. (B) Axial contrast-enhanced CT image shows a low-attenuation infiltrating mass in the middle mediastinum and right middle lobe.

**TABLE 55.1** Imaging Characteristics of Benign Lung Neoplasm (Nonlymphoproliferative)

| Neoplasm | Imaging Characteristics |
|---|---|
| Hamartoma | Smooth or slightly lobulated, sharply defined mass, occasionally calcified ("popcorn")<br>Fat and calcification in solitary pulmonary mass on computed tomography is diagnostic |
| Chondroma | Solitary or multiple nodules; commonly (45%) calcified; associated with the Carney triad |
| Respiratory papillomatosis | Rarely (<1%) intrapulmonary<br>Bilateral, multiple subpleural solid or cystic nodules; may be associated with bronchiectasis or atelectasis |
| Lymphatic malformation | Rarely intrapulmonary; well-marginated, nonenhancing cystic mass; may simulate congenital pulmonary airway malformation or diaphragmatic hernia in neonates; or solid, low-attenuation mediastinal or pulmonary mass in older children |

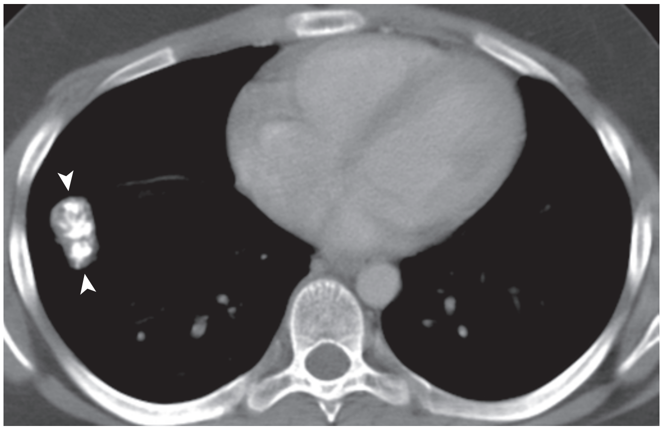


**Figure 55.1. Pulmonary hamartoma.** A 14-year-old boy with incidental calcified lesion noted on chest radiograph (image not shown). Axial contrast-enhanced CT image shows a peripherally located, well-circumscribed, oval shaped smooth mass *(arrowheads)* with popcorn calcifications.

classification and imaging characteristics of lymphoproliferative disorders involving the lungs are listed in Table 55.2.

***Etiology.*** Pulmonary mucosa-associated lymphoid tissue (MALT) and bronchus-associated lymphoid tissue (BALT) is usually inconspicuous in healthy subjects; however, a wide range of antigenic stimulation can induce benign reactive changes of these lymphoid tissues. Primary lymphoid lesions of the lung are increasingly recognized recently due to increases in pediatric organ transplantation, prevalence of human immunodeficiency virus (HIV) infection, and development of potent immunosuppressive therapies. Benign pulmonary lymphoid lesions include reactive lymphoid hyperplasia, nodular lymphoid hyperplasia, follicular bronchiolitis, and lymphoid interstitial pneumonia.[26-28]

Nodular lymphoid hyperplasia (NLH) is relatively rare and represents a benign, localized, reactive polyclonal lymphoproliferative lesion. Follicular bronchiolitis (FB) comprises a benign, polyclonal bronchial MALT hyperplasia in and around the bronchioles. Lymphocytic interstitial pneumonitis (LIP) is characterized by diffuse proliferation of polyclonal lymphocytes and plasma cells in the pulmonary parenchymal interstitium, associated with expansion of the alveolar septa. Because LIP is rarely idiopathic, it is considered an AIDS-defining illness in children younger than 13 years old who are infected with HIV.

***Imaging.*** Features on chest radiography are nonspecific (e-Fig. 55.5A). CT findings are better described,[24,29] though frequently nonspecific, and require correlation with clinical data. Histologic confirmation is required for a definite diagnosis. On CT, NLH usually presents as a discrete nodular mass (2–3 cm in diameter) with mild focal lymphangitic extension. Mediastinal and hilar lymphadenopathy, as well as pleural effusion, are typically absent in NLH (different from malignant lymphoma). FB is limited to the airway without interstitial involvement. It usually presents with bilateral nodules (most commonly 1–3 mm in diameter) of centrilobular/peribronchial distribution, hence having a "tree-in bud" appearance or bilateral patchy ground-glass opacities (e-Fig. 55.5B). There may be bronchial dilation. LIP usually presents as diffuse centrilobular and subpleural nodules[30] (representing local proliferation of lymphoid germinal centers), areas of ground-glass opacity, and bronchovascular and interstitial thickening in both lungs (Fig. 55.6). Peribronchovascular cysts are characteristically distributed in the lower lungs.[24]

***Treatment and Follow-up.*** In general, treatment involves management of underlying disease. NLH is benign and therefore surgical excision is generally curative. The prognosis of FB is generally favorable. Most patients respond to steroids or

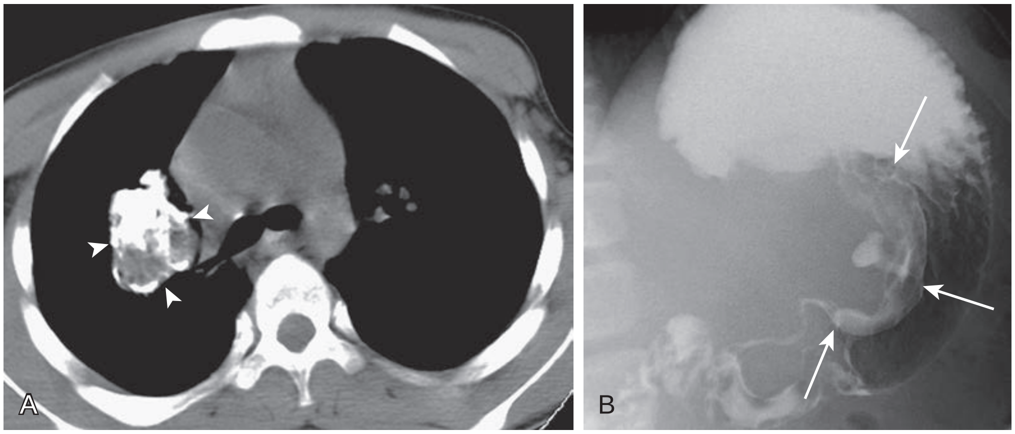

**Figure 55.2. Pulmonary chondroma.** (A) A 14-year-old boy in the setting of the Carney triad. Axial unenhanced CT image shows a large right parahilar mass *(arrowheads)* with extensive calcifications. (B) Upper gastrointestinal study of the same patient demonstrates a large ulcerated exophytic soft tissue mass *(arrows)* in the stomach consistent with gastric leiomyosarcoma.

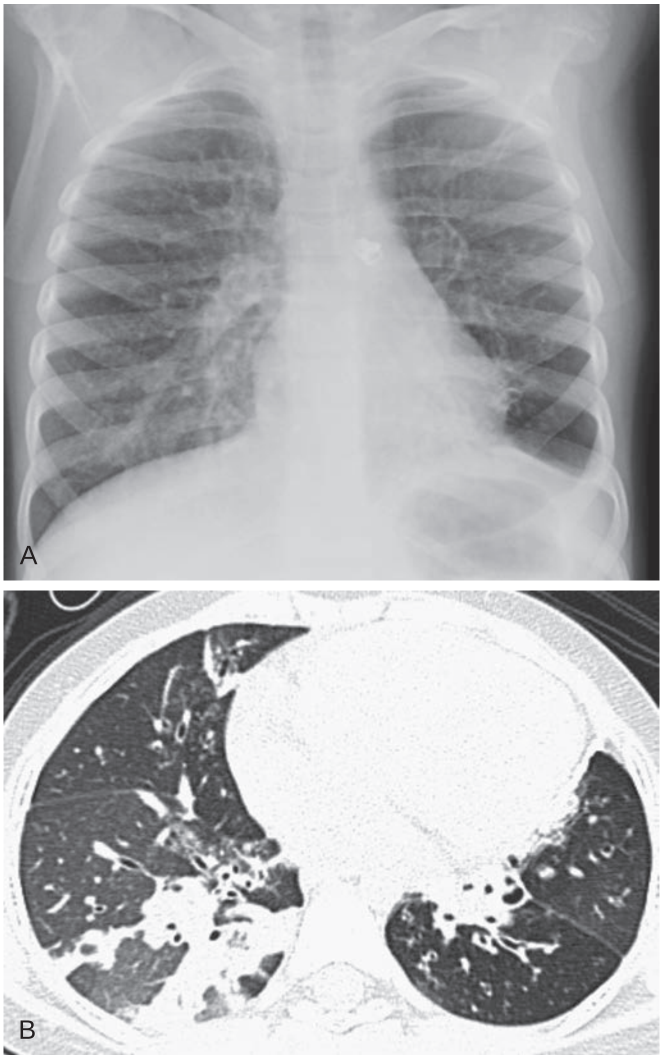

**e-Figure 55.5. Bronchus-associated lymphoid tissue.** A 5-year-old girl who presented with worsening shortness of breath and decreased oxygen saturation. (A) Chest radiograph shows hyperinflation with increased streaky interstitial opacities in both lungs. (B) Axial lung window CT image demonstrates air trappings, mosaic perfusion, and diffuse opacity with cystic bronchiectasis.

**TABLE 55.2** Lymphoproliferative Disorders of the Lungs

| Disorder | Imaging Characteristics |
|---|---|
| **REACTIVE BENIGN PROLIFERATION** | |
| Nodular lymphoid hyperplasia (NLH) | Discrete nodular mass (2–3 cm in diameter) with mild focal lymphangitic extension<br>Rarely mediastinal and hilar lymphadenopathy<br>Absent pleural effusion |
| Follicular bronchiolitis (FB) | Bilateral nodules (most commonly 1–3 mm in diameter) of centrilobular/peribronchial distribution, "tree-in bud" appearance<br>Bilateral patchy ground-glass opacities<br>There may be bronchial dilation |
| Lymphoid interstitial pneumonia (LIP) | Seen in patients with acquired or congenital immunodeficiency<br>Diffuse centrilobular and subpleural nodules<br>Ground-glass opacity<br>Bronchovascular and interstitial thickening<br>Peribronchovascular cysts in the lower lungs |
| **PROLIFERATION IN IMMUNOCOMPROMISED** | |
| Posttransplantation lymphoproliferative disorder (PTLD) | Associated with multiorgan transplant and EBV infection<br>Solitary or multiple lung masses or consolidation<br>Sometimes associated with peripheral ground-glass halo<br>May have associated mediastinal and extrathoracic adenopathy<br>May have air space consolidation, pleural or chest wall masses, pleural or pericardial effusions, and thymic enlargement |
| **PRIMARY MALIGNANT PROLIFERATION** | |
| MALT lymphoma | Single or multiple nodules or areas of consolidation<br>Peribronchovascular distribution<br>Bronchial dilation is common<br>Mediastinal lymphadenopathy |
| Diffuse large B-cell lymphoma (DLBL) | Single or multiple solid pulmonary nodules or masses<br>Cavitation is common (approximately 50%) |
| Lymphomatoid granulomatosis (LYG) | Nodules of peribronchovascular distribution<br>Small thin-walled cysts<br>Conglomerate small nodules |
| **SECONDARY MALIGNANT PROLIFERATION** | |
| Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) | HL: Almost always have associated with mediastinal and/or hilar lymphadenopathy<br>NHL: Isolated lung disease without mediastinal involvement can occur<br>Three main pulmonary patterns:<br>(1) Nodular: single or multiple pulmonary nodules with irregular borders and sometimes central cavitation<br>(2) Lymphangitic: reticular interstitial opacities<br>(3) Alveolar: lobar or segmental consolidation |

*EBV,* Epstein–Barr virus; *MALT,* mucosa-associated lymphoid tissue.

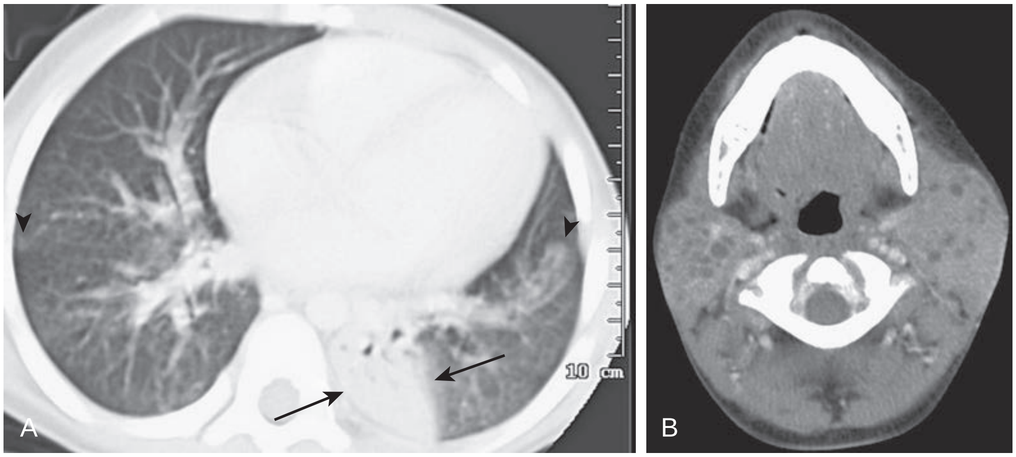

**Figure 55.6. Lymphocytic interstitial pneumonitis.** An 8-year-old girl with human immunodeficiency virus (HIV) infection presenting with increasing shortness of breath. (A) Axial CT image shows bilateral patchy areas of ground-glass attenuation, right greater than left, poorly defined nodules *(arrowheads),* and an area of consolidation in the left lower lobe *(arrows).* (B) Axial, enhanced CT image of neck demonstrates multiple, bilateral parotid lymphoepithelial cysts consistent with HIV parotitis.

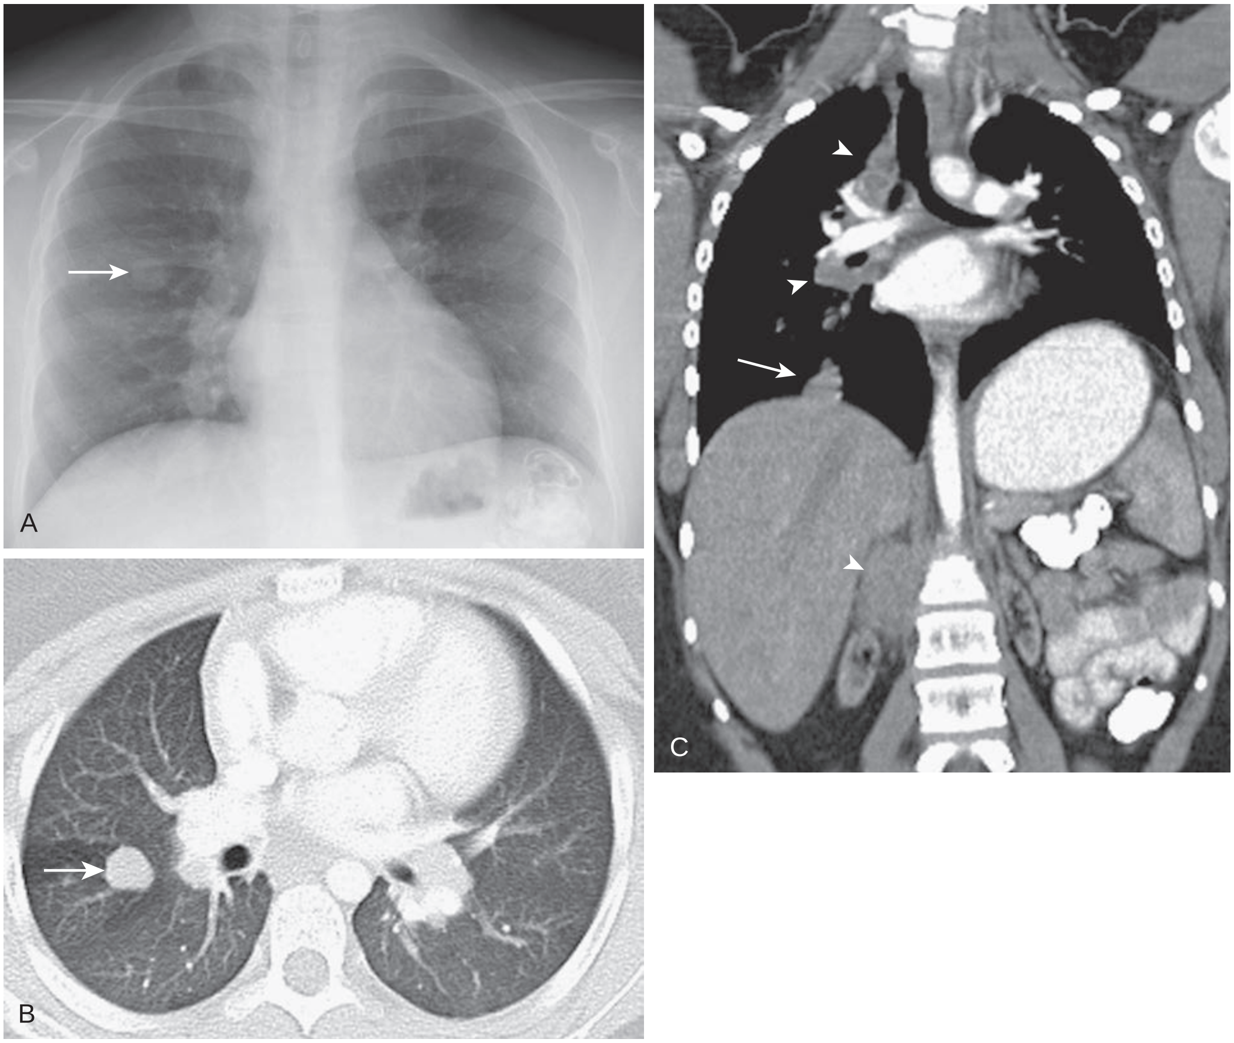

**Figure 55.7. Posttransplantation lymphoproliferative disorder (PTLD).** An 11-year-old girl who presented with PTLD following renal transplantation. (A) Chest radiograph shows a nodular opacity *(arrow)* in the right upper lobe and bilateral hilar lymphadenopathy. (B) Axial lung window CT image demonstrates a right upper lobe lung nodule *(arrow)* corresponding to the opacity noted on chest radiograph. (C) A coronal reformatted CT image shows mediastinal, hilar, and retroperitoneal lymphadenopathy *(arrowheads)* and an additional nodule at the right lung base *(arrow)*. Note the atrophic native kidneys.

azathioprine, although some patients may relapse.[26] Steroid and other immunosuppressive agents are used for treating LIP with variable results. Progressive honeycomb fibrosis or infectious complications may lead to increased mortality in LIP, and low-grade B-cell lymphoma may develop in rare cases.[31]

## Posttransplantation Lymphoproliferative Disorder

***Etiology.*** Posttransplantation lymphoproliferative disorder (PTLD) is a consequence of chronic immunosuppression after solid organ transplantation or, less often, bone marrow transplantation.[32-35] PTLD is intimately associated with Epstein–Barr virus (EBV) infection. The lesions consist of uncontrolled proliferation of B lymphocytes ranging from benign lymphoid hyperplasia to invasive malignant lymphoma. Children are more likely to develop PTLD than adults, most commonly after multiorgan transplant such as heart-lung transplant (up to 33%).[32,36-40] The most common sites for PTLD are the tonsils, cervical nodes, gastrointestinal tract, and chest.[41,42] PTLD tends to occur within the allograft organ itself, as well as in adjacent anatomic regions.[43] Clinical symptoms of PTLD are often vague. Biopsy is typically required to confirm the diagnosis.

***Imaging.*** On chest radiography, the most common finding in PTLD is the presence of multiple well-defined pulmonary nodules with or without mediastinal adenopathy (Fig. 55.7).[40] These are best visualized on CT. These pulmonary nodules may contain air bronchograms, and sometimes have a peripheral ground-glass halo mimicking angioinvasive aspergillosis.[27] Other less frequent patterns of thoracic involvement include air space consolidation, pleural or chest wall masses, pleural or pericardial effusions, and thymic enlargement.[44-46] For a more confident diagnosis, it is helpful to search for extrathoracic PTLD such as thickening of bowel loops, enlarged abdominal lymph nodes, cervical adenopathy, or enlarged oropharyngeal lymphatic tissues.[39,40] Fluorodeoxyglucose positron emission tomography may increase sensitivity and specificity for the diagnosis.[47]

***Treatment and Follow-up.*** Reduction in immunosuppressive therapy remains a primary component of treatment for EBV-positive PTLD.[48] Chemotherapy is used when reduced immunosuppression fails to control disease progression. Newer treatments of PTLD include B-lymphocyte–depleting antibodies and adoptive T-cell immunotherapy using allogeneic or autologous EBV-specific cytotoxic T lymphocytes.[49] EBV vaccination is advocated to be effective prophylaxis against PTLD.

## PRIMARY MALIGNANT PULMONARY NEOPLASMS

Primary malignant pulmonary neoplasms are rare in children and are histologically diverse. The current World Health Organization (WHO) classification system of primary malignant pulmonary neoplasms differs substantially from the prior classification system, particularly with regard to new tumors (e.g., pleuropulmonary blastoma) and reclassification of benign and malignant tumors (e.g., inflammatory myofibroblastic tumor).[50] The most common primary lung malignancies in children are inflammatory myofibroblastic tumor, pleuropulmonary blastoma, and carcinoid tumor.[2,4,51,52] The imaging characteristics of primary malignant lung tumors are listed in Table 55.3.

### Inflammatory Myofibroblastic Tumor

***Etiology.*** Inflammatory myofibroblastic tumor (IMT) is relatively common in children. It is a myofibroblastic spindle cell soft tissue tumor with infiltrative plasma cells, lymphocytes, and eosinophils, defined by the WHO as a low-grade mesenchymal malignancy.[53] Due to the complexity and variable histologic characteristics, it is known by several different terms, including *plasma cell granuloma*, *inflammatory pseudotumor*, *fibroxanthoma*, *myofibroblastic tumor*, *fibrous histiocytoma*, *xanthogranuloma*, or *histiocytoma*.[54,55] A substantial proportion of tumors have *ALK1* gene mutations.[56] The majority of children with IMT are older than 5 years. Approximately 60% of affected children are symptomatic, typically presenting with fever, cough, chest pain, dyspnea, wheezing, or hemoptysis.

***Imaging.*** Radiographically, pulmonary IMT may be seen as solitary (95%) or multiple (5%). IMTs are usually sharply circumscribed, lobulated masses of varying sizes, typically located in the peripheral portion of the lungs. On CT there is usually a soft tissue mass with either homogeneous or heterogeneous attenuation (Fig. 55.8A). Less commonly, there may be both solid and cystic components. IMT may also have an infiltrative pattern simulating an aggressive malignancy (Fig. 55.8B).[57] If the mediastinum is involved or the mass contains calcifications (15%–25%), IMT may mimic a germ cell tumor, neuroblastoma, or metastatic osteosarcoma.

***Treatment and Follow-up.*** Complete surgical resection and close follow-up are necessary for appropriate treatment to avoid recurrences.[58] Sleeve resection is the best option for lesions located in the main-stem bronchus or secondary carina, typically with excellent results.[59]

**TABLE 55.3** Imaging Characteristics of Primary Malignant Lung Tumors

| Neoplasm | Imaging Characteristics |
|---|---|
| Inflammatory myofibroblastic tumor (IMT) | Solitary (95%) or multiple (5%)<br>Usually sharply circumscribed, lobulated mass<br>Typically located in the peripheral portion of the lungs<br>Soft tissue mass with either homogeneous or heterogeneous attenuation, may have both solid and cystic and calcific components |
| Carcinoid or salivary gland tumor | Centrally located lesion: intraluminal soft tissue mass with distal atelectasis or obstructive pneumonitis<br>Peripherally located lesion: oval or lobulated intraluminal or exophytic mass and occasionally calcify |
| Bronchogenic carcinoma | Central mass lesion with bronchial obstruction or, less commonly, small peripheral lesion |
| Pleuropulmonary blastoma | Cystic or mixed cystic and solid lesion adjacent to pleura; can be very large, with mediastinal displacement |
| Epithelioid hemangioendothelioma | Multiple well- or ill-defined nodular opacities up to 3 cm in diameter; very rare in childhood |

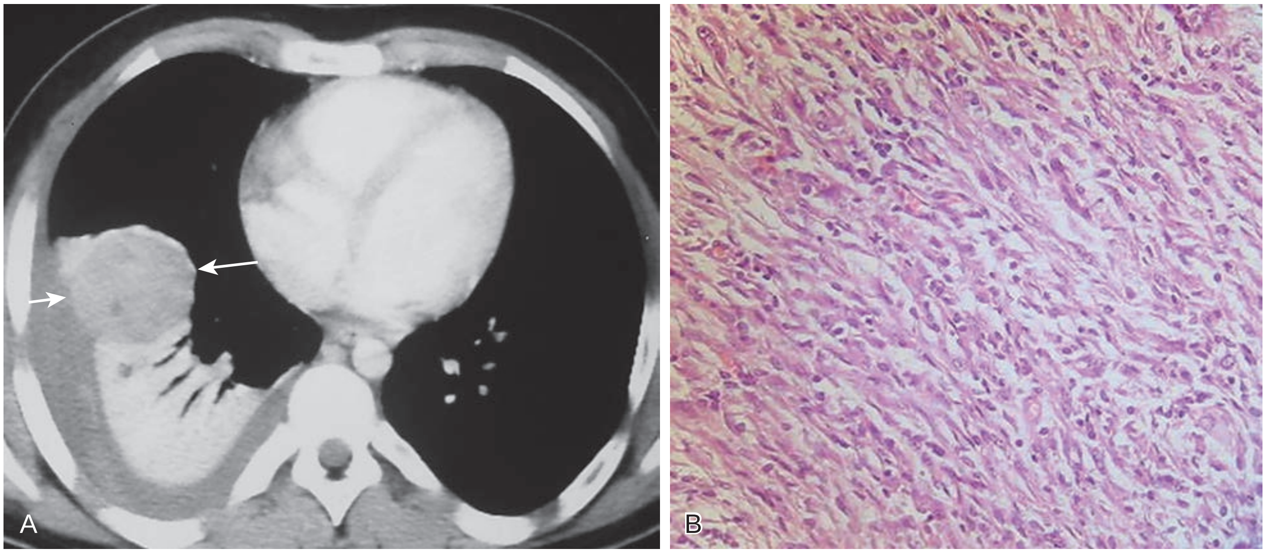

**Figure 55.8. Inflammatory myofibroblastic tumor.** An afebrile 13-year-old boy who presented with increasing dyspnea and right-sided pleuritic chest pain. (A) Axial contrast-enhanced CT of the chest shows a rounded heterogeneously enhancing lesion *(arrows)* located adjacent to an area of atelectatic lung. Pleural fluid at the same level demonstrates increased attenuation consistent with a hemothorax. (B) Photomicrograph (hematoxylin-eosin stain) of the surgical specimen reveals the presence of both spindle-shaped myofibroblasts and inflammatory cells consistent with an inflammatory myofibroblastic tumor of the lung.

## Bronchial Adenoma (Carcinoid Tumor or Salivary Gland Tumor)

***Etiology.*** The term *bronchial adenoma*, which implies a benign disease process, was recently recategorized as either carcinoid or salivary gland tumors by the WHO.[50] The three most common tumors in this group are carcinoid tumor,[60,61] mucoepidermoid tumor, and adenoid cystic carcinoma. Carcinoid tumor accounts for approximately 80% of previously classified pediatric bronchial adenomas, which are low-grade neuroendocrine carcinomas arising in lobar bronchi (75%), main-stem bronchi (10%), or the lung parenchyma (15%).[1,62,63] Mucoepidermoid carcinoma (see Video 55.1, e-Fig. 55.9, and e-Fig. 55.10) and adenoid cystic carcinoma (cylindromas) (Fig. 55.11) arise from the salivary-type mucous cells of the submucosa along the tracheobronchial tree. Adenoid cystic carcinoma is extremely rare in children.[64] Patients with carcinoid tumor and mucoepidermoid carcinoma frequently present with wheezing, cough, hemoptysis, or pneumonia.[62,65,66] Differential diagnosis of these rare tumors includes foreign body aspiration, granulomatous infection, and asthma with mucous plugging.

***Imaging.*** The radiographic presentation depends on the size and location of tumor within the airway or lungs. A centrally located tumor is typically seen as an intraluminal soft tissue attenuation mass with associated distal atelectasis or obstructive pneumonitis. A peripherally located tumor is commonly seen as a sharply marginated, oval, or lobulated intraluminal or exophytic mass.[60,67-70] Associated stippled calcification is seen in up to 30% of carcinoid tumors. CT is particularly helpful for detecting and defining the extrabronchial portion of the tumor and associated adenopathy.

***Treatment and Follow-up.*** The current treatment of choice is surgical resection.[71] Chemotherapy and radiotherapy are reserved for tumors with incomplete surgical resection. Overall survival rate for carcinoid and mucoepidermoid carcinoma is approximately 90%, whereas adenoid cystic carcinoma has a poorer survival rate of 55% because of higher likelihood of distant metastases.[72]

## Bronchogenic Carcinoma

***Etiology.*** Traditionally, the term *bronchogenic carcinoma* has been used to include both small cell and non–small cell lung cancers

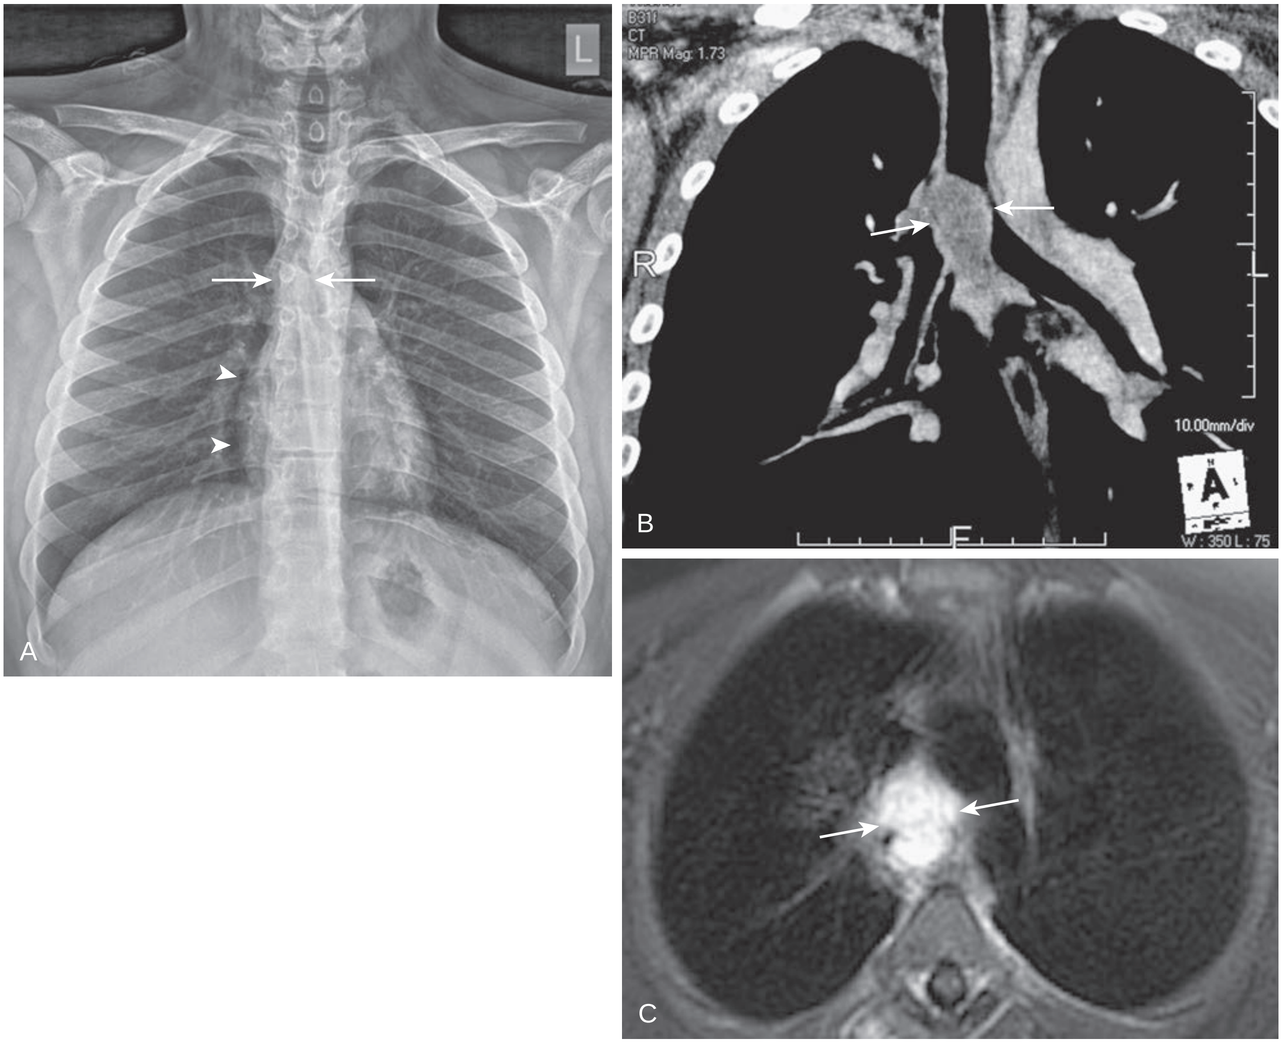

**Figure 55.11. Adenoid cystic carcinoma.** A 14-year-old boy with progressively worsening chronic cough and respiratory difficulty for 1 year who presented with hoarseness and crepitus over the neck. (A) Chest radiograph shows pneumomediastinum *(arrowheads)* and an apparent soft tissue density projecting over the carina *(arrows).* (B) A coronal contrast-enhanced CT image shows a lobulated soft tissue mass *(arrows)* centered near the carina, which results in narrowing of the adjacent airway. (C) Axial contrast-enhanced T1-weighted MRI demonstrates avid enhancement of the mass *(arrows).*

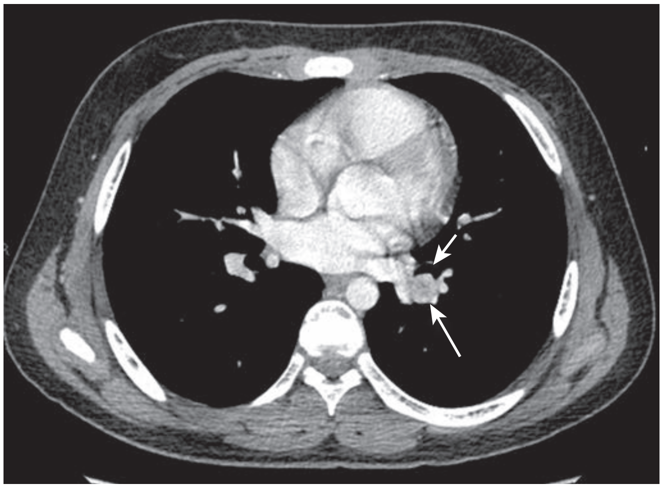
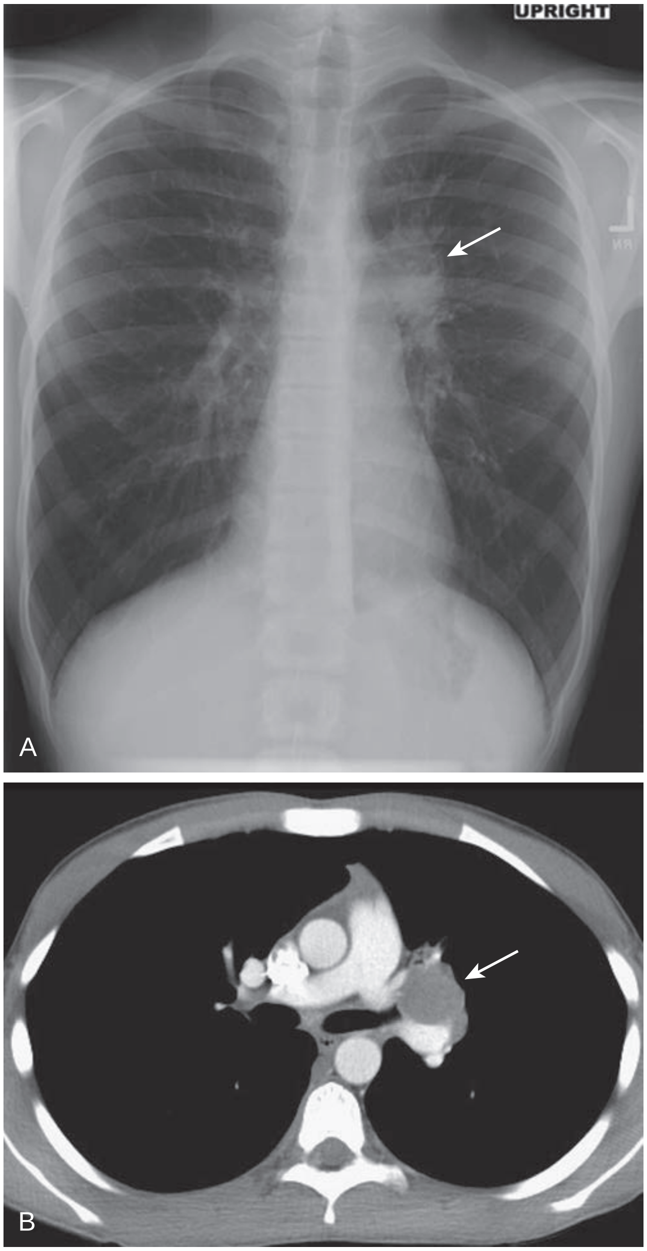


**e-Figure 55.9. Mucoepidermoid carcinoma.** A 9-year-old boy presenting with hemoptysis. Axial contrast-enhanced CT image shows a lobulated soft tissue mass *(long arrow)* centered at the left hilum, which protrudes into the adjacent airway *(short arrow).* CT virtual bronchoscopy demonstrates the protruding mass lesion over the posterior wall of the left main bronchus.



**e-Figure 55.10. Endobronchial mucoepidermoid carcinoma.** A 14-year-old boy presented with cough and fever that had lasted for 1 month. (A) Chest radiograph shows a left hilar mass *(arrow).* (B) Axial contrast-enhanced CT image demonstrates a well-circumscribed, heterogeneously enhancing mass within the left main-stem bronchus *(arrow).* Surgical pathology was consistent with endobronchial mucoepidermoid carcinoma.

(including squamous cell carcinoma, large cell carcinoma, and adenocarcinoma). These tumors are very rare in childhood. In the most recent WHO classification guideline, the term *bronchogenic carcinoma* is not used and each tumor type is listed individually.[50] Among these tumors, adenocarcinoma is the most common in children.[64] Most children with adenocarcinoma present with advanced disease, which results in high mortality rates. Small cell carcinoma, squamous cell carcinoma, and large cell carcinoma are very rare in children.[4,73]

***Imaging.*** On chest radiography, these tumors often present as a solitary pulmonary nodule or central mass, often associated with postobstructive atelectasis or consolidation (e-Fig. 55.12). On CT, the attenuation and enhancement of masses vary substantially among different types of tumors. Concomitant mediastinal or hilar adenopathy, as well as malignant pleural effusion, may also be present. Aggressive tumors may also invade adjacent mediastinal or osseous structures.

***Treatment and Follow-up.*** Surgical resection often combined with subsequent chemotherapy and radiotherapy is the current management of choice. Unfortunately, bronchogenic carcinoma of childhood has been known for its unusually rapid disease course with early metastases.

## Pleuropulmonary Blastoma

***Etiology.*** Pleuropulmonary blastoma (PPB) is an embryonal tumor of the lung; over 90% of affected patients are below 6 years old at diagnosis. It recapitulates the morphogenesis of the fetal lung and may be regarded as a dysontogenetic analog to Wilms tumor, neuroblastoma, and hepatoblastoma. PPB contains primitive mesenchyma and varying degrees of more mature cartilage, skeletal and smooth muscle, and fibrous tissue. A germline mutation in *DICER1* is the genetic cause in the majority of PPB cases, leaving patients at risk for other tumors.[74,75] The three PPB types are (1) type I (purely cystic with primitive mesenchymal cells beneath an intact epithelium), (2) type II (cystic and solid, mesenchymal cells overgrow the septa), and (3) type III (purely solid, complex sarcomatous neoplasm). Cystic type I PPB has a better prognosis than type II, and type II has a better outcome than type III.[75-77] It has been suggested that PPB is probably the same malignant tumor that has been reported in previous studies as mesenchymal sarcoma, malignant mesenchymoma, embryonal sarcoma, primary pulmonary rhabdomyosarcoma, primary pulmonary rhabdomyosarcoma arising in congenital lung cysts, or pulmonary blastoma in children.[78,79] Current data support the assertion that congenital lung cysts do not degenerate to become PPB but that cystic type I PPB may progress to more aggressive type II or type III PPB.[80-84] PPB may metastasize to the central nervous system, bone, and liver.

***Imaging.*** Imaging appearances of PPB depend on the type. PPBs present as solid, cystic, or mixed lesions. On chest radiography, the tumor may appear as a nodule or small mass that rapidly grows or as a large mass occupying the hemithorax. A large PPB may often result in mass effect on mediastinal structures. On CT, type I PPB is typically a cystic lesion often associated with multiple septations (Fig. 55.13), whereas type III PPB is a heterogeneously enhancing solid mass (Fig. 55.14). Type II PPB has a combination of both cystic and solid components (e-Fig. 55.15). Type I PPB is often indistinguishable from CPAM on the basis of radiologic evaluation.[85] Approximately 25% of patients with PPB have other embryonal tumors, most commonly renal cystic nephroma.[86-88]

***Treatment and Follow-up.*** The current treatment of choice for PPB is lobectomy or pneumonectomy.[89] Chemotherapy and local radiotherapy are adjuvant therapies if residual disease is present. Surveillance of *DICER1* mutation carriers may allow the earlier detection of cystic PPB before its progression to type II or III PPB and thereby improve outcomes.[75]

## Epithelioid Hemangioendothelioma

***Etiology.*** Pulmonary epithelioid hemangioendothelioma (PEH) is a rare tumor arising from endothelium with borderline malignant potential. PEH was first described by Dail and Liebow in 1975 as an intravascular bronchoalveolar tumor that may affect bone, soft tissue, liver, and lung. Later studies revealed that intravascular bronchoalveolar tumor and PEH are different manifestations of the same disease.[90,91] Although most of the affected patients are adult women, it may also occur in children.[92] The majority of patients are asymptomatic, and lesions are typically detected incidentally.[93]

***Imaging.*** On chest radiography, PEH typically presents as bilateral multiple pulmonary nodules ranging from 5 mm to 2 cm in diameter. Some patients may present with a solitary lesion

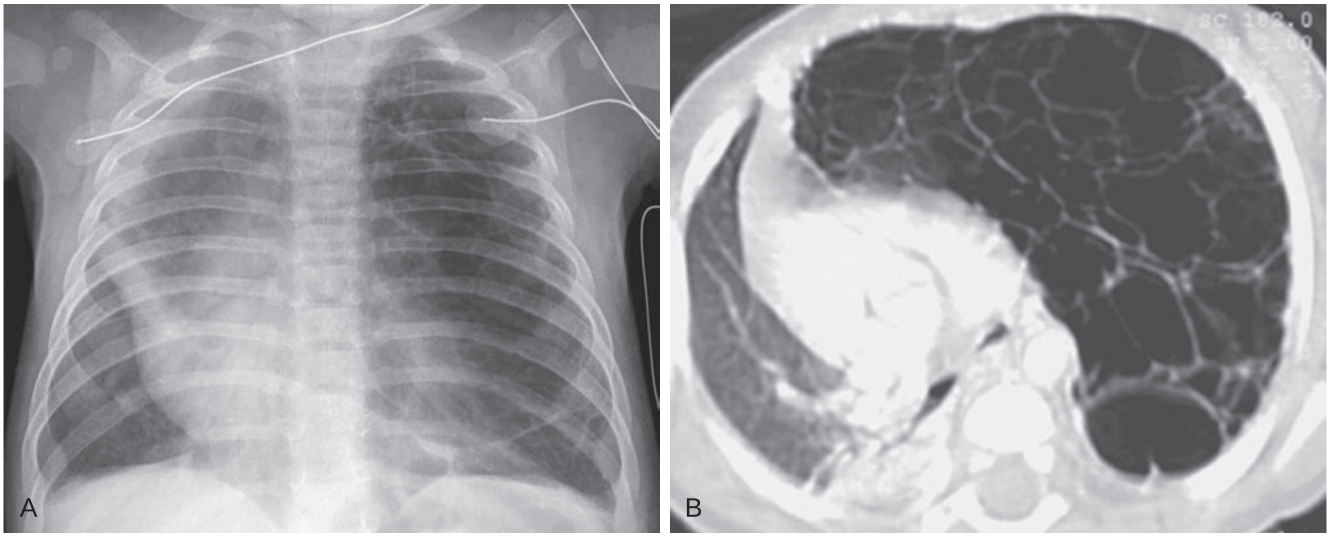


**Figure 55.13. Type 1 Cystic pleuropulmonary blastoma.** A 4-month-old boy with worsening respiratory distress. (A) Chest radiograph demonstrates a large radiolucent lesion with fine septations and multiple cysts within the left lung resulting in mediastinal shift. (B) Axial lung window CT image shows multiple cysts of varying sizes with mass effect on the mediastinum and contralateral right lung.

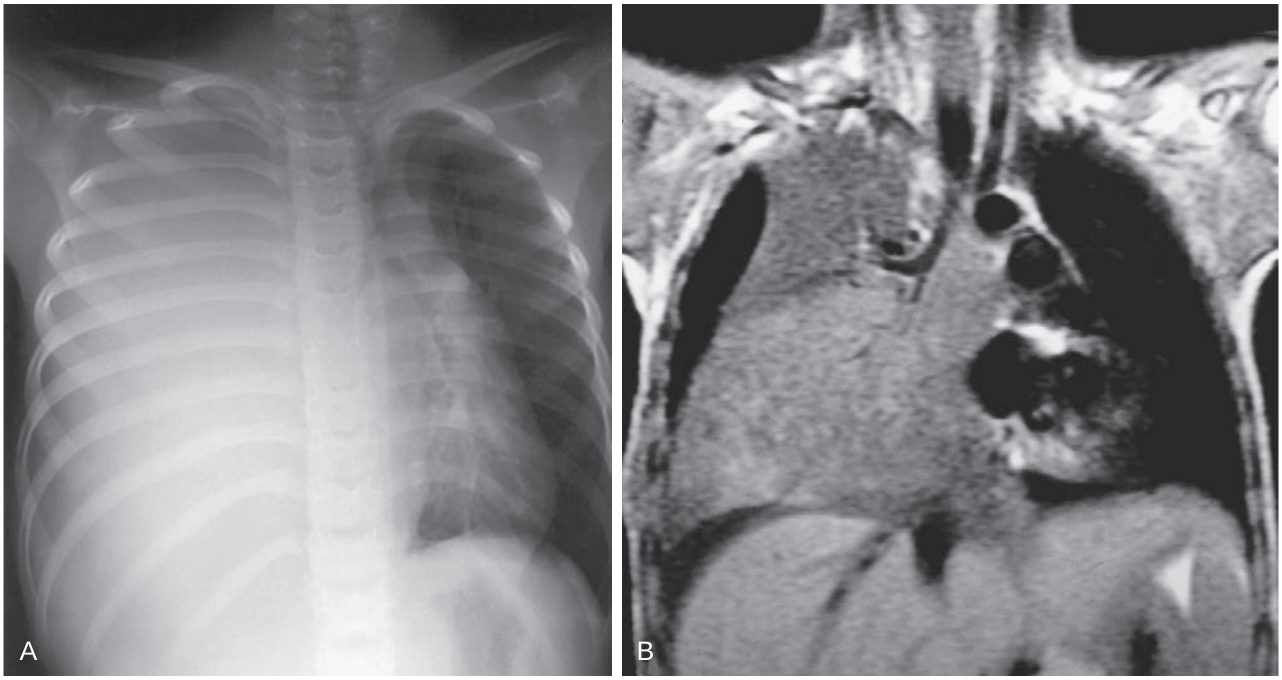
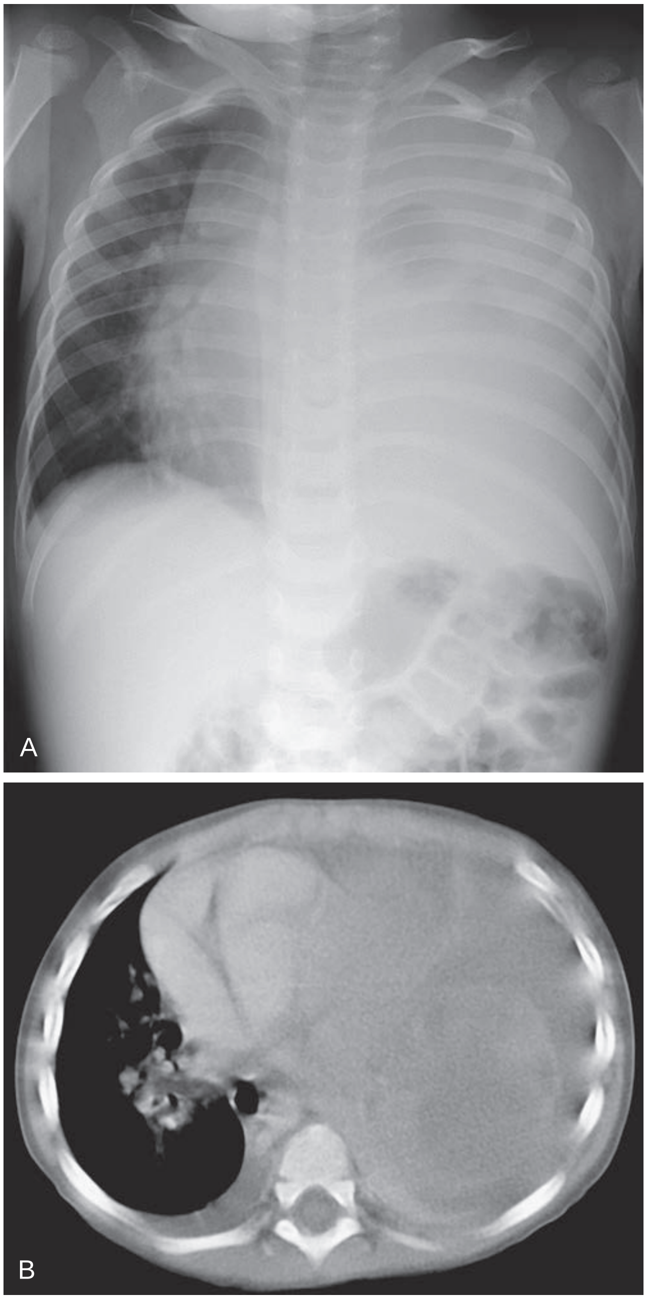


**e-Figure 55.12. Bronchogenic carcinoma.** A 7-year-old girl with cough. (A) Chest radiograph demonstrates a large mass occupying the right hemithorax, with contralateral mediastinal shift. (B) Coronal T1-weighted MRI shows a large right-sided mass encasing the bronchus, abutting the thymus, and extending into the mediastinum. Pathology identified the mass as squamous cell carcinoma.



**e-Figure 55.15. Type II mixed cystic and solid pleuropulmonary blastoma in a 2-year-old boy.** (A) Chest radiograph shows a completely opacified left hemithorax with mass effect producing a rightward cardiomediastinal shift. (B) Axial contrast-enhanced CT image demonstrates bilateral pleural effusion and a large, left-sided, predominantly solid, pulmonary and mediastinal heterogeneously enhancing mass.

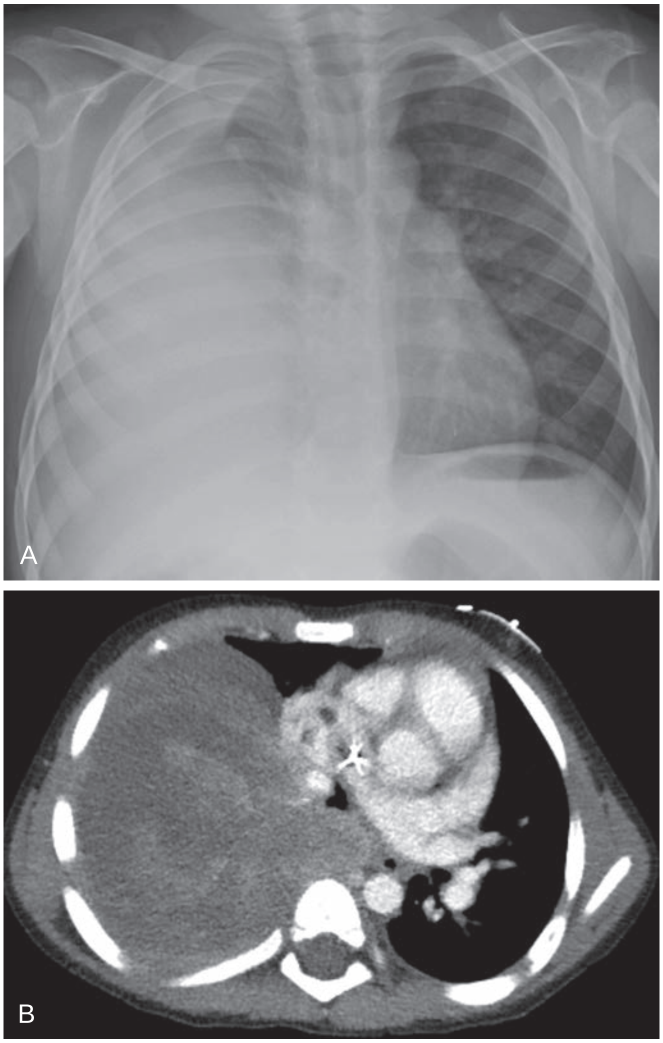


**Figure 55.14. Type III solid pleuropulmonary blastoma.** A 3-year-old boy presenting with tachypnea. (A) Chest radiograph shows near complete opacification of the right hemithorax. (B) An axial contrast-enhanced CT image reveals a large, solid, heterogeneously enhancing mass resulting in leftward mediastinal shift.

(e-Fig. 55.16). Concomitant hilar adenopathy and pleural effusion are seen in less than 10% of cases.[94] On CT, multiple well-defined or ill-defined perivascular nodules located near medium-sized vessels and bronchi are usually seen. Some pulmonary nodules may show calcification.[95,96]

***Treatment and Follow-up.*** Surgical resection is preferred in patients with solitary or a limited number of pulmonary lesions localized within one lobe. Chemotherapy, radiotherapy, and interferon are other treatment choices that are associated with variable results.[97] Close follow-up with no active therapy is usually used for asymptomatic patients with multiple lesions.[93] Recently, vascular endothelium growth factor was proposed as a potential treatment for PEH.

## Primary Malignant Lymphoproliferative Disorder

Primary pulmonary lymphomas are exceedingly rare and represent only 0.5% of all primary lung neoplasms. Malignant forms of lymphoproliferative disorder that, albeit rare, occasionally present with primary lung involvement include (1) extranodal marginal zone lymphoma of MALT origin (MALT lymphoma), (2) diffuse large B-cell lymphoma (DLBCL), and (3) lymphomatoid granulomatosis (LYG). The classification and imaging characteristics of lymphoproliferative disorders involving the lungs are listed in Table 55.2.

***Etiology.*** MALT lymphoma is a form of extranodal marginal zone B-cell lymphoma of MALT origin, characterized by an interstitial infiltrate of small lymphocytes forming a mass-like lesion. MALT lymphomas are frequently associated with autoimmune diseases. DLBCL presents as sheets of medium to large atypical lymphocytes forming a solid lesion. It is characteristically found in immunocompromised patients such as those with transplant or taking cyclosporine. LYG is a rare EBV-associated lymphoproliferative disorder with a propensity for blood vessel destruction, previously considered to be a form of necrotizing vasculitis.[98] The current consensus is that LYG is a distinctive polymorphic form of angiocentric lymphoma[99] with a predilection for extranodal involvement, most frequently of the lung, with a very poor prognosis.[98]

***Imaging.*** On CT, MALT lymphoma usually presents with single or multiple nodules or areas of consolidation of peribronchovascular distribution. Bronchial dilation is common, and mediastinal lymphadenopathy is present in around 30% of cases. DLBCL usually presents as single or multiple solid pulmonary nodules or masses. Cavitation occurs in about 50%.

For LYG, the most common radiographic features are bilateral, poorly defined lung nodules with a basilar predominance (e-Fig. 55.17). The lesions can progress rapidly, coalesce, and commonly cavitate, therefore mimicking Wegener granulomatosis or metastases. Characteristic CT findings of LYG include peribronchovascular distribution of nodules, small thin-walled cysts, and conglomerate small nodules.[29,100]

***Treatment and Follow-up.*** Treatment of MALT lymphoma is usually with chemotherapy or immunotherapy (rituximab).[101] The prognosis of MALT lymphoma is usually good,[102-104] but it tends to recur in the lung and may be complicated by DLBCL.[105] LYG may be resistant to ordinary chemotherapy. Rituximab, combined with other conventional chemotherapy, has been used with promising results.[106-108]

## SECONDARY MALIGNANT CONDITIONS

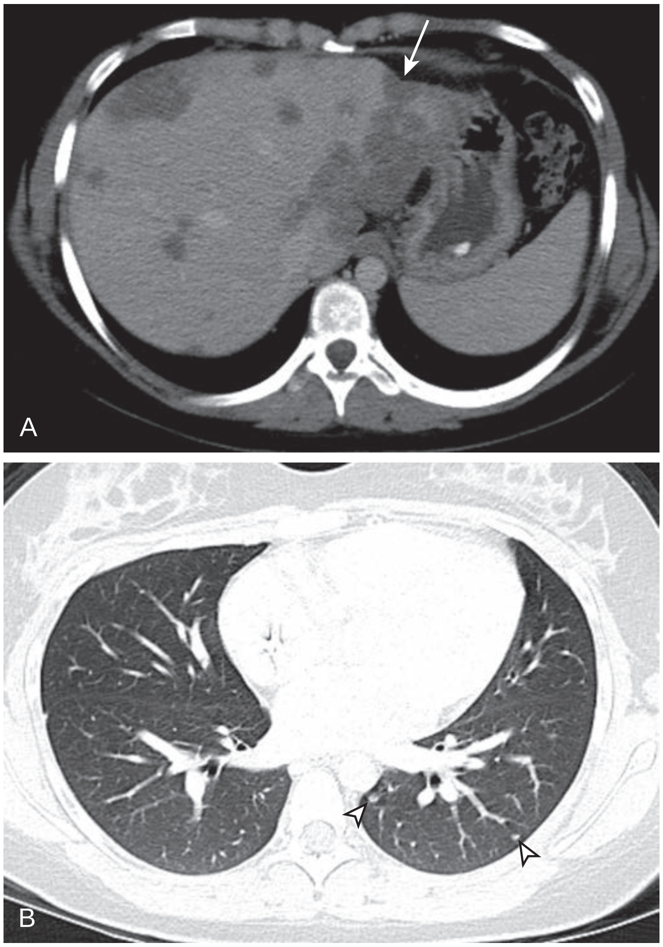
Secondary malignant conditions of the lungs may be caused by metastatic disease or from systemic diseases such as leukemia or lymphoma. Metastatic disease is by far the most common cause of pulmonary malignancy in childhood. Metastatic tumors accounts for approximately 80% of all lung tumors in children.[2] Osteogenic sarcoma and Wilms tumor are the most common tumors with pulmonary metastasis in children.

### Metastases

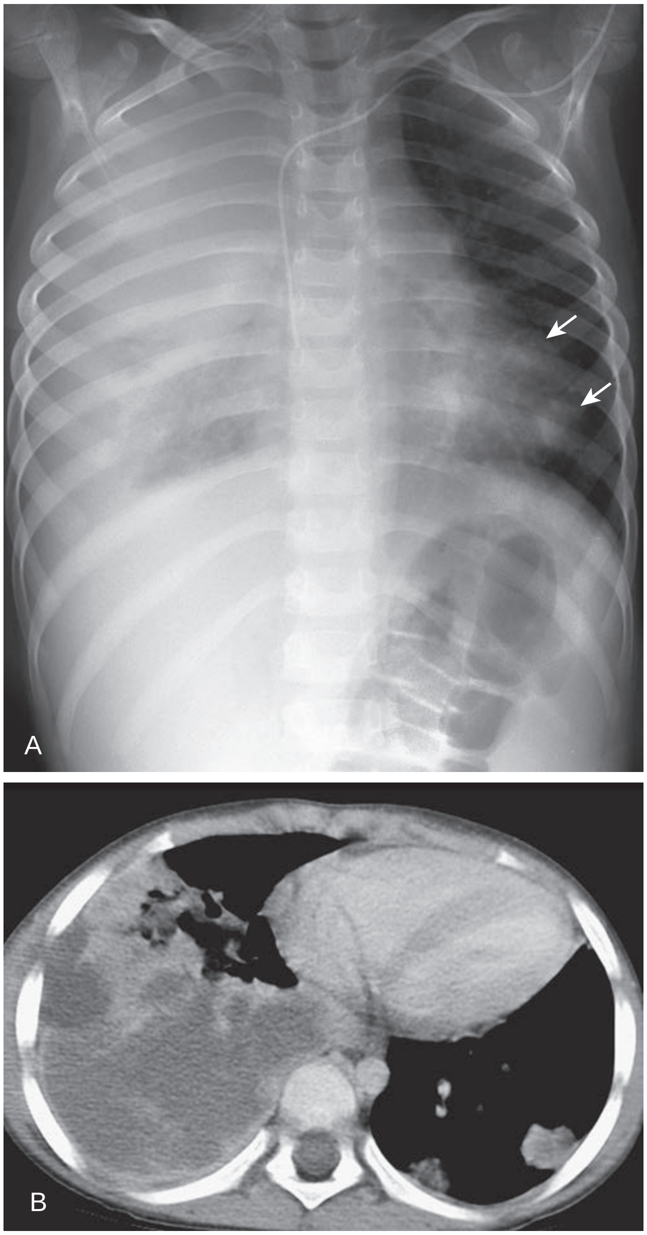
***Etiology.*** Pulmonary metastatic disease most often occurs hematogenously via the pulmonary arterial system. However, it may also occur via lymphatics, airways, or direct invasion.

***Imaging.*** On imaging studies, most metastatic lesions are seen as round and sharply marginated and of homogeneous soft tissue attenuation. They tend to be located subpleurally in the outer two-thirds of the lung. Metastatic lesions often appear to be directly contiguous with a pulmonary artery branch, reflecting their hematogenous origin. A greater number of metastatic lesions are located at the lung bases rather than in the upper lobes, likely because of gravity-dependent increased basilar blood flow. Lymphangitic tumors usually present as reticular or reticulonodular opacities on chest radiography. Thickening of interlobular or interlobar septa and bronchovascular bundles are often seen on CT of children with lymphangitic tumor spread.

CT is sensitive but not specific in detecting pulmonary metastasis. No specific CT features (e.g., location, attenuation, size,



**e-Figure 55.16. Epithelioid hemangioendothelioma.** 13-year-old girl with a history of hepatic epithelioid hemangioendothelioma. (A) Axial enhanced computed tomography image shows numerous hypoattenuating lesions. In the left lobe the lesions coalesce to form a larger confluent mass in a peripheral distribution with capsular retraction *(arrow).* (B) Axial lung window CT image shows two small, subcentimeter noncalcified parenchymal nodules *(arrowheads)* in the left lung.



**e-Figure 55.17. Lymphomatoid granulomatosis type III (form of B-cell lymphoma).** A 5-year-old boy with severe combined immunodeficiency who presented with cough and shortness of breath. (A) Chest radiograph demonstrates marked opacity of the right lung and cardiomediastinal shift to the left, with multiple left-sided nodules *(arrows).* (B) Axial contrast-enhanced CT image shows multiple left-sided cavitating nodules in addition to a large heterogeneous, predominantly low-attenuation, and confluent density within the right lung.

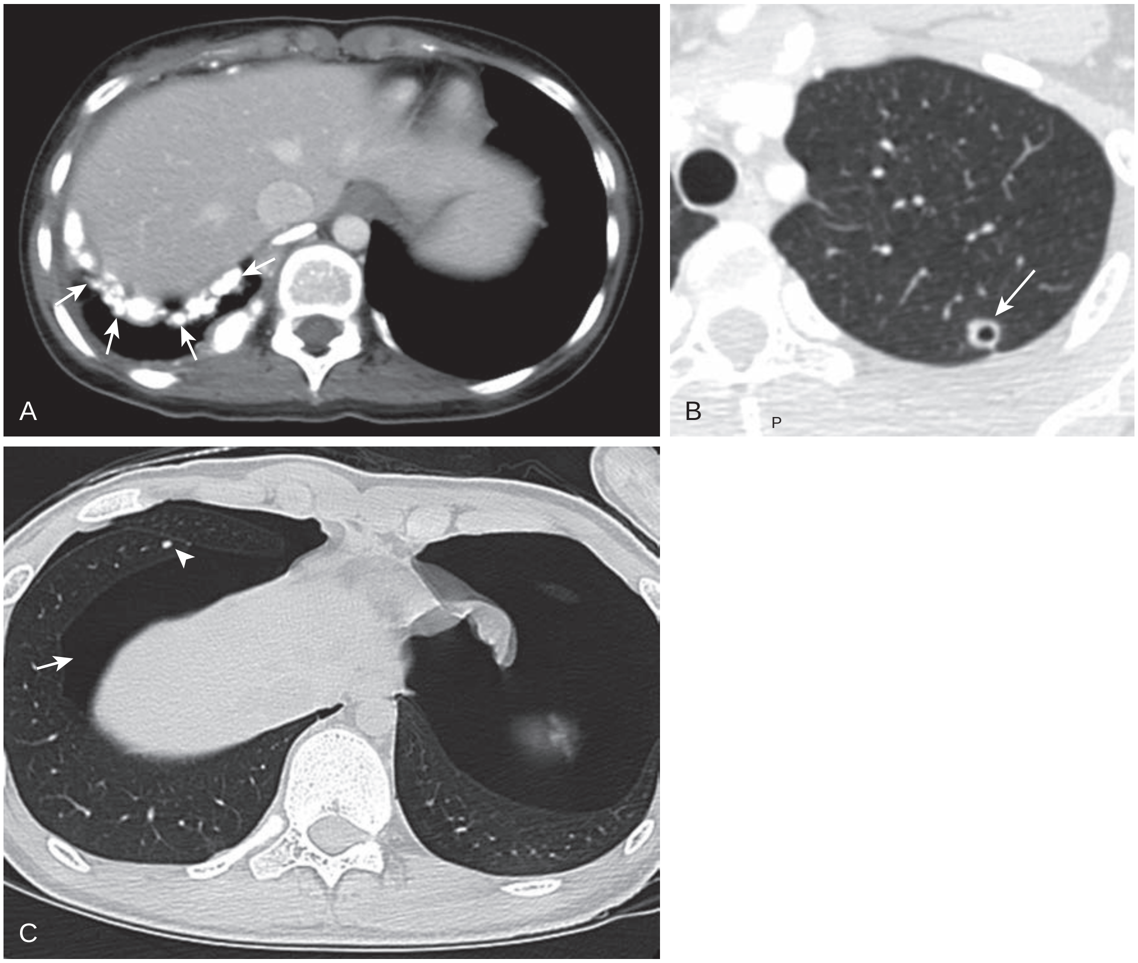


**Figure 55.18. Pulmonary metastases from osteosarcoma.** (A) Axial contrast-enhanced CT image of a 14-year old boy shows numerous calcified nodules of varying sizes, predominantly present at the subpleural lung base *(arrows).* (B) Axial lung window CT image of a 12-year old girl shows a cavitary subpleural nodule *(arrow)* in the left upper lobe. (C) Axial lung window CT image of a 16-year-old boy shows a small metastatic lung nodule *(arrowhead)* associated with a small pneumothorax *(arrow)* at lung base.

margin characteristics) can reliably distinguish benign lesions from malignant pulmonary lesions. However, in general, pulmonary lesions larger than 5 mm in diameter with sharp margins, especially when multiple, are usually malignant.[109] Pulmonary nodules that decrease in size during antineoplastic therapy are usually assumed to be malignant, whereas those that decrease in size without therapy or remain stable during 12 months of follow-up are likely benign.

Although the imaging appearances of the majority of metastatic pulmonary nodules are nonspecific, some primary tumors may produce characteristic pulmonary metastases. Metastatic osteosarcoma may ossify (Fig. 55.18A), cavitate (Fig. 55.18B), or present with pneumothorax (Fig. 55.18C). Lymphangitic spread is most commonly seen in children with rhabdomyosarcoma, neuroblastoma, and lymphoma.

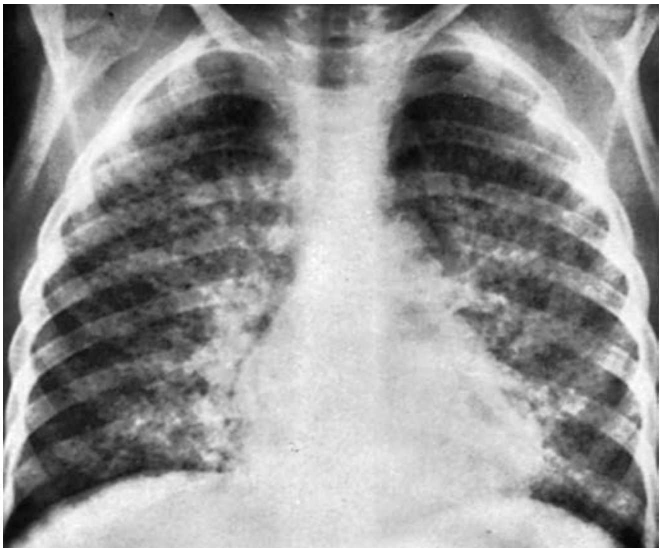
***Treatment and Follow-up.*** Pulmonary metastases have been reported in 10% to 20% of patients with osteogenic sarcoma at initial diagnosis. Approximately 40% to 55% of patients with nonmetastatic osteosarcoma develop lung metastases in the later stages of the disease.[110-114] Number, distribution, and timing, but not the size, of lung metastases are of prognostic value for survival.[115,116] The best treatment for this group of patients is a combination of metastasectomy and adjuvant chemotherapy.[117,118]

The lung is the most common site of metastatic disease in children with Wilms tumor. Traditionally, treatment strategy for metastatic Wilms tumor had been based on lung lesions detectable with chest radiography. Currently, controversy exists over the optimal way for managing small pulmonary lesions that are detected only with CT and are not apparent on chest radiography because of the potential lung toxicity associated with aggressive therapy.[119] Previous studies[120,121] suggested that the majority of these pulmonary lesions represent metastases, and patients with these lesions probably require more aggressive chemotherapy than those children without metastatic disease.[122]

## Leukemia

***Etiology.*** Approximately 20% to 60% of patients with leukemia have histologic evidence of lung involvement at autopsy, but fewer than 5% of these patients present with lung abnormality suggesting leukemic infiltrates on chest radiography.[123] Pulmonary involvement of leukemia is most often seen in patients with acute monocytic and myelogenous leukemia.[124]

***Imaging.*** On chest radiography, leukemic infiltrates usually show a diffuse reticular pattern of opacities (e-Fig. 55.19). Pulmonary nodules and focal homogeneous opacities are also reported in patients with leukemic involvement of lungs. On CT, interstitial thickening in a peribronchial distribution, small pulmonary nodules in a centrilobular or peribronchovascular



**e-Figure 55.19. Pulmonary leukemia.** A 7-year-old boy with biopsy-proven leukemia of the lungs. Chest radiograph shows a reticulonodular pattern of with central confluence. Relative sparing of the apices and the lateral segments of both lungs is evident. No radiographic evidence for adenopathy is present.

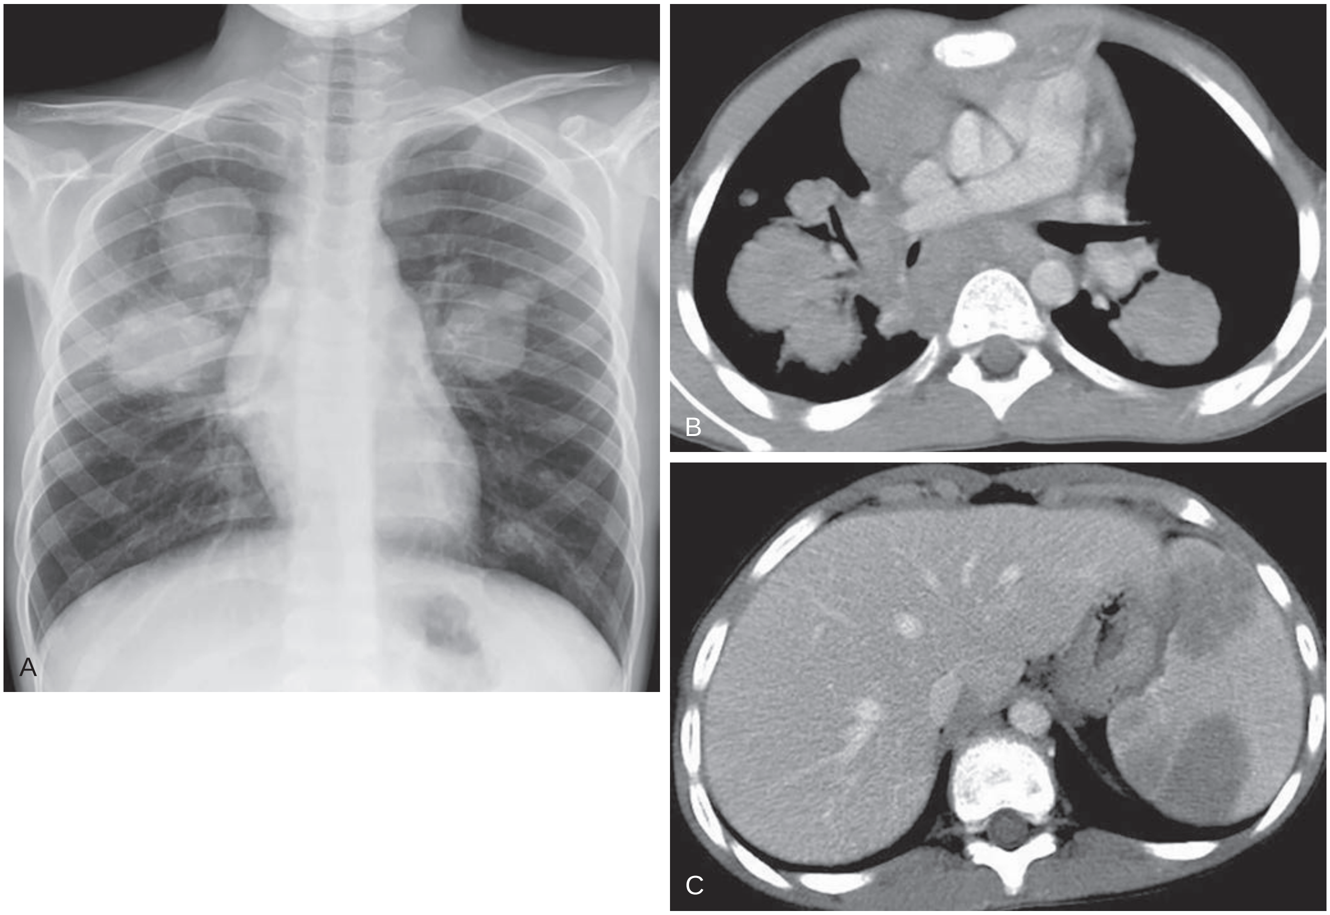


**Figure 55.20. Hodgkin lymphoma.** A 13-year-old boy who presented with cough that had lasted for 6 months. (A) Chest radiograph shows several pulmonary masses in both lungs of varying sizes predominantly in central location. (B) Axial contrast-enhanced CT image demonstrates several, bilateral pulmonary masses of soft tissue density and varying sizes in addition to anterior and posterior mediastinal lymphadenopathy. (C) Axial contrast-enhanced CT image of the upper abdomen shows several hypodense lesions in the spleen likely representing splenic involvement of lymphoma.

distribution, and focal areas of consolidation are common imaging findings.[125,126]

***Treatment and Follow-up.*** Lung biopsy is required for a definitive diagnosis of lung involvement from leukemia. Once the diagnosis is established, multiagent chemotherapy is currently the treatment of choice in pediatric patients with pulmonary leukemic involvement.[127-129]

## Lymphoma

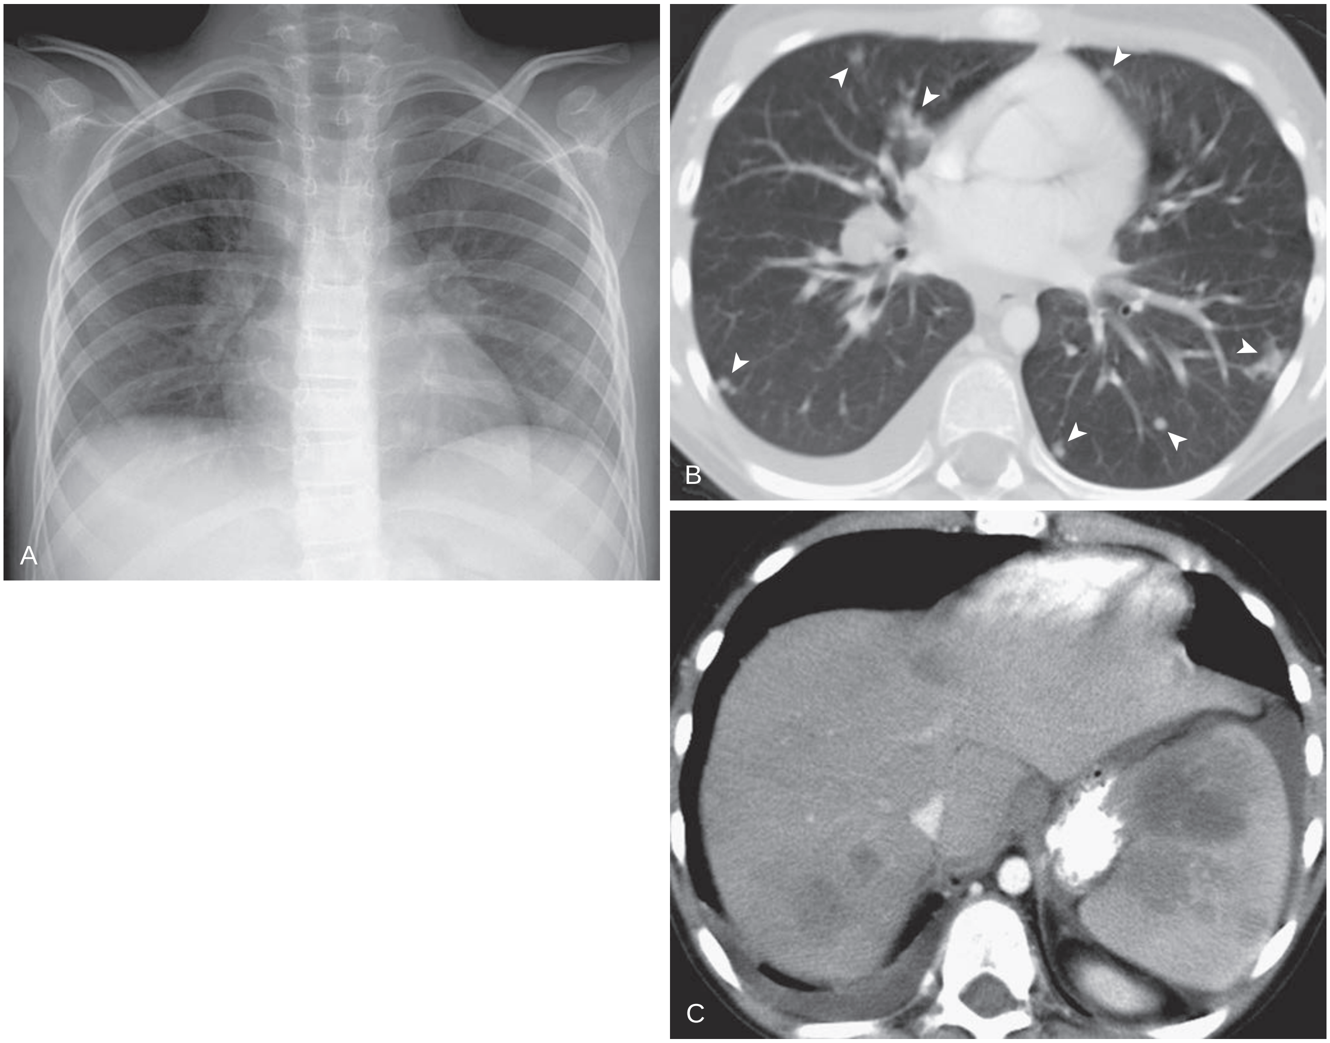
Secondary lymphomatous parenchymal neoplasms are far more prevalent than primary pulmonary lymphoma.[130]

***Etiology.*** Pulmonary parenchymal disease is more prevalent in pediatric lymphoma than that in adults, which is around 12% in Hodgkin disease (HD) and 10% in non-Hodgkin lymphoma (NHL).[131] Lung involvement is almost always seen at initial presentation rather than at disease relapse.[131] In both HD and NHL, the underlying mechanisms of lung involvement are hematogenous spread, lymphangitic dissemination, and, less frequently, direct invasion.

***Imaging.*** Lung involvement of lymphoma in pediatric patients typically presents as one of three patterns[132]: (1) nodular—single or multiple pulmonary nodules with irregular borders and sometimes central cavitation, which is the most common radiographic pattern (Fig. 55.20 and e-Fig. 55.21); (2) lymphangitic—reticular interstitial opacities, which result from venous or lymphatic obstruction caused by hilar or mediastinal adenopathy or from interstitial tumor deposition; and (3) alveolar—lobar or segmental consolidation, which may mimic an infectious process.[133-136] Occasionally, multiple tiny pulmonary nodules in a miliary pattern in children with HD may simulate miliary tuberculosis.[137,138] Pleural effusion is found in less than 5% of children with lymphoma.

Although the imaging appearance of lung involvement in children with HD and NHL is similar on imaging studies, lung involvement is usually concomitantly present with mediastinal or hilar lymphadenopathy in children with HD, whereas lung involvement may occur without associated lymphadenopathy in NHL.[133,139]

***Treatment and Follow-up.*** Chemotherapy is the current treatment of choice. Although infection is more common in pediatric lymphoma patients, especially those undergoing treatment, development of new pulmonary lesions with a poor response to antibiotics may represent lymphoma lesions and therefore should promptly be biopsied for a definitive diagnosis. Pulmonary lesions from lymphoma usually decrease in size, disappear, or leave a parenchymal scar after chemotherapy treatment.[101,140]



**e-Figure 55.21. Hodgkin lymphoma.** A 12-year-old boy with a history of ataxia telangiectasia, who presented with fevers and intermittent dry cough. He had daily fever with a maximum temperature of 104°F, worse at night, and associated with night sweats. (A) Chest radiograph shows mediastinal and hilar lymphadenopathy. (B) Axial lung window CT image demonstrates multiple, small, bilateral, ill-defined pulmonary nodules *(arrowheads)* and a small right pleural effusion in addition to lymphadenopathy. (C) Axial contrast-enhanced CT image shows numerous low-attenuation lesions in the liver and spleen. Biopsy samples from his liver and pleural fluid confirmed the diagnosis of Hodgkin lymphoma.

## KEY POINTS

- Benign pulmonary neoplasms in children are far less common than malignant lesions. The ratio of primary benign to primary malignant to secondary malignant neoplasms is 1.4 : 1 : 11.6.
- Lymphoproliferative disease is common in immunocompromised children. CT features range from pseudotumor, nodules, reticular interstitial pattern, to cysts. Definitive diagnosis relies on tissue biopsy.
- Metastatic disease is, by far, the most common cause of pulmonary malignancy in childhood. The most frequent causes are osteogenic sarcoma and Wilms tumor.
- Secondary pulmonary involvement in systemic diseases such as leukemia or lymphoma is relatively uncommon in children. CT features are nonspecific and include nodules, reticular interstitial pattern, and consolidation, which mimic infectious lung changes. Lung biopsy is required for definitive diagnosis.

# 56 Diffuse Lung Disease

*Evan J. Zucker and Edward Y. Lee*

The pediatric diffuse lung disorders, also known as childhood interstitial lung diseases (chILDs), comprise a rare and heterogeneous spectrum of progressive and often lethal pulmonary pathology. They are characterized by otherwise unexplained respiratory signs and symptoms, hypoxemia, and widespread pulmonary opacities on imaging.[1] The diseases are not limited to the interstitium and may affect the alveoli, airways, blood vessels, lymphatic channels, and pleural spaces. Although much remains unknown, the revised chILD classification scheme, recognizing disorders distinctly occurring in infants under 2 years of age (Box 56.1), along with advances in imaging and lung biopsy techniques, has greatly improved understanding.[1–20] In this chapter, the diseases of infancy are discussed, followed by an overview of diffuse lung disorders more prevalent in children over 2 years of age. The connective tissue, collagen vascular, and storage diseases are detailed in Chapter 57.

## DISORDERS OF INFANCY

### Diffuse Developmental Disorders

***Etiology.*** Diffuse developmental disorders are characterized by marked alveolar gas exchange impairment and are thought to arise early in prenatal lung development. The three main entities within this category are acinar dysplasia, congenital alveolar dysplasia, and alveolar capillary dysplasia with misalignment of pulmonary veins (ACD/MPV). Acinar dysplasia and congenital alveolar dysplasia are caused by arrest of lung development in the pseudoglandular/early canalicular and late canalicular/early saccular phases, respectively. ACD/MPV results from an abnormal location of pulmonary vein branches next to the pulmonary arteries along with medial hypertrophy of the pulmonary arterioles, reduced alveolar capillary density, and maldevelopment of pulmonary lobules; *FOXF1* gene mutations and 16q24.1 microdeletions are implicated in some cases.[1–27]

***Imaging.*** Chest radiographs, often the only imaging available, may initially appear normal but progress to hazy bilateral pulmonary opacities, resembling surfactant deficiency. Lung volumes are typically normal to decreased but increase with ventilator support. Barotrauma-related air leaks such as pneumothorax and pneumomediastinum develop in about half of patients (Fig. 56.1). With concurrent pulmonary hypertension (PHT), the main pulmonary artery may enlarge. Ultimately, imaging findings are nonspecific; however, the diagnosis should be considered in the term neonate with persistent unexplained respiratory distress.[1–27]

***Treatment and Follow-up.*** Patients develop rapidly progressive and nearly always lethal respiratory failure in the first 2 months of life despite treatment for PHT, intensive ventilation, and extracorporeal membrane oxygenation (ECMO). Serial chest radiographs can monitor the progression of the disease and help identify acute complications that may be seen with prolonged ventilatory support. Patients generally do not survive long enough for lung transplantation, the only viable treatment. More than 80% of patients with ACD/MPV have associated extrapulmonary anomalies (e.g., cardiac, gastrointestinal, or genitourinary), for which screening may be performed. Genetic counseling may be offered to relatives of patients with ACD/MPV, which appears heritable in 10% of cases.[1–27]

### Alveolar Growth Disorders

***Etiology.*** Alveolar growth disorders are the most common form of neonatal interstitial lung disease (ILD), caused by an unprogrammed insult to lung development, resulting in defective alveolar formation, lobular simplification, lack of alveolar septation, and airspace enlargement. Prematurity-related chronic lung disease (bronchopulmonary dysplasia [BPD]) is a frequently encountered subtype. Also included within this group are structural pulmonary changes related to chromosomal abnormalities or congenital heart disease and pulmonary hypoplasia due to oligohydramnios, space-occupying masses, and neuromuscular disease, among other etiologies.[1–20,28–34]

***Imaging.*** Features are variable. Chest radiographs in infants with classic BPD show coarse reticular opacities, cystic appearing lucencies, and disordered lung aeration due to alveolar septal fibrosis and hyperinflation. However, with ever-earlier delivery possible, there has been a shift in the imaging features of BPD. Findings in so-called "new" BPD range from near normal to markedly disordered lung parenchyma, variably sized pulmonary lobules, thick perilobular reticular opacities, linear and triangular subpleural opacities, ground-glass opacities, and hyperlucent areas, some of which resemble cysts or may be mistaken for emphysema (Fig. 56.2). Recently, the pulmonary findings of BPD known by radiography and computed tomography (CT) have been successfully delineated by a novel ultrashort echo time (UTE) magnetic resonance imaging (MRI) technique. In infants with trisomy 21, small subpleural cysts are characteristic (Fig. 56.3). In patients with X-linked filamin A gene mutations causing alveolar growth disturbances, characteristic findings include central pulmonary artery enlargement, atelectasis, progressive severe pulmonary hyperinflation, hyperlucency, and peripheral pulmonary vascular hypoattenuation resembling congenital lobar or acquired emphysema (e-Fig. 56.4).[1–20,28–34]

***Treatment and Follow-up.*** Decreasing respiratory support helps reduce BPD incidence and severity. Low-dose corticosteroids, fluid restriction, vitamin A, and patent ductus arteriosus closure are of equivocal benefit. Linear and subpleural opacities seen on CT correlate with interstitial fibroproliferation but not symptom severity. Lung biopsy may be considered to exclude the not-uncommon coexistence of pulmonary interstitial glycogenosis (PIG) (detailed later), which can be steroid-responsive. Lung transplantation is usually inevitable with filamin A mutations due to severe respiratory decline.[1–20,28–34]

### Surfactant Dysfunction Disorders and Related Abnormalities

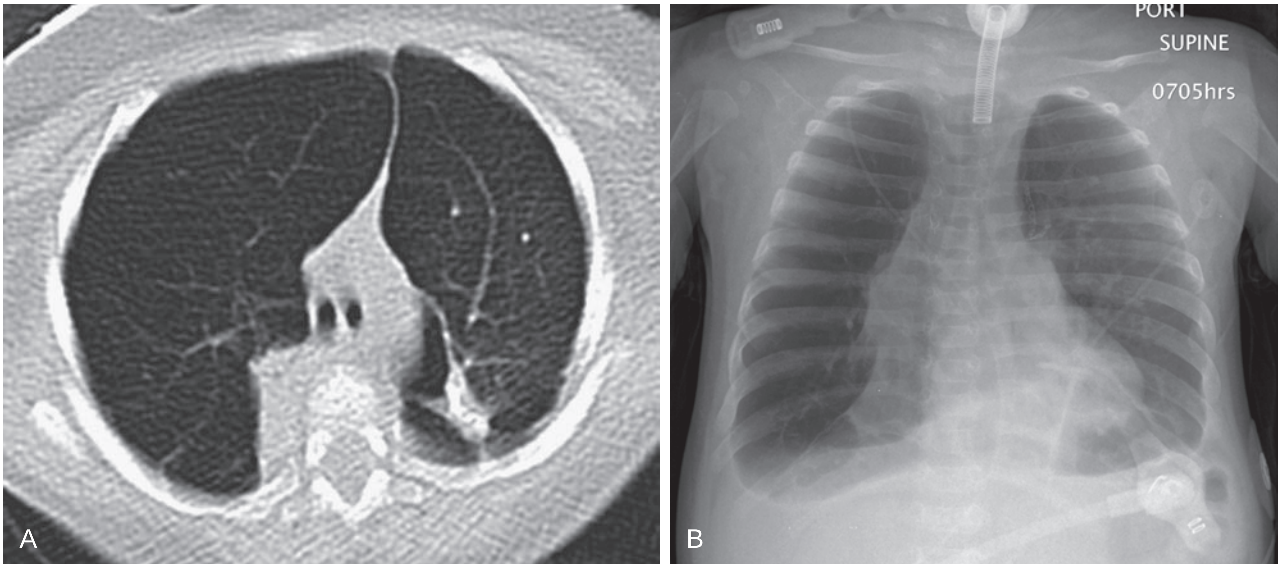
***Etiology.*** These disorders are caused by genetic mutations affecting surfactant metabolism, including surfactant proteins B (SpB) and C (SpC) and the adenosine triphosphate–binding cassette transporter protein A3 (ABCA3). Also included in this category are rare genetic disorders that indirectly influence surfactant production, such as thyroid transcription factor-1 (TTF-1)/NK homeobox 1 *(NKX2.1)* abnormalities ("brain-lung-thyroid syndrome"), lysinuric protein intolerance, and granulocyte-macrophage colony-stimulating factor–Rα mutations. Many etiologies remain uncharacterized.[1–20,35–45]

## Abstract:

The pediatric diffuse lung disorders, also known as childhood interstitial lung diseases (chILDs), refer to a rare and heterogeneous spectrum of pulmonary disorders associated with widespread pulmonary opacities and otherwise unexplained respiratory signs and symptoms. They are characteristically progressive and associated with significant morbidity and often mortality. The revised chILD classification scheme, recognizing disorders distinctly occurring in infants less than 2-years-old, combined with advances in imaging and lung biopsy techniques, has greatly improved understanding of these insidious and enigmatic disease. In this chapter, the disorders of infancy are discussed, followed by an overview of diffuse lung disorders more prevalent in children over 2 years of age. Distinctive imaging findings as well as disease pathogenesis and treatment options are highlighted.

## Keywords:

diffuse lung disease
childhood interstitial lung disease
chILD
neuroendocrine cell hyperplasia of infancy
pulmonary interstitial glycogenosis
crazy paving
bronchiolitis obliterans



**e-Figure 56.4. Filamin A gene mutation.** Axial computed tomography image at 4 months of age (A) and a chest radiograph at 6 months of age (B) in a female infant with progressive respiratory insufficiency depict severe pulmonary hyperinflation and hyperlucency with pulmonary vascular attenuation and posteromedial atelectasis.

### BOX 56.1 Classification System of Interstitial Lung Diseases in Infants

**DIFFUSE DEVELOPMENTAL DISORDERS**

Acinar dysplasia
Congenital alveolar dysplasia
Alveolar capillary dysplasia with misalignment of pulmonary veins

**ALVEOLAR GROWTH DISORDERS**

Prenatal: secondary pulmonary hypoplasia
Postnatal: chronic lung disease

- Prematurity-related chronic lung disease (bronchopulmonary dysplasia)
- Chronic lung disease in term infant

Associated chromosomal or genetic abnormalities

- Trisomy 21
- Other (e.g., filamin A mutation)

Associated congenital heart disease

**SURFACTANT DYSFUNCTION/RELATED ABNORMALITIES**

Surfactant dysfunction disorders

- *SpB* genetic mutations (pulmonary alveolar proteinosis and variants)
- *SpC* genetic mutations (chronic pneumonitis of infancy; also pulmonary alveolar proteinosis, desquamative interstitial pneumonitis, and nonspecific interstitial pneumonia)
- Adenosine triphosphate–binding cassette transporter protein A3 genetic mutation (pulmonary alveolar proteinosis; also CPI, diffuse interstitial pneumonitis, and nonspecific interstitial pneumonia)
- Congenital GM-CSF receptor deficiency (pulmonary alveolar proteinosis histologic pattern)
- Thyroid transcription factor-1 genetic mutations
- Others: histology consistent with surfactant dysfunction, unrecognized genetic disorder

Lysinuric protein intolerance (pulmonary alveolar proteinosis histologic pattern)

**SPECIFIC CONDITIONS OF UNKNOWN OR POORLY UNDERSTOOD ETIOLOGY**

Neuroendocrine cell hyperplasia of infancy
Pulmonary interstitial glycogenosis

- Primary
- Associated with other pulmonary conditions, especially alveolar growth disorders

Modified with permission from Lee EY, Cleveland RH, Langston C: Interstitial lung disease in infants and children: new classification system with emphasis on clinical, imaging, and pathologic correlation. In: Cleveland RH, ed. *Imaging in Pediatric Pulmonology*, New York: Springer; 2011.

***Imaging.*** Chest radiographs show diffuse or patchy hazy granular pulmonary opacities. CT demonstrates diffuse ground-glass opacity, consolidation, interlobular septal thickening, or a crazy-paving pattern typical of pulmonary alveolar proteinosis (PAP) (detailed in a later section) (Fig. 56.5). With increasing age, ground-glass opacities recede, and progressively larger and more numerous cysts develop (e-Fig. 56.6). Pectus excavatum may develop due to the effects of chronic lung disease on the growing chest wall.[1–20,35–45]

***Treatment and Follow-up.*** The diagnosis can be established by genetic testing, obviating lung biopsy. The mainstays of treatment are chronic ventilator support, nutritional supplementation, and potential lung transplantation, with anecdotal roles for pulse corticosteroids, hydroxychloroquine (Plaquenil), and azithromycin. Targeted gene therapy remains an area of investigation.[1–20,35–45]

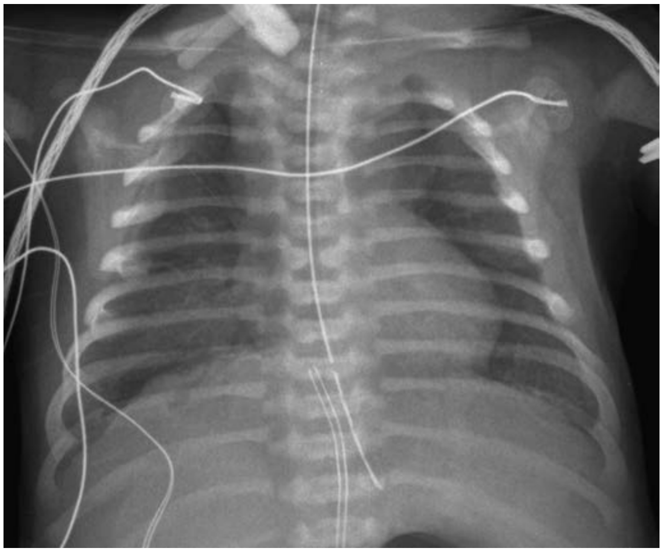


**Figure 56.1. Alveolar capillary dysplasia/misalignment of the pulmonary veins in a full-term newborn.** Chest radiograph demonstrates hazy bilateral pulmonary opacities, pneumomediastinum, and a right pneumothorax.

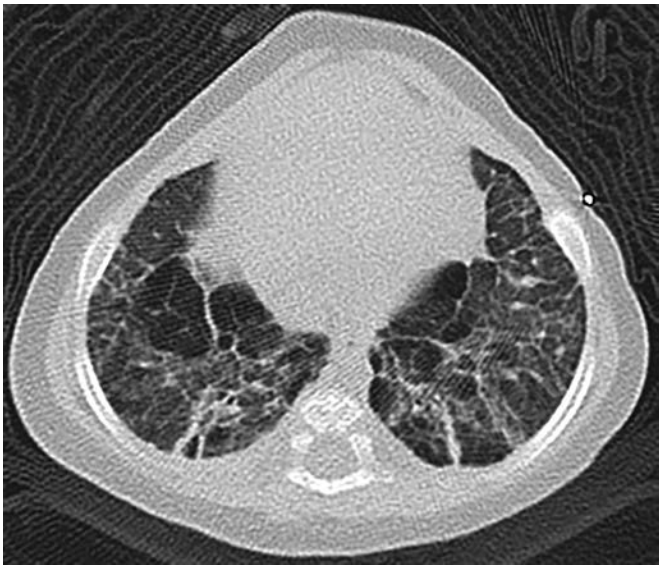

**Figure 56.2. Bronchopulmonary dysplasia (alveolar growth disorder) in a 5-month-old, ex-28-week premature female.** Axial CT image shows diffuse architectural distortion, lobular simplification and hyperlucency resembling emphysema, and thickening of perilobular septae.

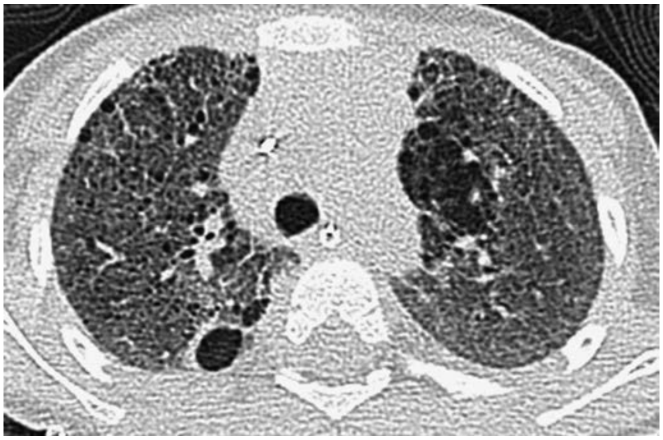
## Specific Conditions of Unknown or Poorly Understood Etiology

### Neuroendocrine Cell Hyperplasia of Infancy

***Etiology.*** The etiology of neuroendocrine cell hyperplasia of infancy (NEHI) is unknown. Histopathologically, the disease (previously referred to as persistent tachypnea of infancy) is characterized by increased numbers of pulmonary neuroendocrine cells (PNECs), which function in oxygen sensing and fetal lung development and normally rapidly decline after the neonatal period. Some cases have an identifiable genetic component, including links to *NKX2.1* mutations.[1–20,46–53]



**e-Figure 56.6. Surfactant dysfunction related to ABCA3 gene mutations in a 15-month-old infant.** Axial CT image reveals extensive ground-glass pulmonary opacification and numerous cysts.

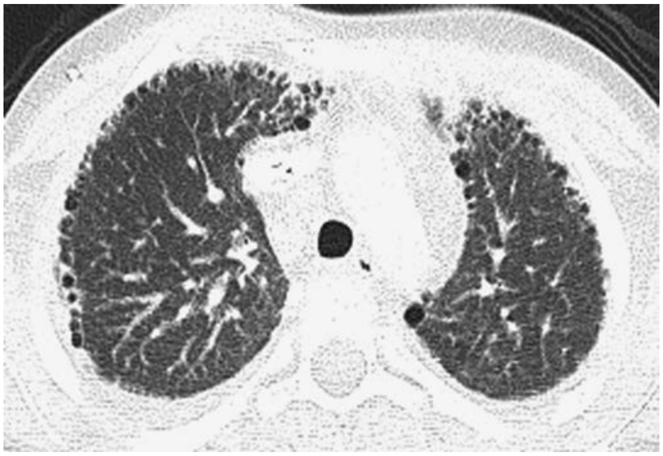


**Figure 56.3. Alveolar growth disorder related to trisomy 21 in a 10-year-old.** Axial CT image reveals numerous bilateral subpleural cysts.

***Imaging.*** Chest radiographs demonstrate hyperinflation and variable increased perihilar opacity resembling bronchiolitis or reactive airways disease (Fig. 56.7). CT characteristically shows a mosaic attenuation pattern indicating air trapping that affects at least four lobes, with geographic ground-glass opacities most prominent in the right middle lobe, lingula, and paramediastinal lung regions (Fig. 56.8). In experienced hands, the sensitivity and specificity of CT for NEHI diagnosis are reported to be 78% to 83% and 100%, respectively; thus CT may obviate the need for lung biopsy.[1–20,46–53]

***Treatment and Follow-up.*** Treatment of NEHI at present is supportive, geared toward preventing hypoxemia and infection and maintaining nutritional support. Although patients may be persistently symptomatic or require long-term oxygen therapy, the prognosis is usually favorable, without progressive respiratory failure or directly attributable death. In later life, acute exacerbations may occur due to intermittent air trapping or infection.[1–20,46–53]

### Pulmonary Interstitial Glycogenosis

***Etiology.*** The etiology of PIG, previously known as infantile cellular interstitial pneumonitis and histiocytoid pneumonia, remains unknown. PIG is characterized histopathologically by infiltration of the interstitium with immature mesenchymal cells containing copious cytoplasmic glycogen and staining positively for vimentin. The lack of PIG in lung biopsies from children older than 10 months suggests that the disorder may be related to lung growth and development. Patchy PIG and alveolar growth abnormalities commonly coexist.[1–20,54–59]

***Imaging.*** Chest radiographs show progressive hyperinflation and evolve from a fine interstitial to a coarse interstitial or alveolar pattern. CT may demonstrate pulmonary architectural distortion, hyperinflated/hyperlucent areas, ground-glass opacities (diffuse, segmental, or subsegmental), interlobular septal thickening, and linear opacities (Fig. 56.9). Because patchy PIG often coexists with alveolar growth abnormalities, the specific imaging features of “pure” PIG are uncertain. In one reported case of PIG, the multiple, small, scattered, air-filled, cystic-appearing changes were most likely attributable to the concomitant alveolar growth abnormality.[1–20,54–59]

***Treatment and Follow-up.*** Most patients require supplemental oxygen. Pulse glucocorticoids, which accelerate lung maturation, may be beneficial and are therefore often recommended. Overall, the prognosis is favorable, with no directly attributable deaths. However, greater mortality and morbidity rates are expected with concomitant growth abnormalities and PHT. During the first several months of life, marked improvement often occurs clinically, radiologically, and histologically, although hyperinflation may persist for years.[1–20,54–59]

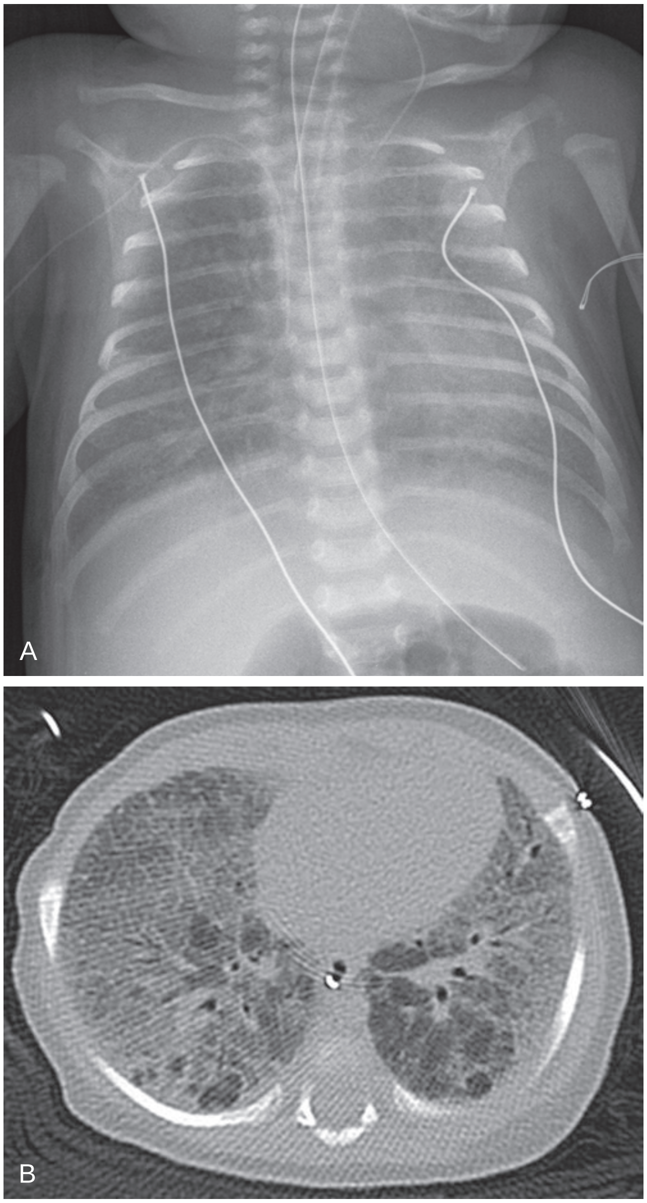

**Figure 56.5. Surfactant dysfunction related to ABCA3 gene mutations in a 4-week-old term female.** (A) Frontal chest radiograph shows diffuse bilateral hazy pulmonary opacities in a pattern resembling neonatal respiratory distress syndrome (RDS). (B) Axial CT image confirms diffuse bilateral ground-glass opacities along with septal thickening and areas of crazy paving.

## DISORDERS OF CHILDHOOD

### Pulmonary Alveolar Proteinosis

***Etiology.*** PAP is characterized by the abnormal accumulation of surfactant, a lipoproteinaceous material, within the alveoli, preventing normal gas exchange. The acquired form of PAP seen in older children and adults is most often caused by autoantibodies to granulocyte macrophage colony-stimulating factor (GM-CSF), impairing surfactant clearance. However, any number of processes that hinder alveolar macrophage function, ranging from leukemia to toxic exposure, can cause the same PAP end result.[1–20,60–67]

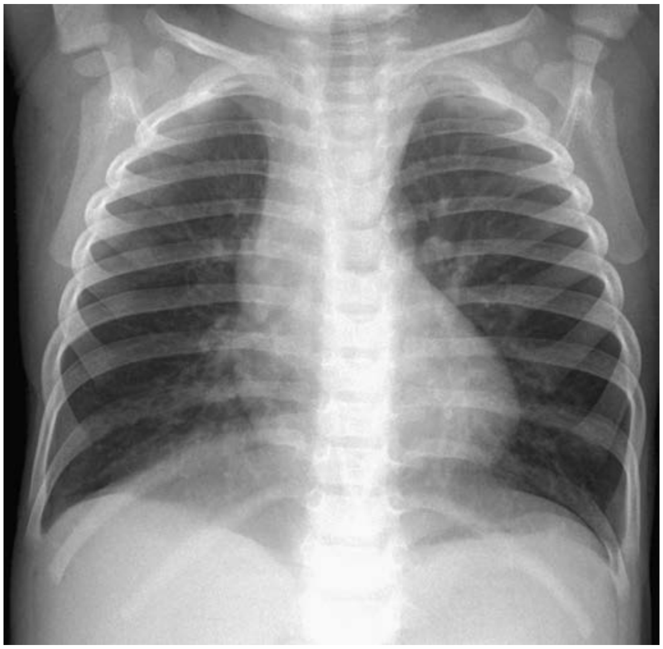

**Figure 56.7. Neuroendocrine cell hyperplasia of infancy in a 15-month-old.** Chest radiograph demonstrates pulmonary hyperinflation and parahilar opacities resembling reactive airways disease or bronchiolitis.

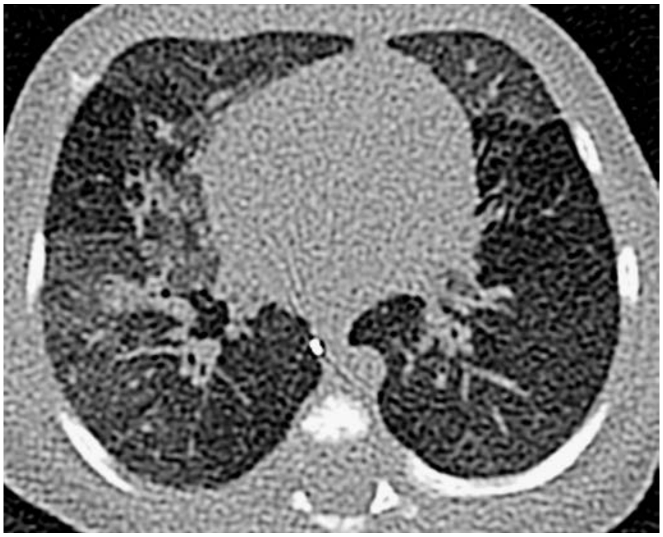

**Figure 56.8. Neuroendocrine cell hyperplasia of infancy in a 13-day-old male.** Axial expiratory CT image shows characteristic geographic ground-glass opacities involving the paramediastinal right middle lobe and lingula, as well the right lower lobe.

*Imaging.* Imaging cannot differentiate the various etiologies of PAP. Chest radiographs demonstrate symmetric perihilar opacities that extend to the periphery but are generally not as densely consolidative as would be expected in bacterial pneumonia. CT shows bilateral ground-glass opacities with smooth intralobular and interlobular septal thickening in polygonal shapes, an appearance known as “crazy-paving”[1–20,60–67] (Fig. 56.10).

*Treatment and Follow-up.* PAP is preferably confirmed by bronchoscopy with bronchoalveolar lavage and transbronchial biopsy rather than surgical lung biopsy. Serologic testing for GM-CSF antibodies should be performed to distinguish between autoimmune and secondary PAP. For secondary PAP, treatment efforts should focus on identifying the underlying cause. For autoimmune PAP, repeated whole-lung lavage is the current treatment of choice, although aerosolized GM-CSF therapy appears promising. Immunosuppression with rituximab or mycophenolate mofetil also has been tried. CT can be used to monitor treatment response.[1–20,60–67]

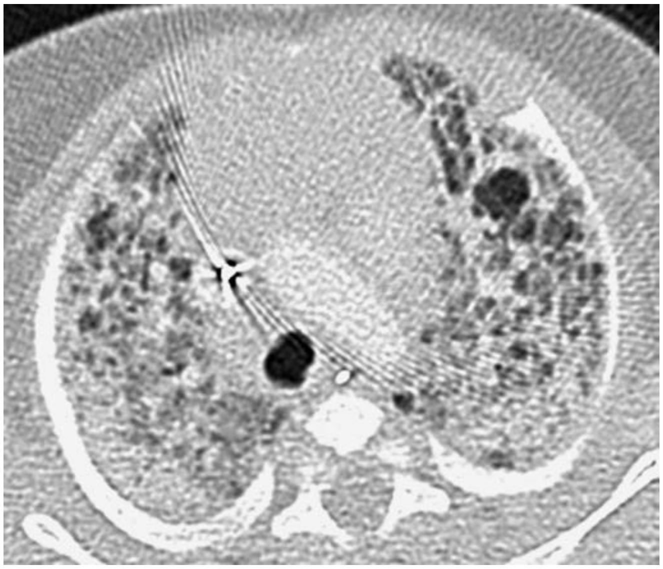

**Figure 56.9. Alveolar growth disorder and pulmonary interstitial glycogenosis in a 5-month-old former 25-week premature infant.** Axial computed tomography image shows cystlike hyperlucent lobules, thick reticular perilobular opacities, and ground-glass opacities.

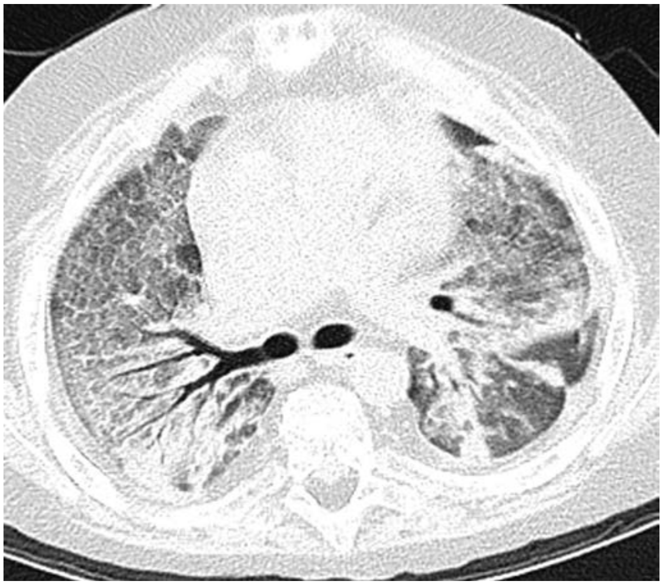

**Figure 56.10. Pulmonary alveolar proteinosis in an 8-year-old male.** Axial CT image shows a characteristic crazy-paving pattern with ground-glass opacities superimposed on inter- and intralobular septal thickening.

## Pulmonary Lymphangiectasia and Lymphangiomatosis

*Etiology.* Pulmonary lymphangiectasia is characterized by congenital or acquired dilation of the lymphatics draining the pulmonary interstitial and subpleural spaces. Pulmonary lymphangiomatosis is caused by proliferation of complex lymphatic channels with secondary lymphatic dilation. In both disorders, the disease may be limited to the lung or involve additional thoracic and/or extrathoracic sites.[1–20,68–73]

***Imaging.*** Chest radiographs demonstrate diffuse hazy opacities and bilateral pleural effusions. CT shows diffuse, smooth thickening of the interlobular septae and peribronchovascular interstitium, patchy ground-glass opacities, and pleural effusions (often chylous) (e-Fig. 56.11). Abnormalities are usually less marked in patients presenting beyond infancy. MRI demonstrates hyperintensity of the pulmonary interstitium on T2-weighted sequences and pleural effusions. Lung findings are very similar in pulmonary lymphangiectasia and lymphangiomatosis. However, lymphangiomatosis more often presents in late childhood and involves extrapulmonary sites, including lytic bone lesions and mediastinal soft tissue edema.[1–20,68–73]

***Treatment and Follow-up.*** Patients with congenital disease may be stillborn or present at birth with severe respiratory distress, leading to death within hours of life. Mechanical ventilation and pleural drainage invariably are required. Patients with long-term survival have variable degrees of respiratory compromise and are managed with supplemental oxygen at home, symptomatic therapy, fluid restriction, and dietary measures. Many other palliative options have been tried with variable success, including propranolol, corticosteroids, interferon-alpha, various chemotherapeutics, and radiotherapy.[1–20,68–73]

## Bronchiolitis Obliterans

***Etiology.*** Bronchiolitis obliterans (BO) is characterized by a fibroblastic reparative response to small airway injury, leading to airway occlusion. While viral infection is the most common precipitant, other etiologies include graft–versus–host disease and chronic allograft rejection postlung transplant. Terminology for BO in the literature is inconsistent, causing confusion. The clinical manifestation may be termed "bronchiolitis obliterans syndrome," whereas the histopathologic correlate is a spectrum termed "constrictive bronchiolitis" or "obliterative bronchiolitis," depending on the degree of airway lumen occlusion that is present.[1–20,74–84]

***Imaging.*** Chest radiographs may be normal. Abnormal findings, most commonly hyperinflation, are nonspecific. A unilateral hyperlucent lung with normal or decreased volume is characteristic of Swyer–James–Macleod syndrome, the result of BO affecting the growing lung. CT findings consist of air trapping accentuated on expiration, parenchymal hyperlucency, mosaic attenuation, bronchial wall thickening, bronchiectasis, and pulmonary vascular hypoattenuation (e-Fig. 56.12), findings are often bilateral and asymmetric. The presence of both hyperlucency and pulmonary vascular hypoattenuation is highly specific for moderate/severe nontransplant BO. With a correlating clinical history and a fixed obstructive pattern on pulmonary function testing, CT is diagnostic, thus avoiding lung biopsy.[1–20,74–84]

***Treatment and Follow-up.*** In the absence of bronchiectasis, BO can be difficult to distinguish from the more common acute viral bronchiolitis. Follow-up imaging thus can be helpful; bronchiolitis will eventually resolve, while BO will persist or worsen. In postinfectious BO, the extent of CT findings correlate with lung function. Postlung transplant, BO is known to increase mortality after the first postoperative year, and thus CT screening is prudent. Recent reports also suggest that serial CT monitoring of airway dimensions after transplant may help predict the presence and severity of BO. For transplant-associated BO, corticosteroids, azithromycin, N-acetyl cysteine, and possibly methotrexate appear beneficial.[1–20,74–84]

## Hypersensitivity Pneumonitis

***Etiology.*** Also known as extrinsic allergic alveolitis, hypersensitivity pneumonitis (HP) is characterized by pulmonary inflammation related to inhalational exposure of organic antigens, usually arising from birds, fungi, or dusts. Other precipitants include spray paints, glues, epoxy resins, insecticides, and drugs such as methotrexate. HP may be subcategorized as acute, subacute, or chronic based on the duration of exposure (hours, weeks to months, or months to years, respectively). Of note, cigarette smoking appears to protect against HP, possibly by inhibiting alveolar macrophage activity.[1–20,85–87]

***Imaging.*** In both acute and subacute HP, chest radiographs characteristically show diffuse micronodular interstitial prominence and opacities in the mid to lower lungs, resembling pulmonary edema or pneumonia. However, radiographs may appear normal, with findings visible only on CT in 40% of cases. CT demonstrates small (1–3 mm) poorly defined centrilobular nodules (reflecting bronchiolitis), ground-glass opacities (reflecting alveolitis), and air trapping, with relative sparing of the upper lungs. The "head-cheese" sign, a conglomerate of ground-glass opacity, mosaic attenuation indicating air trapping, and interspersed normal lung, is classic for subacute HP. On radiography and CT, the chronic form is characterized by volume loss and fibrotic changes with irregular linear/reticular opacities, architectural distortion, and honeycombing (e-Fig. 56.13).[1–20,85–87]

***Treatment and Follow-up.*** The most important aspect of treatment is identifying and eliminating exposure to the inciting antigen. The imaging findings associated with the acute and subacute forms of the disease regress with antigen removal. However, chronic changes persist and may progress. Systemic corticosteroids are the only dependable drug therapy but do not affect the long-term outcome. Irreversible fibrosis may be so severe that lung transplantation is needed.[1–20,85–87]

## Diffuse Pulmonary Hemorrhage Disorders

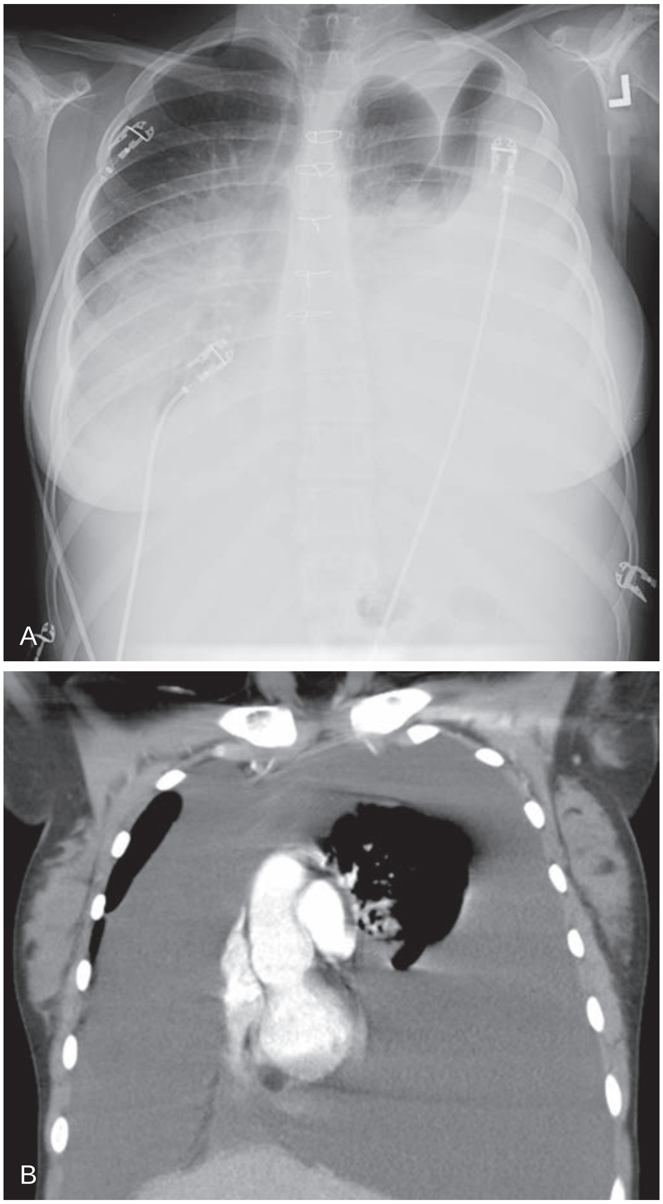
***Etiology.*** Diffuse pulmonary hemorrhage disorders can be subcategorized according to the presence or absence of capillaritis, which is characterized pathologically by inflammatory disruption of the interstitial capillary network. Disorders with capillaritis include idiopathic pulmonary capillaritis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyangiitis, Goodpasture syndrome, idiopathic pulmonary-renal syndrome, systemic lupus erythematosus, and drug-induced capillaritis. Disorders without capillaritis include idiopathic pulmonary hemosiderosis, acute idiopathic pulmonary hemorrhage of infancy, Heiner syndrome (pulmonary disease caused by food sensitivity, usually to cow's milk), coagulation disorders, and cardiovascular disorders such as pulmonary veno-occlusive disease and pulmonary arteriovenous malformation.[1–20,88–92]

***Imaging.*** The classic radiographic appearance of acute diffuse pulmonary hemorrhage consists of bilateral symmetric airspace opacities in a "butterfly" or "batwing" pattern. However, opacities may be asymmetric or unilateral. CT is more sensitive and shows patchy ground-glass opacities (Fig. 56.14) and consolidation acutely. With organizing or repetitive hemorrhage, findings evolve to interlobular septal thickening, nodular opacities, and potentially a crazy-paving pattern. Multiple bilateral variably-sized pulmonary nodules with cavitation are characteristic of granulomatosis with polyangiitis (e-Fig. 56.15).[1–20,88–92]

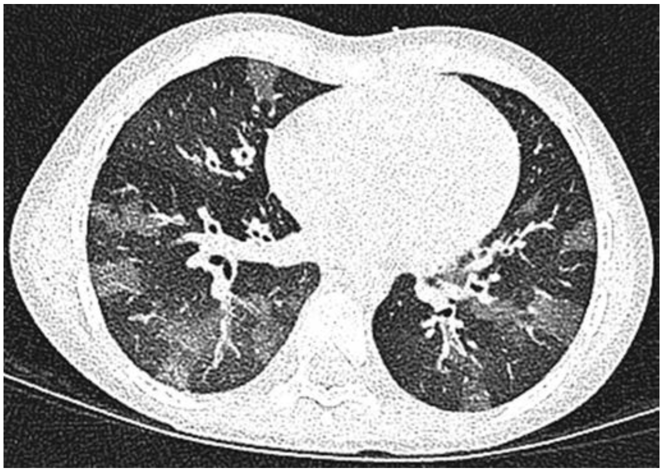
***Treatment and Follow-up.*** Distinguishing between pulmonary hemorrhage with capillaritis versus without capillaritis is critical, because pulmonary capillaritis often requires aggressive immunosuppressive therapy. Because imaging findings are similar in the many conditions causing pulmonary hemorrhage, a lung biopsy often is necessary for a definitive diagnosis. With treatment, CT findings typically improve.[1–20,88–92]

## Nonspecific Interstitial Pneumonia

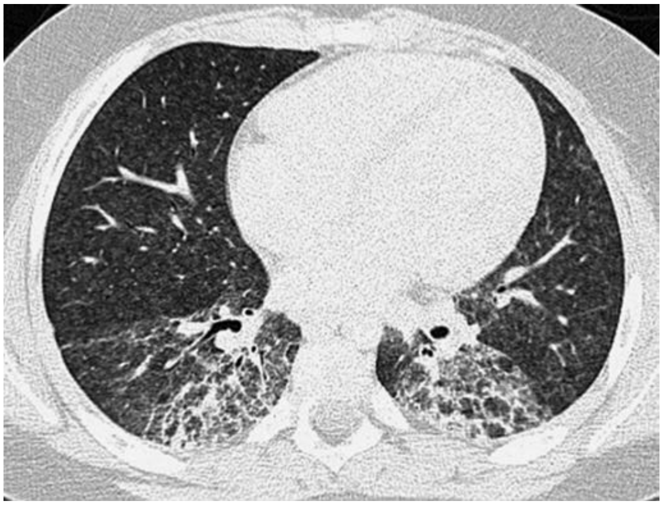
***Etiology.*** Nonspecific interstitial pneumonia (NSIP) can be idiopathic, familial, or the final common pathway of several other disorders, including autoimmune connective tissue and collagen vascular diseases, genetic surfactant disorders, and HP. It has a



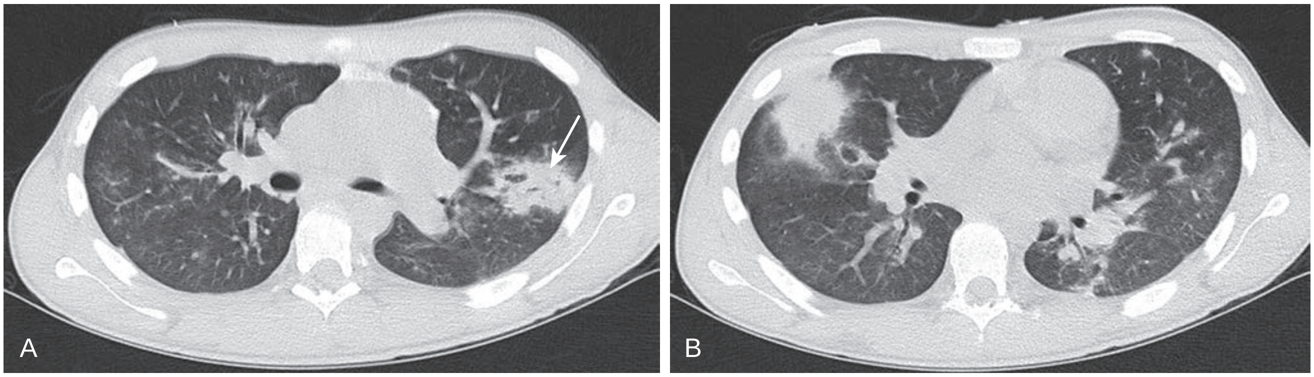
**e-Figure 56.11. Congenital systemic lymphangiectasia in a 16-year-old female.** Frontal chest radiograph (A) and coronal computed tomography (B) image show marked and partially loculated bilateral pleural effusions.



**e-Figure 56.12. Bronchiolitis obliterans in a 3-year-old female.** Axial expiratory CT image shows characteristic findings of mosaic attenuation, parenchymal hyperlucency, bronchial wall thickening, and bronchiectasis.



**e-Figure 56.13. Acute-on-chronic hypersensitivity pneumonitis in a 10-year-old.** Axial CT image demonstrates diffusely scattered small centrilobular nodular opacities, as well as lower lobe volume loss and reticular fibrotic opacities.



**e-Figure 56.15. Granulomatosis with polyangiitis (formerly Wegener's granulomatosis) in a 15-year-old male.** Axial CT images (A and B) show bilateral irregular pulmonary masses, one with suspected cavitation in the left upper lobe (A, *arrow*). Superimposed ground-glass opacities are present.

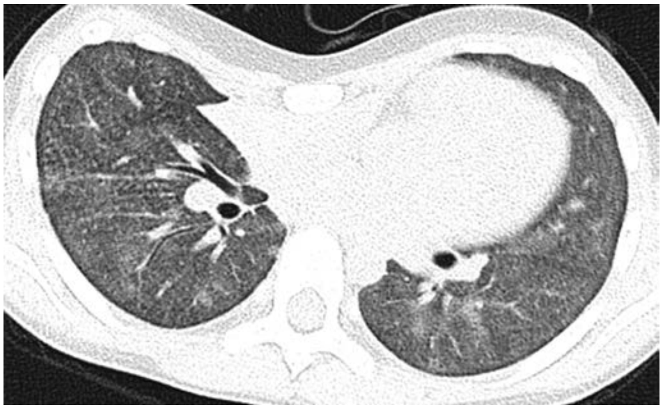


**Figure 56.14. Idiopathic pulmonary hemosiderosis in an 8-year-old female.** Axial CT image shows diffuse bilateral ground-glass nodular opacities.

characteristic histopathologic appearance with temporally and spatially uniform interstitial lymphoplasmacytic inflammation and varying degrees of fibrosis. Cellular and fibrotic subtypes have been described.[1–20,93–95]

***Imaging.*** Best characterized by CT, the typical imaging findings are ground-glass and fine linear or reticular opacities, predominantly at the lung periphery. Traction bronchiectasis, volume loss (predominantly in the lower lobe), and honeycombing may develop over time. Dilation of the esophagus is characteristic of scleroderma, which has an NSIP pattern (e-Fig. 56.16).[1–20,5,93–95]

***Treatment and Follow-up.*** CT findings of NSIP can resolve or persist, depending on the degree of fibrosis. Immunosuppressive therapy often is beneficial. However, patients with progressive disease may require lung transplantation.[1–20,93–95]

## Organizing Pneumonia

***Etiology.*** Organizing pneumonia is characterized histologically by intraluminal organizing fibrosis in the distal airways and airspaces (bronchioles, alveolar ducts, and alveoli). When idiopathic, it may be termed "cryptogenic organizing pneumonia." However, it can result from various causes, including asthma, drug reaction, aspiration pneumonia, autoimmune disease, chemotherapy, bone marrow transplantation, and other conditions stimulating a lung reparative response. The term "bronchiolitis obliterans organizing pneumonia" has been discarded because of its potential confusion with BO, a distinct entity.[1–20,96–100]

***Imaging.*** Imaging findings are variable, with CT most frequently showing peripheral patchy consolidation with or without surrounding ground-glass opacity. Commonly, air bronchograms and mild bronchial dilatation are found within areas of consolidation. Other recognized findings include the atoll or reverse halo sign (central ground-glass opacity surrounded by consolidation) (Fig. 56.17), small pulmonary nodules along bronchovascular bundles, linear and bandlike subpleural opacities, perilobular thickening, and progressive fibrosis.[1–20,96–100]

***Treatment and Follow-up.*** Although organizing pneumonia has many underlying causes, overall, corticosteroids are the best treatment option. Rarely, it may remit spontaneously. The prognosis is generally favorable, with up to an 80% cure rate reported. Imaging findings related to inflammation will improve/resolve on follow-up, whereas irreversible fibrotic changes may persist or worsen.[1–20,96–100]

## Pulmonary Infiltrate With Eosinophilia

***Etiology.*** The eosinophilic lung diseases are a diverse group of disorders characterized by peripheral or tissue eosinophilia, with interstitial and intraalveolar eosinophils at pathology. Three subcategories are recognized: eosinophilic disease of unknown cause, eosinophilic disease of known cause, and eosinophilic vasculitis. Diseases of unknown cause include simple pulmonary eosinophilia (or Löffler syndrome), acute eosinophilic pneumonia (AEP), chronic eosinophilic pneumonia (CEP), and idiopathic hypereosinophilic syndrome. Diseases of known cause include allergic bronchopulmonary aspergillosis (ABPA), bronchocentric granulomatosis, parasitic infections, and drug reactions. Eosinophilic vasculitis includes allergic angiitis and granulomatosis (Churg–Strauss syndrome).[1–20,101–106]

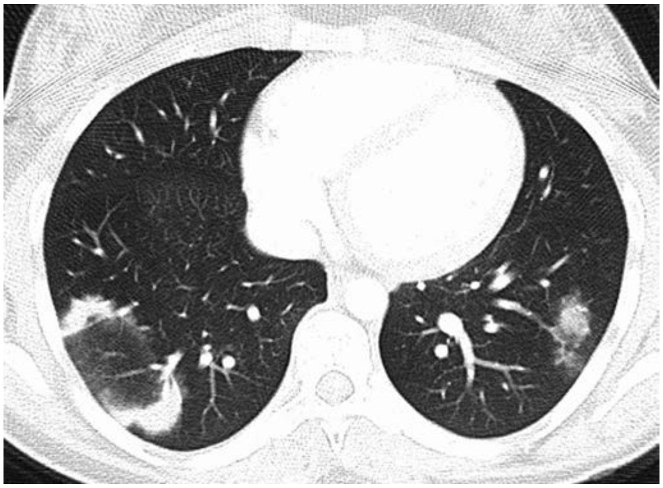

**Figure 56.17. Sjögren syndrome in a 15-year-old.** Axial CT image depicts a patchy consolidation of the peripheral left lower lobe and a ground-glass opacity surrounded by consolidation ("atoll" or "reverse halo" sign) of the peripheral right lower lobe representing sites of organizing pneumonia.

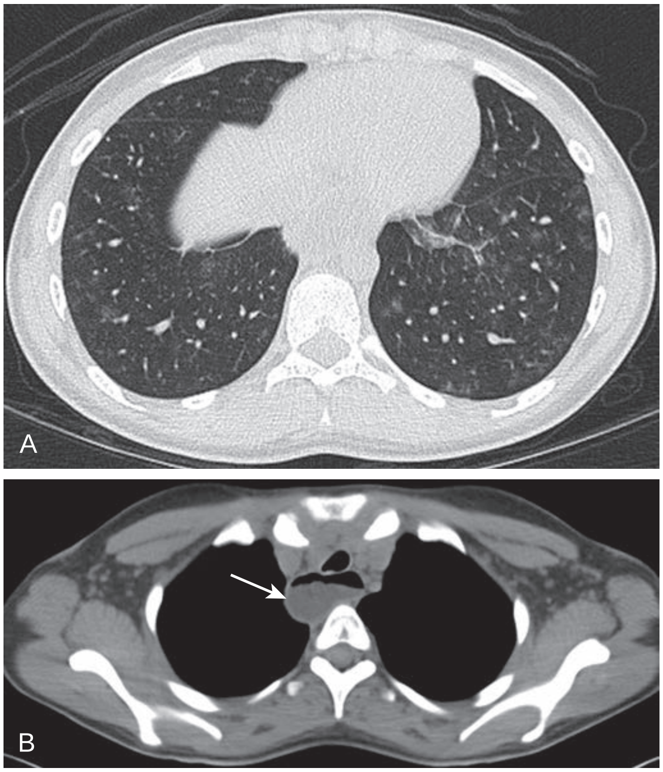
***Imaging.*** Imaging findings of interstitial, alveolar, or mixed interstitial-alveolar opacities are in general nonspecific, but certain key features may suggest the underlying diagnosis. CEP and drug-induced pulmonary infiltrate with eosinophilia (PIE) demonstrate a characteristic pattern of peripheral consolidation with sparing of the central lung zones (a "photographic negative" or "reversed" pulmonary edema pattern), allowing a highly specific diagnosis in the setting of peripheral eosinophilia (Fig. 56.18). AEP presents radiographically with bilateral reticular opacities, possibly with consolidation and pleural effusion. On CT, bilateral patchy ground-glass opacity and often interlobular septal thickening, consolidation, or poorly defined nodules are seen. The imaging findings of AEP mimic those of more common entities such as pulmonary edema and acute respiratory distress syndrome, potentially delaying diagnosis. ABPA demonstrates central bronchiectasis with or without mucoid impaction; the presence of mucoid impaction of the large airways is referred to as the "finger-in-glove" sign. Simple pulmonary eosinophilia and idiopathic hypereosinophilic syndrome characteristically demonstrate pulmonary nodules with ground-glass halos. Bronchocentric granulomatosis demonstrates focal masses and nodules or lobar consolidation with atelectasis. Findings in persons with Churg-Strauss syndrome include subpleural consolidation, centrilobular nodules, bronchial wall thickening, and interlobular septal thickening.[1–20,101–106]

***Treatment and Follow-up.*** Imaging findings, even if nonspecific, can localize potential sites for lung biopsy. Corticosteroids are the treatment of choice, resulting in prompt and complete response. In persons with AEP, relapses do not occur after cessation of corticosteroids, although they can occur with CEP. Therapy may be tailored to the underlying cause; for example, antiparasitic medications may be used in a case of parasite-induced PIE.[1–20,101–106]



**e-Figure 56.16. Mixed connective tissue disease in a 13-year-old female.** (A) Axial computed tomography (CT) image in lung windows shows basilar-predominant ground-glass nodular opacities with subpleural sparing, findings compatible with nonspecific interstitial pneumonia (NSIP). (B) Axial CT image in mediastinal windows reveals a dilated fluid-filled esophagus (*arrow*), characteristic of a scleroderma-like pattern.

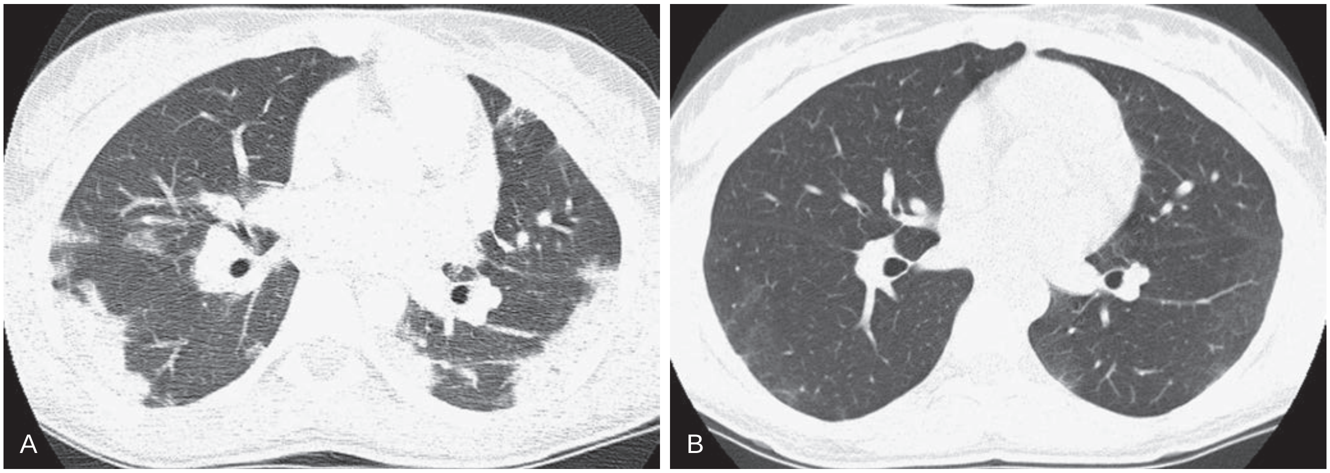


**Figure 56.18. Drug-induced (minocycline) pulmonary infiltrate with eosinophilia in an 18-year-old.** Axial CT images show characteristic peripheral consolidations at the time of diagnosis (A) and marked improvement after 2 weeks of corticosteroid therapy and cessation of the inciting drug (B).

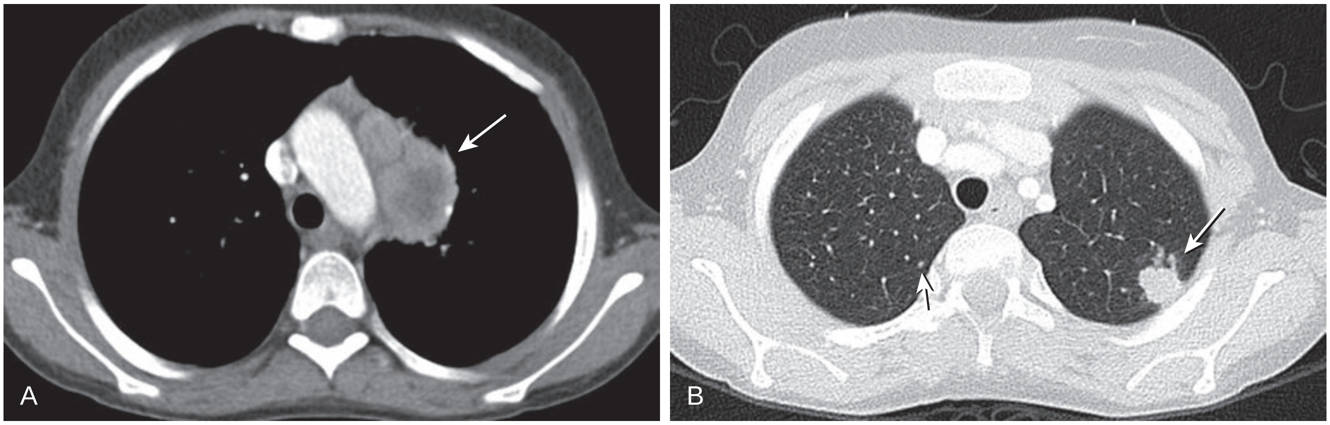

**Figure 56.19. Chronic granulomatous disease in a 16-year-old male.** Axial CT images show necrotic prevascular mediastinal lymphadenopathy (A, *arrow*) and an irregular nodular left upper lobe consolidation (B, *long arrow*). Multiple smaller nodules were also present, one seen in the right upper lobe (B, *short arrow*).

## Chronic Granulomatous Disease

***Etiology.*** Chronic granulomatous disease (CGD) is a rare inherited immunodeficiency disorder that usually is caused by a mutation in one of the four genes encoding subunits of the phagocyte nicotinamide adenine dinucleotide phosphate, impairing superoxide production and oxidative burst mechanisms that normally assist in killing fungal and intracellular catalase-positive bacterial organisms. The lungs are the most common site of infection. Histologically, granulomatous inflammation and often necrosis are present, with surrounding chronic inflammation and fibrosis, hence the name chronic granulomatous disease.[1–20,107–111]

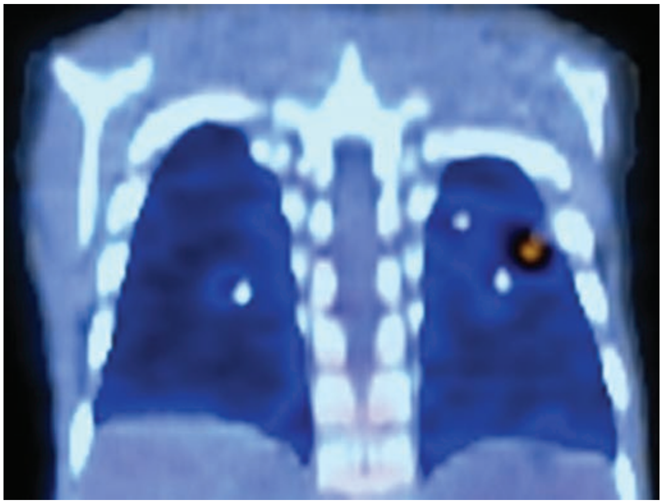
***Imaging.*** A variety of imaging findings may present in patients who have chronic, recurrent infections, including consolidation, ground-glass opacities, tree-in-bud opacities, and centrilobular or random (even miliary) nodules acutely, with bronchiectasis, septal thickening, air trapping, abscess formation, fibrosis, cysts, and honeycombing with long-standing disease. Other common thoracic findings include mediastinal and/or hilar lymphadenopathy, pleural thickening, empyema, vertebral or rib osteomyelitis, and chest wall invasion[1–20,107–111] (Fig. 56.19).

***Treatment and Follow-up.*** CGD is treated with lipophilic antibiotics, antifungal agents, interferon-γ, abscess drainage, surgical resection, and stem cell transplantation. Prophylactic antibiotics and antifungals are beneficial. Fluorine-18 fluorodeoxyglucose positron emission tomography is more reliable than CT for distinguishing between active and dormant disease activity (e-Fig. 56.20). Improved diagnosis and treatment have allowed survival into adulthood.[1–20,107–111]

## Cystic Fibrosis

***Etiology.*** Cystic fibrosis (CF) is caused by autosomal-recessive mutations in the CF transmembrane regulator (CFTR) gene. It is the most common genetic disorder leading to chronic pulmonary disease in children. Recurrent infections develop, in addition to numerous extrapulmonary manifestations such as meconium ileus in infancy. With progressive disease, chronic inflammatory changes occur that lead to alteration of airway walls with epithelial erosion, partial replacement of the mucosa by granulation tissue, progressive airway dilation resulting in bronchiectasis, and fibrotic/obliterative changes involving the small airways.[1–20,112–119]

***Imaging.*** Chest imaging in early CF may be normal or show mild to moderate air trapping and/or bronchiectasis (Fig. 56.21). In more advanced disease, bronchiectasis that is predominant in the upper lobes, bronchial wall thickening, centrilobular nodular and tree-in-bud opacities, and mucus plugging with air trapping



**e-Figure 56.20. Chronic granulomatous disease in a 6-year-old.** Coronal fused fluorodeoxyglucose–positron emission tomography/computed tomography image in this patient undergoing evaluation before bone marrow transplantation demonstrates multiple bilateral pulmonary nodules, only one of which has high fluorodeoxyglucose avidity. A subsequent biopsy of this nodule revealed active fungal infection.

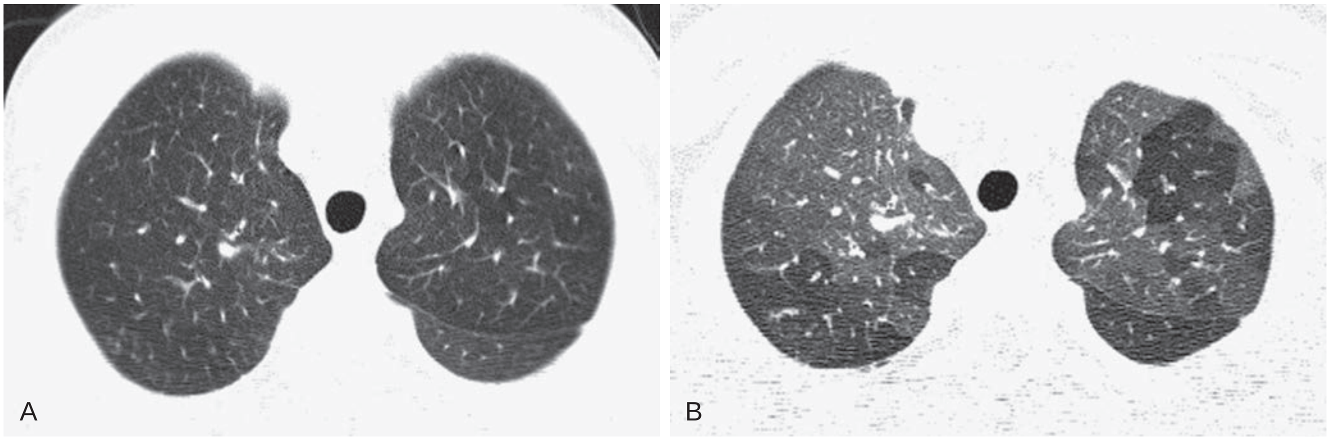


**Figure 56.21. Cystic fibrosis in a 12-year-old.** Paired inspiratory (A) and expiratory (B) phase axial CT images from within this patient with mild pulmonary cystic fibrosis show no bronchiectasis but demonstrate mosaic attenuation from air trapping that is accentuated on the expiratory phase.

occur (Fig. 56.22). A finger-in-glove pattern of mucoid impaction similar to ABPA may be observed. Because of recurrent infections, mediastinal and hilar lymphadenopathy often are present. Bronchial artery hypertrophy and tortuosity may also develop due to chronic airway inflammation. Both radiographic and CT CF scoring systems are available and correlate with lung function although primarily used for research purposes. UTE MR is under investigation as a radiation-free alternative for CF imaging, and the addition of hyperpolarized gas is promising for functional ventilation assessment.[1–20,112–119]

***Treatment and Follow-up.*** Treatment traditionally has focused on the managing/preventing the sequelae of the disease. The standard of care most recently has included oral azithromycin, inhaled tobramycin, hypertonic saline solution, and dornase alfa (Pulmozyme), which functions to break down thick secretions. Additional antibiotics are used depending on the type of infections present and the resistance pattern. Several novel small molecules are now approved for patients with specific mutations: ivacaftor (Kalydeco) with at least one *G551D* mutation and lumacaftor/ivacaftor (Orkambi) for homozygous *F508del* mutations. Targeted gene therapies remain an area of active investigation.[1–20,112–119]

## Pulmonary Disease in Association With Immunosuppression

***Etiology.*** Immunosuppression predisposes to a variety of pulmonary infections that may present as diffuse lung disease. Commonly encountered conditions include medication-related immunosuppression (organ transplant drug maintenance, high-dose steroids, or chemotherapy), human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), and congenital immunodeficiency. Patients are at risk for inoculation by both typical organisms and atypical pathogens (e.g., fungal, viral, mycobacterial).[1–20,120–128]

***Imaging.*** Imaging findings are variable depending on the immune status and offending pathogens. However, certain CT patterns are associated with specific infections. For example, ground-glass opacity is seen in pneumocystis and cytomegalovirus; nodules <1 cm are seen in viral pneumonia; nodules >1 cm, potentially cavitary, and the halo sign (ground-glass opacity surrounding a solid nodule) are typical of invasive aspergillosis; tree-in-bud nodules (centrilobular with linear branching) are seen in infectious bronchiolitis, including endobronchial tuberculosis; and consolidation is typical of bacterial pneumonia. Mediastinal/hilar lymphadenopathy and extrathoracic manifestations may also be present (Fig. 56.23). There should be a low threshold to obtain CT even if radiographs are normal to exclude occult abnormalities with potentially dire consequences in these high-risk patients.[1–20,120–128]

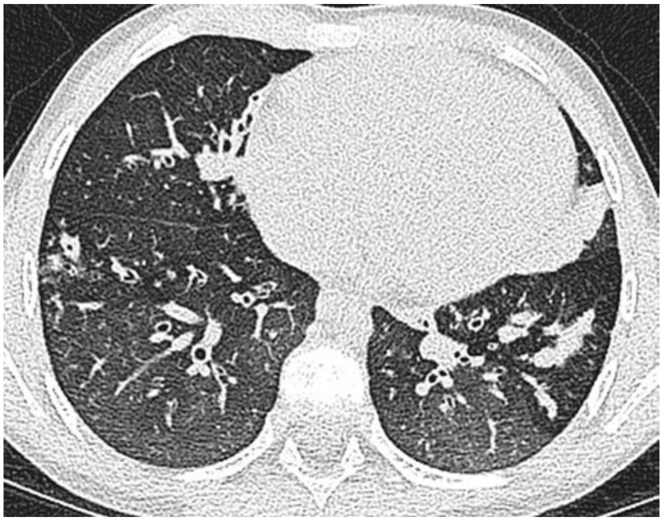

**Figure 56.22. Cystic fibrosis in a 10-year-old female.** Axial expiratory CT image shows multifocal mosaic attenuation indicating air-trapping, bronchiectasis, bronchial wall, thickening, and mucus plugging most marked in the lingula, left lower lobe, and right middle lobe.

***Treatment and Follow-up.*** Broad-spectrum coverage is initially advisable, including antibacterial, antifungal, and antiviral agents, tailored when the specific pathogen(s) are isolated. If feasible, immunosuppressive regimens may be weaned (or antiretroviral therapy increased for HIV). Opportunistic infections can quickly become life-threatening, and thus extreme vigilance is needed. Prophylactic coverage may also be warranted in some circumstances (e.g., for pneumocystis in HIV with low CD4 count). In one series of children with diffuse lung disease, overall mortality in immunocompromised patients was >50% compared with 16.3% for immunocompetent hosts.[1–20,120]

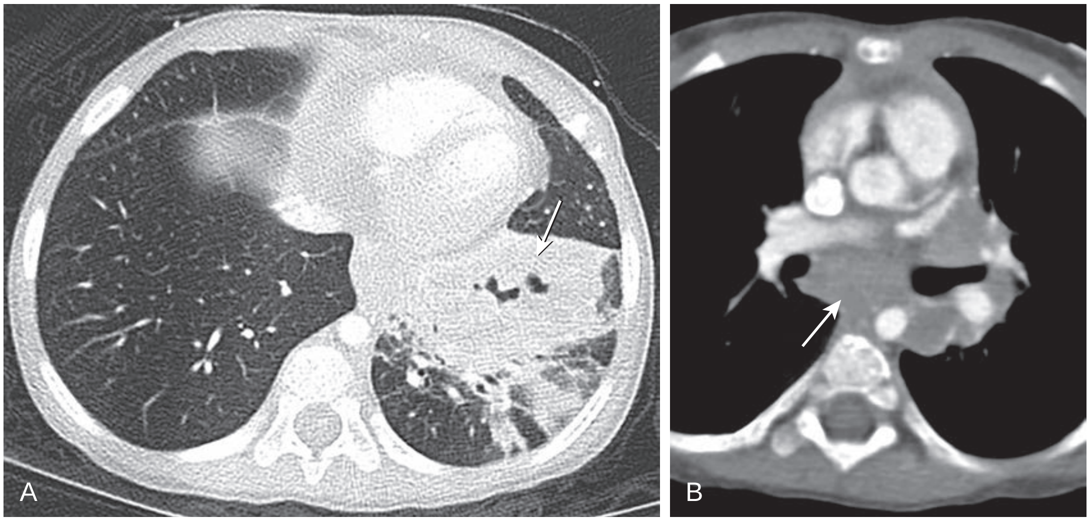

**Figure 56.23. Congenital neutropenia.** Axial CT images in a 2-year-old male who presented with cough and fever shows a cavitary left lower lobe consolidation consistent with necrotizing pneumonia (A, *arrow*) and extensive subcarinal and left hilar lymphadenopathy (B, *arrow*).

## KEY POINTS

- The revised chILD classification scheme, recognizing unique disorders occurring under 2 years of age, has allowed substantial progress in our understanding of pediatric diffuse lung disease. Many of these diseases have a genetic basis and also affect extrapulmonary sites.
- CT findings in NEHI are characteristic with hyperinflation, mosaic attenuation, and geographic ground-glass opacities that are most prominent in the right middle lobe, lingula, and paramediastinal lung regions.
- A crazy-paving pattern (ground-glass opacity superimposed on interlobular septal thickening) is suggestive of but not specific for PAP and also can be observed with diffuse pulmonary hemorrhage, for example. PAP itself is a histopathologic entity with numerous underlying causes including congenital surfactant deficiency in infants.
- Chylous pleural effusions are typical of pulmonary lymphangiectasia and lymphangiomatosis.
- Other important radiologic patterns and signs in pediatric diffuse lung disease include focal diffuse air trapping ± linear scarring or cystic changes in alveolar growth disorders; air trapping, vascular hypoattenuation and bronchiectasis in BO; peripheral-predominant ground-glass, fine reticular opacities, and bronchiectasis with lower-lobe predominance in NSIP; photographic negative or reversed pulmonary edema pattern in CEP and drug-induced PIE; the atoll or reversed halo sign (central ground-glass opacity surrounded by consolidation) in organizing pneumonia; the finger-in-glove sign (mucoid impaction of large airways) in ABPA and CF; and the halo sign (central consolidation surrounded by ground-glass opacity) in invasive aspergillosis.

# Pulmonary Manifestations of Systemic Disease

*Julie Currie O'Donovan and Beverley Newman*

Many systemic diseases of childhood involve the pulmonary parenchyma. The pulmonary manifestations may in fact prompt the patient or parents to seek medical attention and frequently a chest radiograph is obtained early in the illness. Therefore the radiologist can play an important role in directing the diagnostic workup by recognizing that the pulmonary findings reflect an underlying condition. In some patients, such as those with pulmonary edema or sickle cell disease, the radiograph shows the pulmonary findings adequately to continue appropriate clinical care. In many patients, however, the chest radiograph provides initial clues to the diagnosis but is otherwise nonspecific and prompts further investigation with computed tomography (CT). Techniques such as controlled ventilation inspiratory/expiratory breath-holding (see Chapter 49) and more recently available CT volume scans (mitigating the need for sedation) continue to reduce breathing artifacts and thus improve lung parenchymal assessment.

This chapter will discuss several specific systemic diseases affecting the lung as well as the effects of generalized systemic illness on the lung. In addition, it will detail pulmonary injury that occurs following therapy such as hematopietic stem cell transplantation and extrinsic agents including chemotherapy, radiation therapy, inhalation injury, and ingestion of hydrocarbons and mineral oil. Finally, near drowning events and conditions with pulmonary calcifications will be described.

## SPECIFIC SYSTEMIC DISEASES

### Vasculitis and Collagen Vascular Disease

### Overview

Pediatric patients with pulmonary vasculitis typically present in their teen years. Vasculitides affecting the small vessels are the most likely to cause pulmonary parenchymal disease, and granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis) and idiopathic pulmonary capillaritis are the most common of these disorders in children. Microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg–Strauss syndrome) also involve the lung parenchyma but are rarely seen in children.[1-4]

GPA typically presents with a triad of necrotizing granulomatous lesions in both the upper and lower respiratory tract, as well as glomerulonephritis. MPA is a nongranulomatous necrotizing vasculitis almost always seen with glomerulonephritis. EGPA typically presents with asthma and blood eosinophilia.[1]

Pulmonary involvement is seen less commonly in children than in adults with collagen vascular diseases (CVDs) such as juvenile arthritis, dermatomyositis, systemic sclerosis (scleroderma), systemic lupus erythematosus (SLE), and mixed connective tissue disease. The highest incidence of pulmonary involvement is seen in children with systemic sclerosis (59%–91%) and it is associated with significant morbidity and mortality rates.[5,6] Abnormal pulmonary function tests (PFTs) can act as a monitoring tool to identify children who would benefit from further evaluation with high-resolution CT (HRCT).[6] Symptomatic lung disease is significantly less common in juvenile idiopathic arthritis and SLE, reported in only 5% of patients.[7]

Pulmonary hemorrhage may occur in the vasculitides and in CVDs (e-Fig. 57.1) and has high morbidity and mortality rates (50%–90%).[1,8] Additionally, the vasculitides and CVDs both may cause pulmonary renal syndrome, which is the manifestation of pulmonary hemorrhage and glomerulonephritis. It often occurs in GPA and SLE.[1,2]

***Etiology.*** Most of the pulmonary vasculitides are immunologically mediated although up to half of pediatric capillaritis cases are antibody negative.[4] GPA, MPA, and EGPA are associated with antineutrophil cytoplasmic antibodies (ANCAs) and are sometimes referred to as *ANCA-associated systemic vasculitides*.[1]

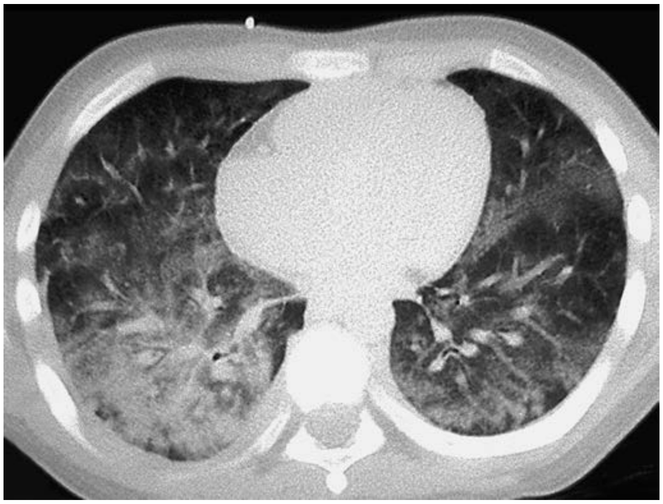
Most of the CVDs also have an autoimmune mechanism, SLE being the classic autoimmune condition associated with antinuclear antibody. These disorders are associated with a variable degree of inflammation of multiple organ systems, including the lung. Depending on the specific disorder, patients may present with arthritis, serositis, vasculitis, other soft tissue inflammation, or all of these.

***Imaging.*** The imaging findings of pulmonary vasculitis and CVDs are summarized in Table 57.1. The most frequent imaging findings of GPA are variable sized nodules (seen in up to 70% of patients), followed by ground-glass opacities and airspace consolidation; 17% of the nodules showed cavitation in a pediatric population, and up to 50% of nodules are reported to be cavitary in a general population, with higher incidence of cavitation in nodules larger than 2 cm. The nodules are characteristically surrounded by a halo of ground-glass opacity, which represents hemorrhage[9-11] (Fig. 57.2). Airway wall thickening may also be seen, but airway strictures are significantly less common in children (3%) compared with adults (up to 59%).[9] Diffuse alveolar hemorrhage (occurring in 44% of pediatric GPA) is characterized by lobular or lobar regions of ground-glass opacity or airspace consolidation on CT.[11-13] It may also show the "crazy paving" pattern on CT, especially as it evolves.[14]

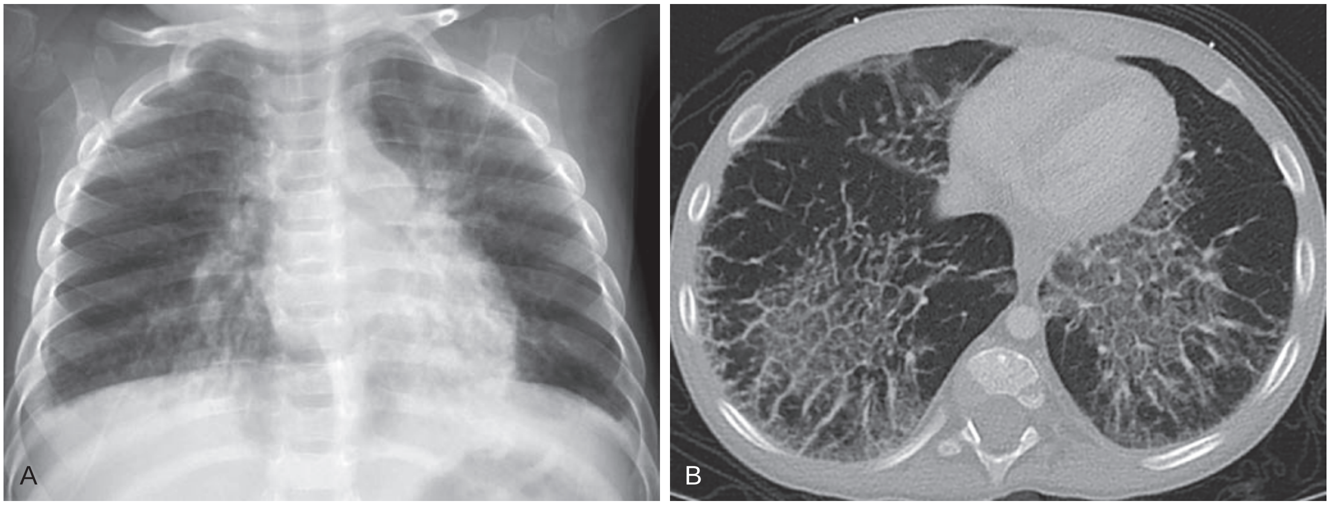
In the case of CVDs, pleural and pericardial effusions are the most common findings in the chest. Pulmonary parenchymal abnormalities are significantly less common but follow a similar pattern for most of these disorders and include ground-glass opacity and interstitial septal thickening, which may progress to pulmonary fibrosis. Despite normal chest radiographs or only minimal radiographic abnormalities in children with systemic sclerosis, HRCT demonstrates ground-glass opacities, peripheral areas of pulmonary fibrosis, and subpleural micronodules (Fig. 57.3).[5] Serious and even life-threatening lung disease has been described in some children with systemic juvenile idiopathic arthritis (JIA), including interstitial lung disease, alveolar proteinosis/endogenous lipoid pneumonia, and pulmonary hypertension (e-Fig. 57.4). Pulmonary manifestations may be related to a macrophage activation syndrome.[14,15] "Shrinking lung syndrome" has been described in SLE and represents decrease in lung volume that manifests radiographically by an elevated diaphragm.[8,14,16]

***Treatment and Follow-up.*** Treatment for the vasculitides and CVDs is primarily aimed at suppressing the immune response, typically with corticosteroids and chemotherapeutic agents, as well as newer biologic drugs when appropriate.

Patients who develop diffuse alveolar hemorrhage often show evolving changes on CT follow-up. A more linear and interstitial type of pattern may develop with interlobular septal thickening and the appearance of the crazy paving pattern. If episodes of hemorrhage recur, this may also progress to interstitial fibrosis.[12] Pulmonary involvement with CVD may progress to interstitial



**e-Figure 57.1. Pulmonary hemorrhage in a teenage boy with pulmonary vasculitis resulting from collagen vascular disease.** The patient presented with hemoptysis. CT image shows diffuse but somewhat patchy ground-glass opacification in both lungs.



**e-Figure 57.4. Systemic juvenile idiopathic arthritis and acute exacerbation in a 2-year-old.** No clinical evidence of infection. (A) Chest radiograph shows perihilar increased interstitial markings, more confluent right lower lobe opacity and right pleural effusion. (B) Axial CT image (lung window) shows peripheral reticular changes and bilateral basilar interlobular septal thickening with ground-glass opacity suggestive of some fibrosis, as well as alveolar proteinosis (confirmed on bronchoscopy).

[*] Specific imaging findings are a spectrum from ground-glass opacities to airspace consolidation.

[†] Nodules in juvenile arthritis seen in lipoid pneumonia.

[‡] Seen as subpleural micronodules and were not considered a dominant finding.

*Data from references*[1,5,7,8,13]*, and Feng RE, Xu WB, Shi JH, et al. Pathological and high resolution CT findings in Churg-Strauss syndrome.* Chin Med Sci J. *2011;26(1):1–8.*

pulmonary fibrosis regardless of treatment, with advanced stages showing honeycombing. Pulmonary artery hypertension may also develop with advanced lung disease, especially in systemic sclerosis and systemic JIA.

Follow-up imaging is primarily determined by clinical needs, symptoms, or both. Follow-up chest radiograph can be helpful but CT is more likely to show subtle changes. Progression of abnormal PFTs in patients with juvenile systemic sclerosis over time correlate with worsening of changes on CT, suggesting that PFTs could potentially be used as a marker to determine when follow-up CT may be needed.[6]

## Sickle Cell Disease

### Overview

Acute chest syndrome (ACS), an illness that occurs in up to 50% of children with sickle cell disease (SCD), is characterized by chest pain, leukocytosis, fever, and a new pulmonary opacity. It is a primary cause of death and hospitalization in all patients with SCD and in children usually occurs between 2 and 4 years of age.[17] ACS also occurs in patients with other sickle hemoglobinopathies.[18] When not fatal, it may lead to chronic lung disease (4%) and pulmonary hypertension.[19]

***Etiology.*** The etiology of ACS is complex and not always known. In a large multicenter study, established causes were microvascular occlusion and infarction (16%), infection (29%), fat emboli from bone marrow infarcts (9%), and unknown in 46%. *Chlamydia*, *Mycoplasma*, and viral agents were the most common pathogens in cases caused by infection. One-third of patients presented with symptoms of long bone pain caused by vasoocclusive crisis and developed ACS 2 to 3 days later.[20]

***Imaging.*** Radiographic findings of ACS by definition include the presence of a pulmonary opacity (e-Fig. 57.5) but are otherwise nonspecific. Opacities were noted in the lower lobes in about 90%, and pleural effusion was noted in 55% of patients in a large multicenter study (see Table 57.1).[20]

Although CT is not generally used in the setting of ACS, chronic sickle cell lung disease has been studied. Abnormal findings are most pronounced at the lung bases and include parenchymal bands, interlobular septal thickening, architectural distortion, and traction bronchiectasis. Honeycombing is unusual, in contrast to other types of pulmonary fibrosis.[21]

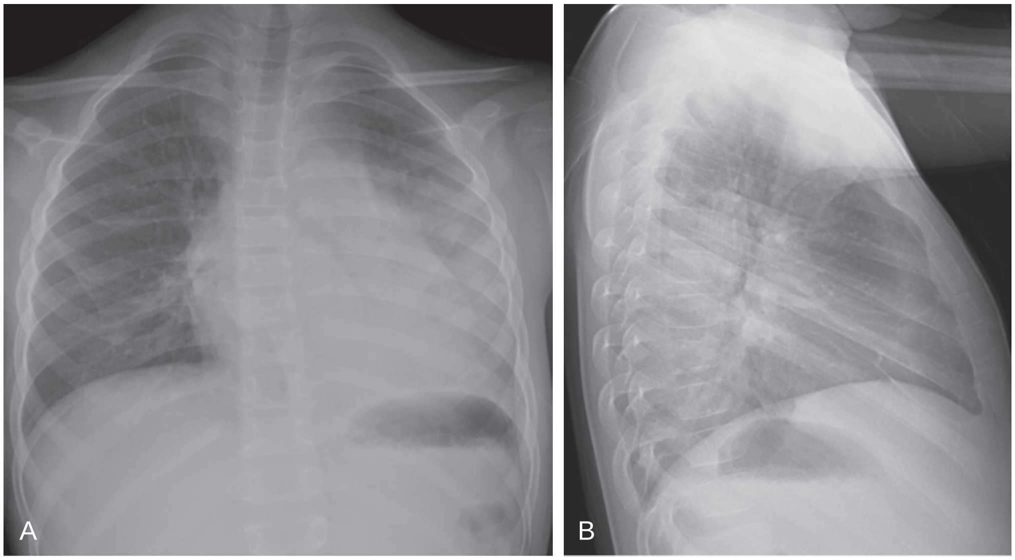
***Treatment and Follow-up.*** Therapy for ACS includes hydration, analgesia, respiratory support (including bronchodilators), broad-spectrum antibiotics, transfusion therapy, and sometimes corticosteroids.[22] Imaging follow-up is primarily dictated by clinical course and usually only requires radiography.

## Langerhans Cell Histiocytosis

### Overview

*Langerhans cell histiocytosis (LCH)* is the preferred term for the condition showing a proliferation of a group of histiocytes known as *Langerhans cells*. Langerhans cells are of myeloid dendritic cell origin and contain characteristic Birbeck bodies on histology.[23] The peak age at initial diagnosis is 1 to 3 years, and most patients present with osseous lesions.[23] LCH is currently classified according to the extent of involvement, whether it involves a single site (better prognosis) or multiple sites (higher risk of long-term problems). The involvement of “risk organs” (bone marrow, liver, or spleen) indicates a poorer prognosis and demands more aggressive treatment.[24]

Pulmonary involvement is reported to be present in 10% of all patients with LCH and 23% to 50% of children with multisystem LCH, with a mean age of 11.9 months in one study.[14,23,24] Disease-free survival in these patients was 69%, with 3 out of 4 deaths occurring when “risk organs” other than the lung were involved. Although lung disease was traditionally considered a poor prognostic indicator in LCH, recent studies have shown that it does not adversely affect outcome. Primary pulmonary LCH (single site) is rare in children and is typically seen in young adult smokers.[24,25]



**e-Figure 57.5. Sickle cell disease with acute chest syndrome.** An 8-year-old boy with sickle cell disease who presents with fever. (A and B) Posteroanterior and lateral chest radiographs show dense airspace consolidation in the left lower lobe with a small pleural effusion.

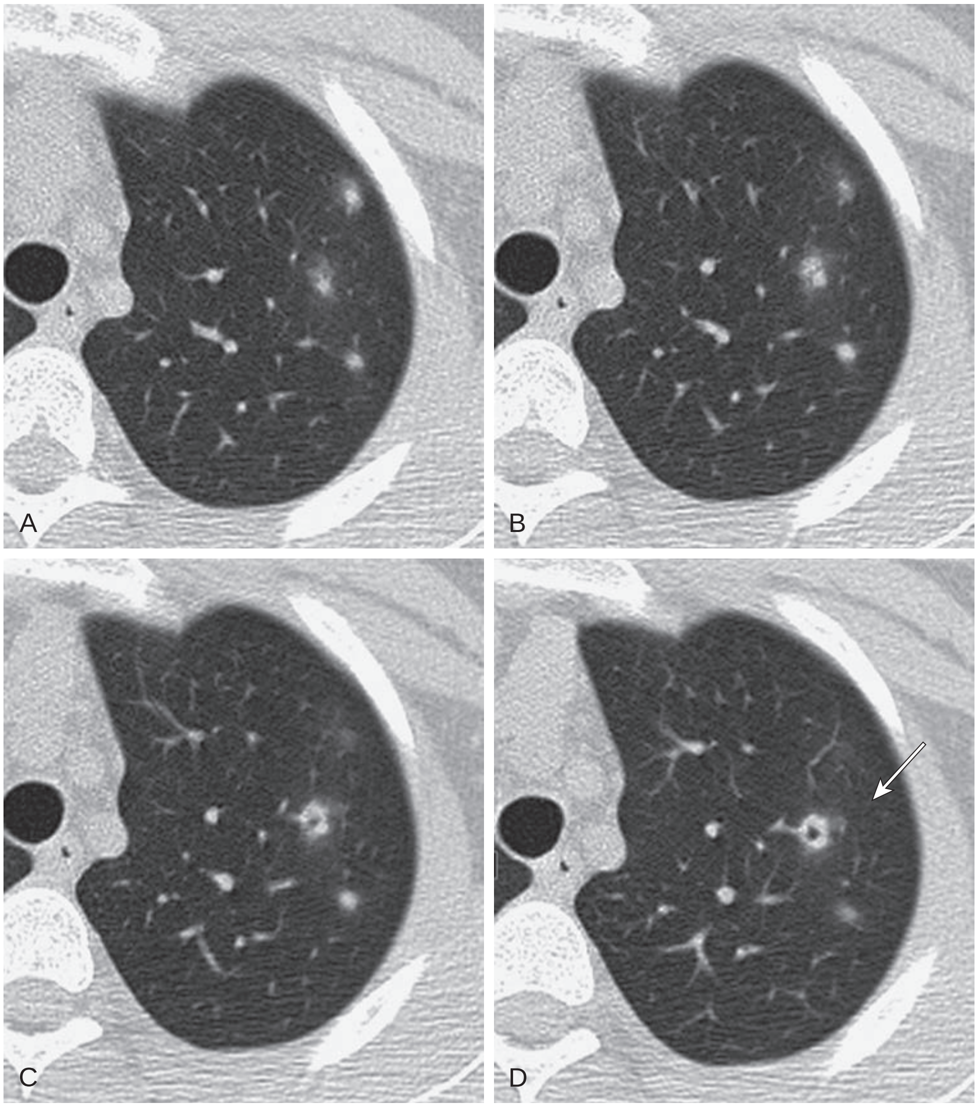


**Figure 57.2. Granulomatosis with polyangiitis (Wegener).** This 16-year-old girl had a history of vasculitic skin lesions and headache. Computed tomography (CT) of the sinuses revealed inflammatory changes *(not shown).* Axial CT images of the chest (A–D) show a left upper lobe cavitary lesion *(D, arrow),* as well as several solid pulmonary nodules (A–C), all with surrounding halos of ground-glass opacity. Lung biopsy was positive for granulomatosis with polyangiitis.

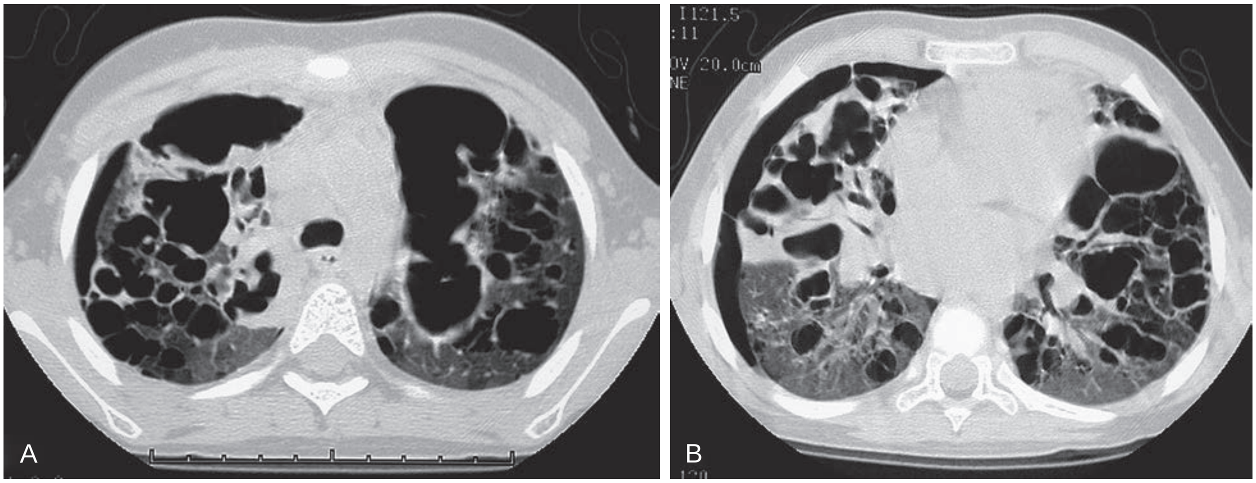
***Etiology.*** The etiology of LCH is not known. Most investigators believe it to be an immune-mediated condition, in which the Langerhans cells accumulate and cause an inflammatory reaction. In the lungs, destructive granulomatous lesions occur in the interstitial tissues, bronchial and bronchiolar epithelium, and subpleural septa and may eventually lead to cystic lesions.[23] Pulmonary fibrosis occurs later in 10% of children.[26]

***Imaging.*** Radiologic findings of LCH vary widely with the extent of the disease and are summarized in Table 57.1. The initial chest radiograph may be normal. Small nodules and cysts may be seen, with upper lobe involvement equal to or more extensive than lower lobe involvement (Fig. 57.6). The reticular appearance noted on a chest radiograph is often from multiple small cysts.[23,27] LCH is the most common cause of acquired extensive cystic lung disease in children (e-Fig. 57.7). Spontaneous pneumothorax is reported to occur in about 11% of patients with pulmonary involvement and may be the first indicator of pulmonary disease.[27] However, it may also be a manifestation of more advanced disease, as in adolescents who more often have large coalescent cysts (see e-Fig. 57.7).[14]

CT is indicated for neonates with LCH and any patient with abnormalities on the chest radiograph.[24] CT findings in LCH are characterized by small nodules (with or without cavitation) with upper and middle lobe predominance (see Fig. 57.6).[14,23,28] The pulmonary late-stage disease shows interstitial thickening and cystic spaces of variable diameter (see e-Fig. 57.7).[23] The pleura may be thickened and sometimes replaced by a thick layer of granulomatous tissue. However, pleural effusions are rare.[29] Mediastinal and hilar adenopathy is also rare in children with pulmonary LCH.[23,27]

***Treatment and Follow-up.*** Treatment of pulmonary LCH depends on the extent of disease and whether "risk" organs are involved. Generally, the first line of treatment is corticosteroids, vinblastine, or both, with duration of therapy being determined by response. Radiation therapy has fallen out of favor except for treating unstable bone lesions.[24] Imaging follow-up for pulmonary LCH depends on clinical symptoms. If abnormalities were present on initial chest radiographs, radiographs can be used for follow-up with CT reserved for progression and/or problem solving.



**e-Figure 57.7. Progressive advanced changes in Langerhans cell histiocytosis (LCH) of the lungs.** This child first presented at age 2 years with LCH involving both temporal bones and cystic lung disease. The patient was treated with chemotherapy and returned at age 4 years with increasing respiratory distress. The chest radiograph (not shown) showed a marked interval increase in bilateral cystic lung changes and suggested a possible small right pneumothorax. (A and B) High-resolution computed tomography shows that multiple cysts of varying sizes have largely replaced much of the lung parenchyma; loculated right pneumothorax was confirmed. Within 3 weeks, the patient developed a large left pneumothorax and died of this cystic lung process 1 week later.

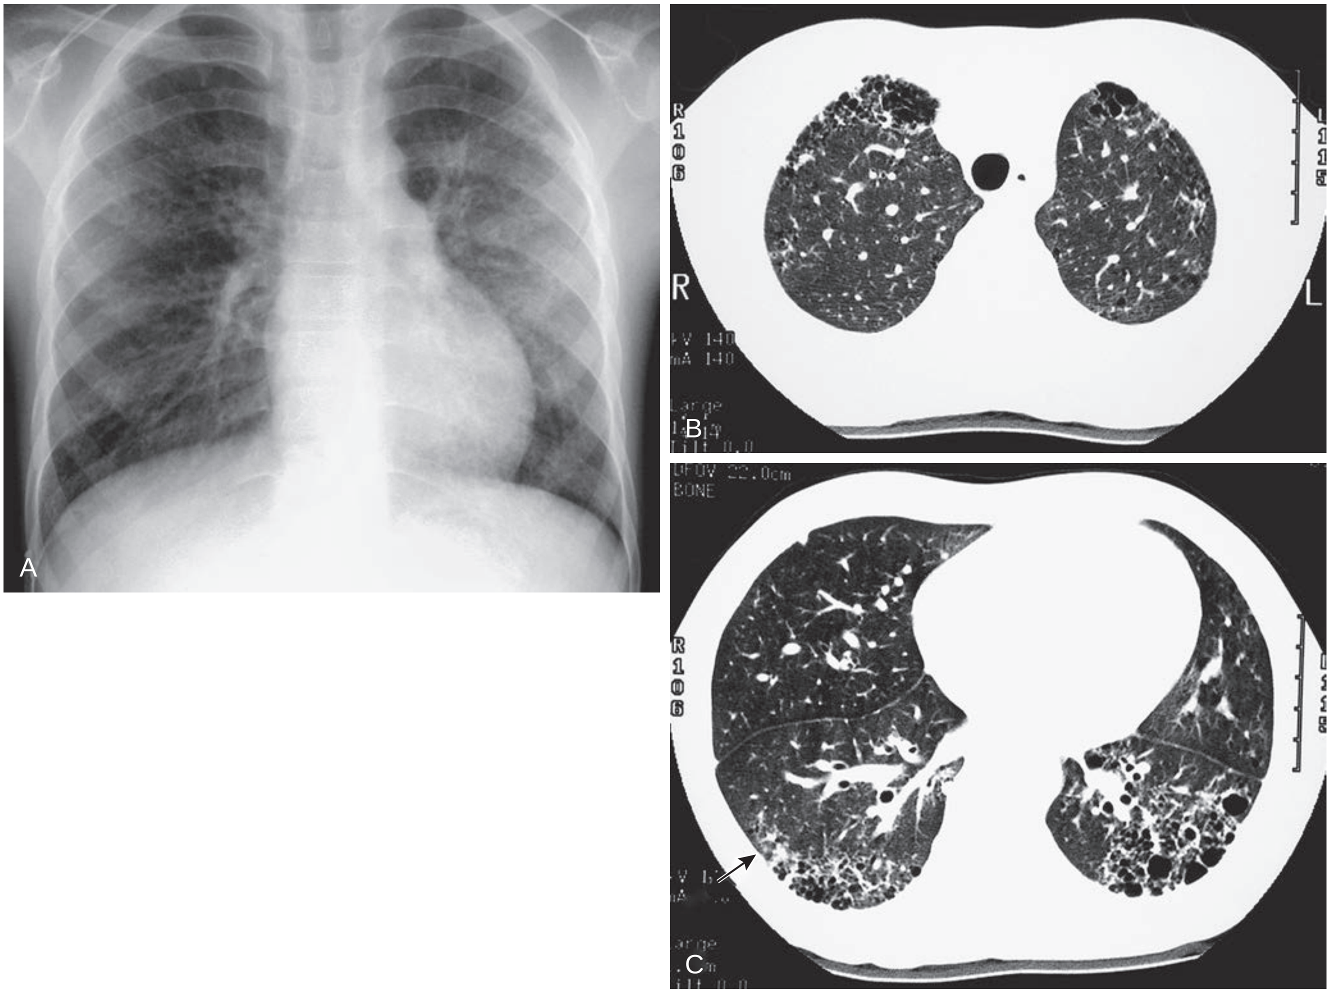


**Figure 57.3. Systemic sclerosis (scleroderma) in an 8-year-old girl diagnosed at age 5 years.** (A) Frontal chest radiograph shows mild increase in perihilar linear opacities. (B) High-resolution computed tomography (HRCT) of upper lung zones shows thin-walled, small cystic areas anteriorly in both lungs and a few small scattered subpleural lucencies and opacities more posteriorly. (C) HRCT through lower lung zones shows honeycomb pattern dependently in both lungs. More lateral area in right lung shows more ground-glass opacity *(arrow)* that may represent active disease.

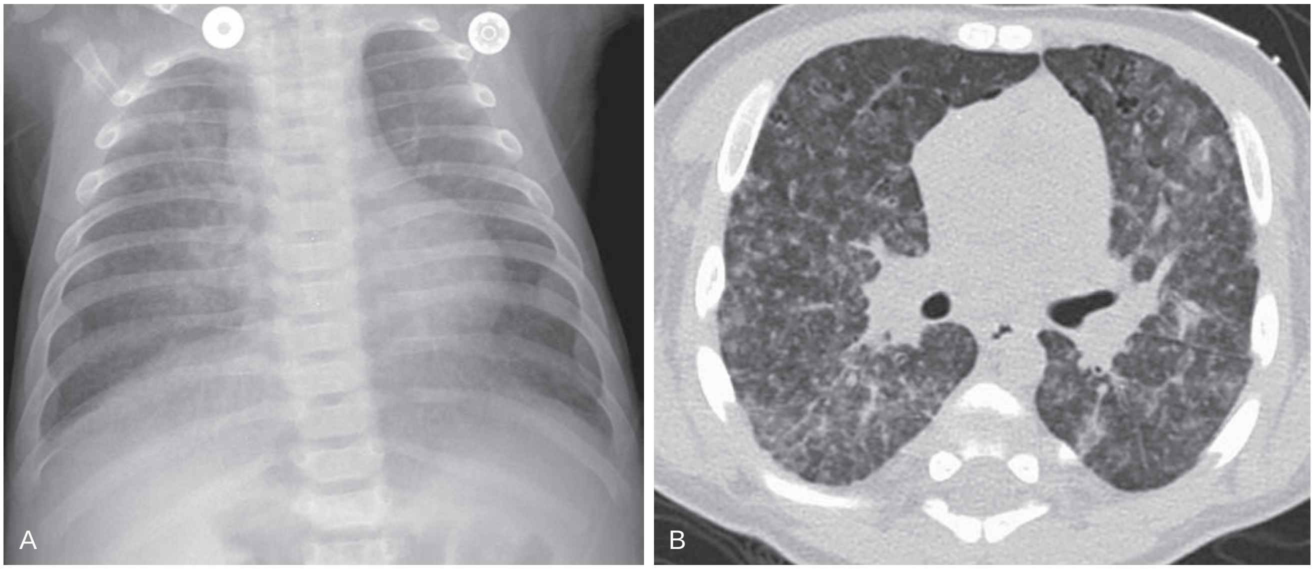

**Figure 57.6. Langerhans cell histiocytosis of the lungs in a 2.5-month-old boy who initially presented with a skin rash.** (A) Anteroposterior chest radiograph shows a coarse reticulonodular interstitial pattern. (B) Axial CT image in a lung window shows the coarse reticulonodular interstitial pattern with some small thin-walled cysts seen in the anterior lung bilaterally.

### Gaucher Disease and Niemann–Pick Disease

#### Overview

These two lysosomal storage disorders have a wide range of pathologic expression in different organ systems most frequently affecting the bone marrow, liver/spleen and/or central nervous system, and rarely affecting the lung parenchyma. Gaucher disease is more common than Niemann–Pick. Gaucher neuronopathic type 3 is more likely to affect the lung than is Niemann–Pick type B.[30-33]

***Etiology.*** Both of these disorders are transmitted by an autosomal recessive inheritance pattern and genetic mutations have been identified for all types. Gaucher disease is caused by a deficiency of the enzyme glucocerebrosidase that results in an accumulation of the lipid glucocerebroside in phagocytic cells, so-called Gaucher cells. Niemann–Pick disease is caused by a deficiency of sphingomyelinase, resulting in accumulation of the lipid sphingomyelin in the Niemann–Pick cells. These lipid-laden "foamy" macrophages deposit in various tissues, and may infiltrate the lung causing pulmonary symptoms.[30-33] Niemann–Pick disease has been associated with endogenous lipoid pneumonia in several patients and was the presenting condition in three adult patients[34,35]

***Imaging.*** Both Gaucher and Niemann–Pick disease cause a diffuse reticulonodular pattern on chest radiographs. CT abnormalities have also been described in both, including ground-glass opacities, areas of consolidation, and interstitial thickening (Fig. 57.8). Mediastinal findings of lymphadenopathy and thymic enlargement are also reported in Gaucher disease.[31-37] Niemann–Pick type C2 occurs in infants and has been reported to cause a crazy paving pattern on CT (e-Fig. 57.9).[32,33]

***Treatment and Follow-up.*** Visceral involvement may improve with enzyme replacement therapy in Gaucher disease, and this therapy may offer an alternative to lung transplantation.[38] The current treatment for Niemann–Pick disease with pulmonary involvement is whole lung lavage.[34,35] Regarding follow-up imaging, chest radiographs have been recommended every 2 years for patients with Gaucher disease to monitor the lungs.[37] In the setting of known pulmonary involvement, CT follow-up would be more sensitive than plain radiography for subtle changes if clinically needed.

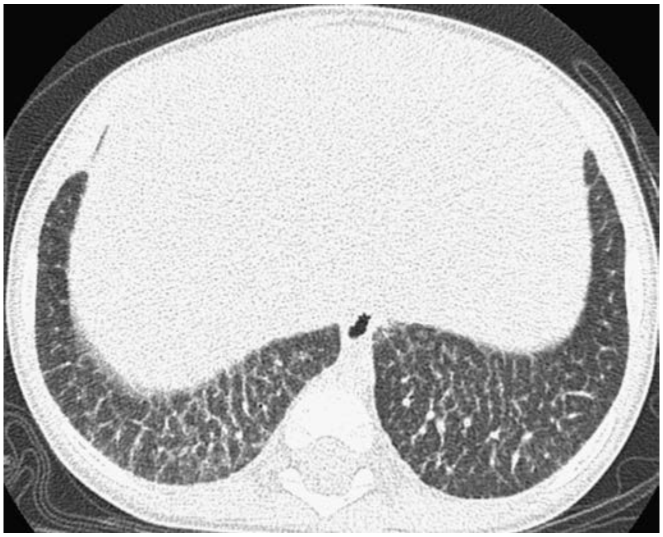

**Figure 57.8. Niemann–Pick disease type B.** Axial CT image from a 22-month-old shows diffuse interstitial septal thickening. *(Courtesy of Paul Guillerman, MD, Houston, Texas.)*

## PULMONARY CONDITIONS OCCURRING WITH GENERALIZED SYSTEMIC ILLNESS

### Pulmonary Edema

#### Overview

Pulmonary edema is the excessive accumulation of water and solute in the lung tissues. Functionally, pulmonary edema is divided into two general categories: (1) those cases having elevated pulmonary venous pressure (cardiogenic or hydrostatic) and (2) those associated with increased capillary permeability with normal microvascular pressure (noncardiogenic). Pulmonary edema may also have mixed etiologies, and sometimes the actual mechanism is unknown. Cardiogenic pulmonary edema is far less common in children than in adults.

#### Cardiogenic Pulmonary Edema

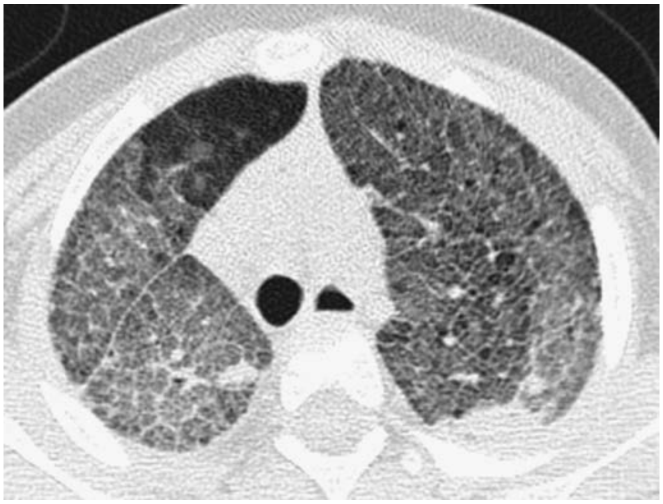
***Etiology.*** In children, cardiogenic edema usually occurs in infants less than 6 months of age as the result of congenital heart disease (CHD) such as left-to-right shunting lesions, left ventricular outlet obstruction, or obstruction of pulmonary venous return (Fig. 57.10).[39] Affected infants often present with nonspecific symptoms, including feeding difficulties, grunting, diaphoresis, wheezing, and retractions.[39] Rarely, pulmonary edema may be the presenting manifestation of CHD. In an older child, cardiomyopathy is the usual cause of cardiogenic edema (e-Fig. 57.11).

***Imaging.*** On the chest radiograph, cardiomegaly is usually found except in instances of pulmonary venous obstruction, in which interstitial edema is present in the absence of cardiac enlargement (see Fig. 57.10).

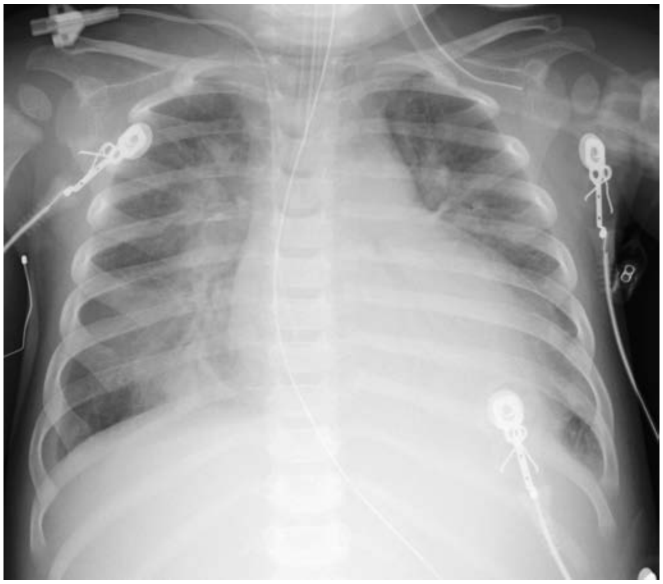
Early findings in interstitial edema in children with cardiogenic pulmonary edema are indistinct vascular margins and bronchial wall thickening. Interlobular septal thickening (septal lines or Kerley B lines) and interlobar fissural thickening are also seen. In infants and young children, fissural thickening is often more easily recognized than Kerley lines and is therefore an important diagnostic clue in children (see Fig. 57.10). An indirect radiographic finding frequently seen in children with CHD is hyperinflation. This may be a pitfall if the imager attributes the findings of peribronchial thickening and hyperinflation to airways disease and does not recognize them as subtle findings of interstitial edema. Alveolar edema usually occurs after development of interstitial edema and is the most recognizable radiographic finding of pulmonary edema. The classic appearance of acute alveolar edema is a central or "butterfly" distribution of airspace disease, with central edema and sparing of the lung periphery. Pleural effusions are also usually present (see e-Fig. 57.11). In children, pulmonary edema is frequently asymmetric, unilateral, or even lobar in distribution. This can be related to patient position (given the dependent nature of the edema) or more commonly due to the presence of asymmetric pulmonary arterial supply or pulmonary venous drainage in patients with CHD.

Although not commonly used to diagnose pulmonary edema, CT is sensitive for the detection of pulmonary edema of any etiology. CT shows peribronchial cuffing, septal lines, ground-glass opacities, and airspace consolidation in order of increasing severity (e-Fig. 57.12).[40,41]

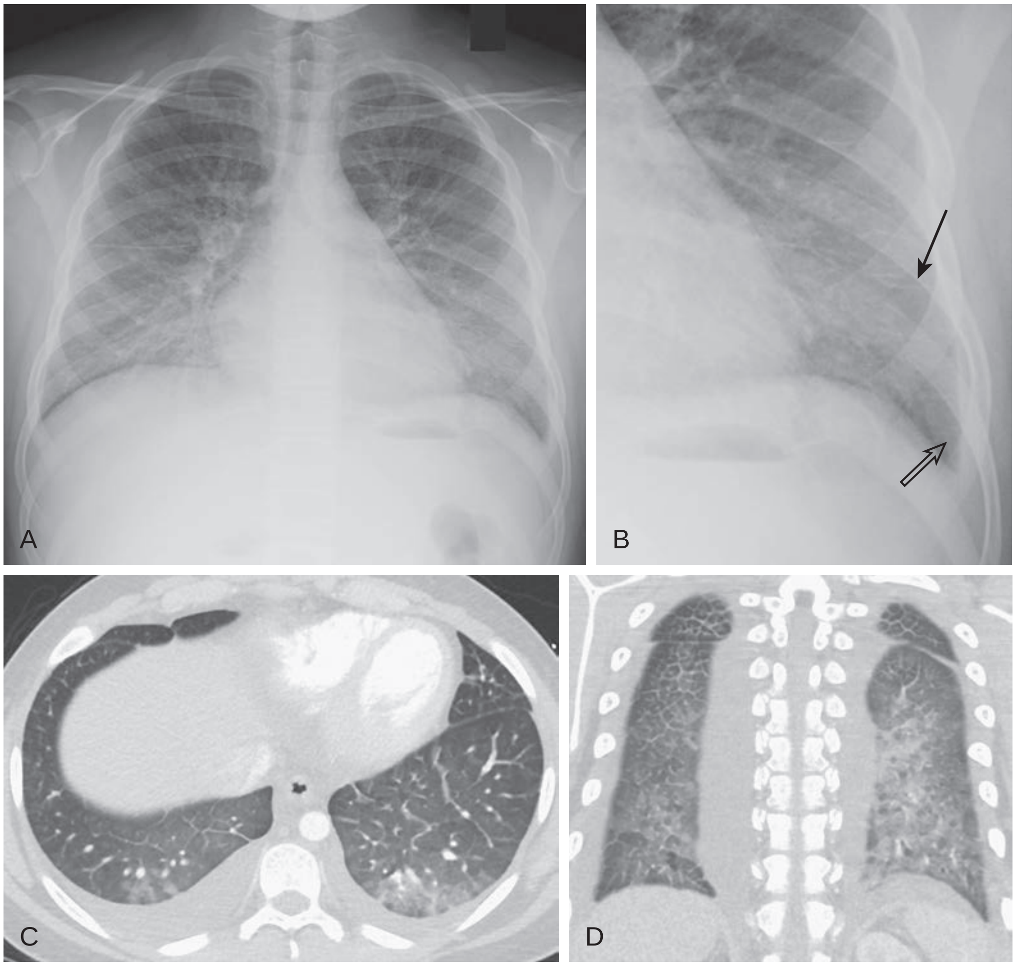
***Treatment and Follow-up.*** Treatment for cardiogenic pulmonary edema is generally supportive and includes corrective (interventional or surgical) or palliative treatment for CHD. Diuretics and inotropes may be used for cardiac dysfunction. Ventilator support is provided, if needed. Extracorporeal membrane oxygenation and other types of ventricular assist devices are now being used more frequently in the setting of pediatric cardiac failure.[42] Typically, imaging follow-up with chest radiography is adequate, although CT may be used to clarify the vascular anatomy.



**e-Figure 57.9. Niemann–Pick disease type C2.** Axial CT image from a 23-month-old shows extensive crazy paving with the exception of the spared anterior right upper lobe. *(Courtesy of Paul Guillerman, MD, Houston, Texas.)*



**e-Figure 57.11. Dilated cardiomyopathy.** A 14-month-old girl presented with 24 hours of increased work of breathing and wheezing. Portable chest radiograph shows characteristic cardiomegaly, perihilar and bibasilar distribution of airspace opacity caused by pulmonary edema, and a small right pleural effusion.



**e-Figure 57.12. Glomerulonephritis.** A 13-year-old boy with history of asthma presented with 5 days of shortness of breath and was found to be hypoxic. (A and B) Posteroanterior chest radiograph and magnified view show pulmonary edema with interstitial septal lines *(arrow)* and tiny left pleural effusion *(open arrow).* (C and D) Axial and coronal CT images depict typical findings of pulmonary edema showing interlobular septal thickening, dependent ground-glass opacity, and bilateral small pleural effusions. The child was diagnosed with postinfectious glomerulonephritis.

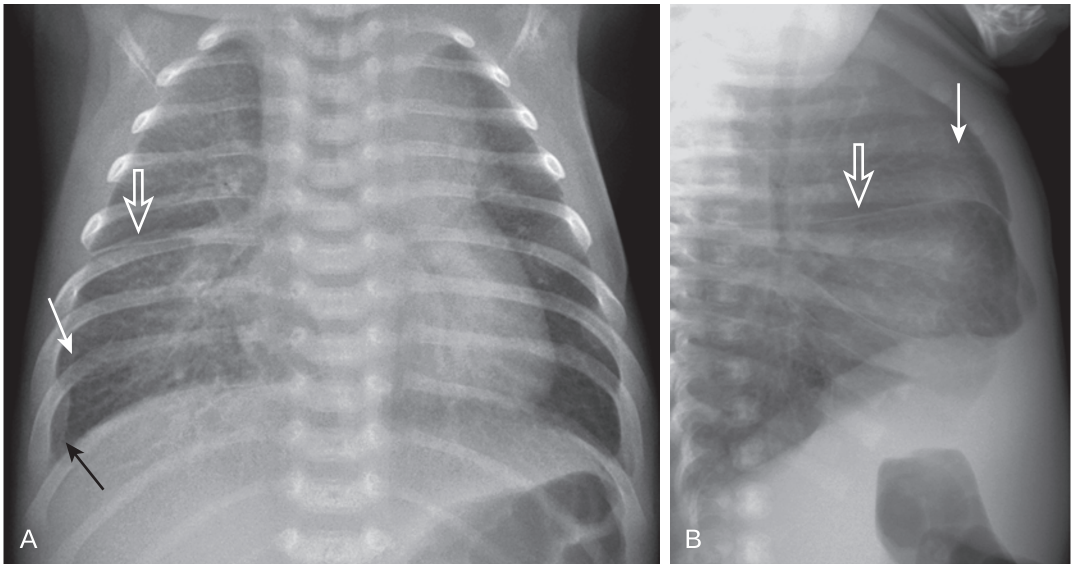


**Figure 57.10. Pulmonary edema caused by obstructed pulmonary venous return (cor triatriatum).** This 6-week-old infant presented to the emergency department with tachypnea and feeding difficulties. (A and B) Anteroposterior and lateral chest radiographs show normal heart size and subtle interstitial edema characterized by hyperinflation, septal lines *(white arrows),* fissural thickening *(open arrows),* and tiny right pleural effusion *(black arrow).* Cor triatriatum was shown by echocardiography.

### Noncardiogenic Pulmonary Edema

***Etiology.*** The frequent causes of noncardiogenic pulmonary edema in children are sepsis, near-drowning, neurogenic pulmonary edema, renal disease (see e-Fig. 57.12), and upper airway obstruction (e-Fig. 57.13). Other less common causes of noncardiogenic pulmonary edema include aspiration pneumonia, hydrocarbon pneumonitis, smoke inhalation, and drug reactions.[43] Pulmonary edema may also develop after inhalation of a variety of noxious fumes or soluble aerosols. Aspiration of hypertonic water-soluble contrast agents may also produce pulmonary edema.

Many episodes of noncardiogenic pulmonary edema progress to acute respiratory distress syndrome (ARDS). ARDS accounts for 1% to 3% of pediatric intensive care admissions, and the mortality rate in various series ranges from 40% to 60%. Sepsis, near-drowning, pneumonia, and smoke inhalation are the most frequent antecedents to pediatric ARDS. The typical course of ARDS progresses through stages of immediate lung injury, exudative alveolitis, fibroproliferative repair, and, in survivors, recovery.[43] A specific definition for pediatric ARDS (PARDS) was recently developed and published by the Pediatric Acute Lung Injury Consensus Conference Group. In brief, the onset of PARDS is defined by hypoxemia and a new chest imaging abnormality occurring within 7 days of a known clinical insult. Additionally, the associated respiratory failure must not be fully explained by cardiac failure or fluid overload.[44]

***Imaging.*** Chest radiographic abnormalities in glomerulonephritis and nephrotic syndrome are often sufficiently characteristic to allow the radiologist to suggest the correct diagnosis. A child or teenager presents without a known cardiac history with a basilar predominant interstitial edema pattern, often with pleural effusions (see e-Fig. 57.12). Glomerulonephritis may reportedly be distinguished from nephrotic syndrome by its tendency to show mild cardiomegaly and increased pulmonary vascularity.[45] Pericardial effusion is also more common in the setting of renal disease.

Like the clinical course, the radiographic pattern for ARDS is a multiple-stage continuum.[46,47] Initially, the radiograph is reflective of the initial insult, or it may be normal. In 12 to 24 hours, bilateral pulmonary opacities develop, consistent with noncardiogenic pulmonary edema, and opacities become progressively more confluent.[47] Subsequent improvement or continued worsening may be seen in the next several days. For patients with progression, the course often is then complicated by air leak phenomena (pneumothorax, pneumomediastinum, pulmonary interstitial emphysema), with or without ventilator-associated infections. Subsequently, further progression to chronic changes of fibrosis may occur.[43,46,47]

***Treatment and Follow-up.*** Treatment of noncardiogenic pulmonary edema is directed toward the primary cause, and is generally supportive. Ventilatory support is often needed. The use of positive end-expiratory pressure with mechanical ventilation has been shown by CT to improve ventilation of dependent regions of the lung in a setting of ARDS.[47,48] Extracorporeal membrane oxygenation is increasingly being used for children with severe respiratory failure. Pulmonary edema from neurogenic causes or upper airway obstruction usually resolves fairly rapidly, often within 12 to 48 hours.[39] Typically, imaging follow-up will be performed with chest radiography, as needed.

Survivors of ARDS may have long-term sequelae, often demonstrable by pulmonary function testing. Follow-up chest radiographs most often show a return to normal (80%) but may demonstrate increased interstitial markings, hyperaeration, or both.[43,47,49]

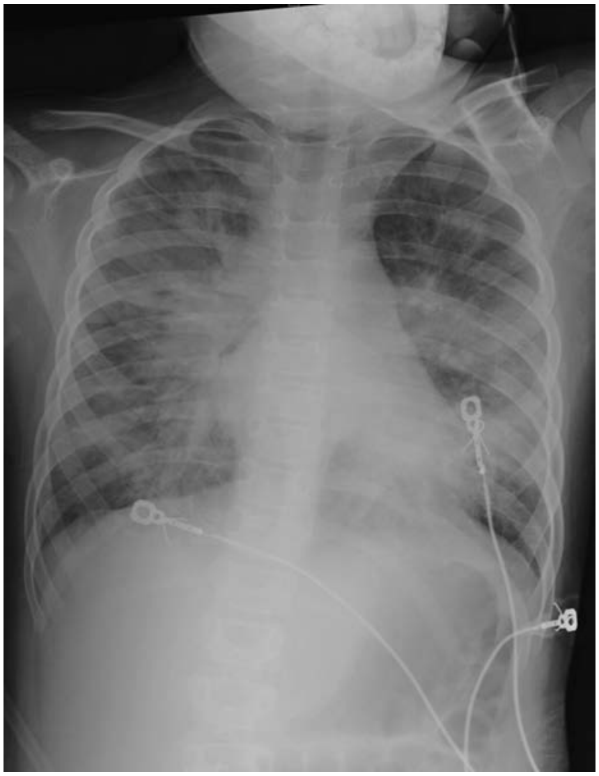
## LUNG INJURY RELATED TO THERAPY AND CAUSED BY EXTRINSIC AGENTS

### Graft–Versus–Host Disease

### Overview

Pediatric solid organ and hematopoietic stem cell transplant (HSCT) pulmonary complications include edema, hemorrhage, infection (immunosuppression confers susceptibility to unusual organisms; see Chapters 54 and 56), rejection, drug reactions, posttransplant lymphoproliferative disorder (see Chapter 55), and graft–versus–host disease (GVHD). As treatment and prophylaxis have become more precise, noninfectious pulmonary disease has become more important.

***Etiology.*** GVHD is an immune reaction of allogeneic donor cells to host tissues in HSCT. Early acute GVHD most commonly



**e-Figure 57.13. Pulmonary edema due to upper airway obstruction.** This 4-year-old girl was admitted to the intensive care unit for asthma with hypoxia and wheezing. She had an acute exacerbation one night and was noted to also have obstructive sleep apnea. The following morning this anteroposterior view of the chest showed pulmonary edema pattern caused by upper airway obstruction, which promptly resolved when her obstructive airway symptoms were addressed more aggressively.

affects the skin, liver, and gastrointestinal tract, and rarely the lung. However, GVHD, especially chronic, represents a major long-term cause of morbidity and mortality in HSCT, and prompt recognition is important.[50] Idiopathic pneumonia syndrome (IPS) (early) and bronchiolitis obliterans (BO) (late) are the most common pulmonary conditions related to GVHD.[51] Acute IPS is defined as manifesting with widespread alveolar damage and pulmonary dysfunction without evidence of infectious, cardiac, and renal abnormality or fluid overload. The classification of IPS now includes other entities such as diffuse alveolar hemorrhage, acute respiratory distress syndrome, and organizing pneumonia. The etiology is likely multifactorial including conditioning toxicity, inflammatory cytokine release, immunologic factors, and occult infection.[50] Pulmonary cytolytic thromboemboli and alveolar proteinosis are less common entities that may be related to GVHD.

***Imaging.*** Chest radiographs are frequently nonspecific. The clinical presentation and time since transplant in conjunction with CT findings are helpful in generating a useful differential diagnosis. Imaging defines the extent of the abnormality and its evolution.

IPS is characterized by rapidly progressive clinical symptoms with nonspecific lobar, multilobar, or diffuse alveolar or reticular opacities that may be indistinguishable from pulmonary edema or infection (Fig. 57.14A).[50] The radiographic findings in organizing pneumonia are described in Chapter 56. BO is characterized on CT by patchy mosaic perfusion, air trapping (expiratory imaging is helpful), and bronchiectasis (Fig. 57.14B and C).

***Treatment.*** Treatment includes steroids and supportive care. Organizing pneumonia related to HSCT has a worse prognosis than other organizing pneumonias.[50] BO is treated with steroids but the disease usually has a slowly progressive course.

## Drug-Induced Pulmonary Disease

### Overview

Although a large number of pharmacologic agents may cause or exacerbate pulmonary disease in adults, the incidence and types of pulmonary effects specific to children are generally unknown.[52] Cause and effect are difficult to establish, and the time between drug administration and reaction is highly variable.

***Etiology.*** Chemotherapeutic agents (such as cyclophosphamide, bleomycin, busulfan, cisplatin, nitrosureas, mitomycin-C, and methotrexate) are the most common drugs associated with pulmonary toxicity (occurring in up to 10% of patients).[53,54] These medications may cause interstitial pneumonitis or fibrosis, hypersensitivity reaction, ARDS, or organizing pneumonia, previously known as bronchiolitis obliterans with organizing pneumonia (BOOP). Amiodarone is used for cardiac arrhythmias and may cause interstitial fibrosis, organizing pneumonia, or both.[53] Airway hyperreactivity has been associated with ingestion of aspirin and nonsteroidal antiinflammatory agents. Hypersensitivity reactions may be produced by methotrexate, sulfonamides, and nitrofurantoin.[53] Noncardiogenic pulmonary edema may result from overdoses of heroin, morphine, methadone, and cocaine.[53,55] Pulmonary hemorrhage may be seen after administration of anticoagulants, surfactants, and penicillamine.[52]

***Imaging.*** Radiographic findings of drug-induced reactions are variable and nonspecific, consisting of heterogeneous pulmonary opacities, homogeneous pulmonary opacities, or both.[52]

CT provides better characterization of pulmonary findings and therefore is more useful for early diagnosis of pulmonary toxicities. The imaging findings depend on the histologic process and may include interstitial disease, alveolar disease, or both.[52,53] Interstitial pneumonitis and fibrosis, typical of bleomycin, produce ground-glass opacities, areas of consolidation, and irregular linear opacities that tend to predominate in the lower lung zones. Methotrexate pulmonary toxicity resembles hypersensitivity pneumonia, showing ground-glass opacities and poorly defined centrilobular nodules.

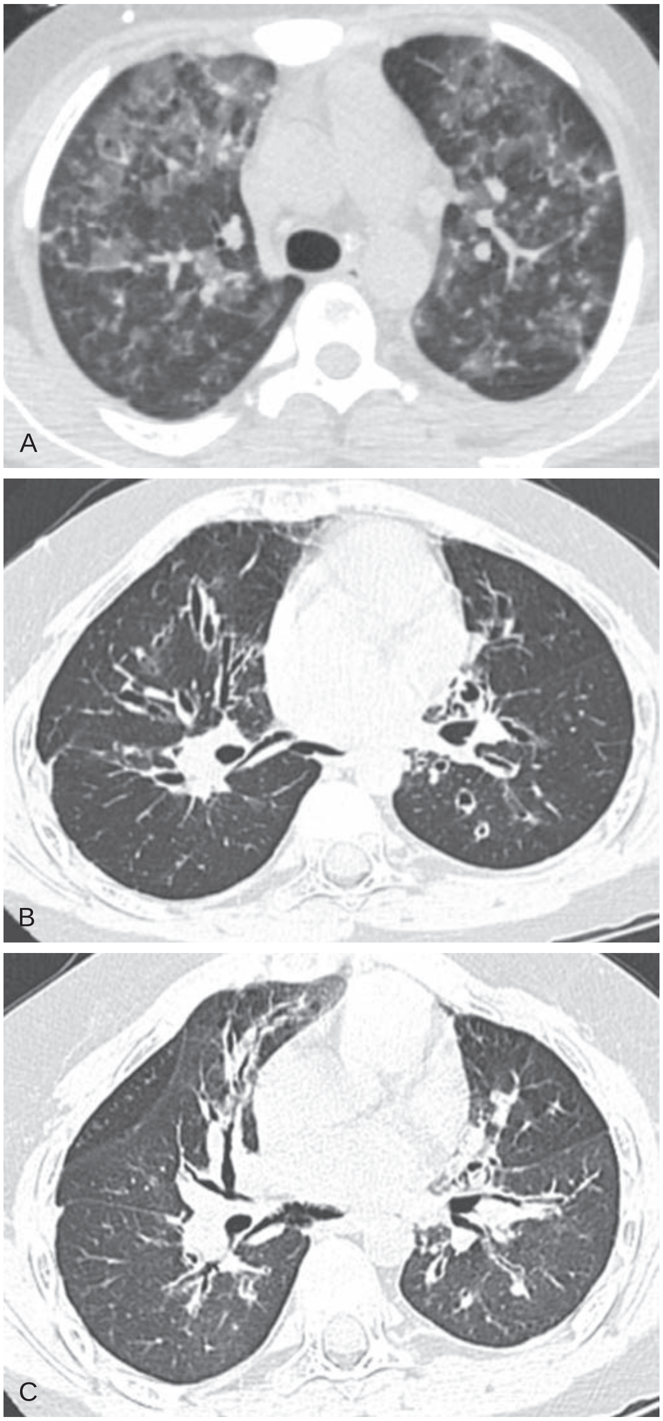


**Figure 57.14. Graft–versus–host disease complicated by idiopathic pneumonia syndrome (IPS) and bronchiolitis obliterans (BO) in two different patients.** (A) A 19-year-old patient 2 months after hematopoietic stem cell transplant (HSCT) with acute respiratory distress. Note patchy bilateral ground-glass opacity and centrilobular nodules. Hemosiderin-laden macrophages were present at bronchoalveolar lavage suggesting IPS with pulmonary hemorrhage. The patient responded promptly to steroids. (B and C) A 10-year-old patient, 2 years after HSCT with BO. Axial inspiratory (B) and expiratory (C) CT images demonstrate mosaic perfusion, scattered peribronchial thickening, bronchiectasis, and exiratory air trapping anteriorly.

ARDS, previously discussed, results in predominantly dependent airspace consolidation. Organizing pneumonia is the least common pattern with chemotherapy and shows peribronchial or subpleural areas of consolidation.[53]

Airway reactivity is associated with air trapping on imaging. The appearance of noncardiogenic pulmonary edema and pulmonary hemorrhage has been discussed earlier in this chapter.

***Treatment and Follow-up.*** Removal of the causative agent is the ideal management for drug-induced pulmonary disease if the toxicity can be recognized and the removal is feasible. Unfortunately, some pulmonary toxicities are irreversible. If symptoms persist, radiography and CT may help in follow-up management.

## Radiation Damage to the Thorax

### Overview

Lung damage may follow radiation therapy given primarily to the lungs, the mediastinum, the chest wall, or the total body. The incidence of radiation damage to the lung in adult patients treated for lung cancer, mediastinal lymphoma, and breast cancer ranges from 5% to 20%.[56] An even larger portion of patients may have changes in pulmonary function tests, although most of these patients remain symptom free.[57]

In pediatric patients, whole-lung irradiation to 12 gray (Gy) was used in the third national Wilms tumor study from 1979 to 1986 and 15 patients (approximately 10%) developed radiation pneumonitis (that may have been exacerbated by chemotherapeutic agents dactinomycin or doxorubicin).[57] Data from the Childhood Cancer Survivor Study showed a 4-times increased risk of lung fibrosis at 5 years or more after diagnosis among children who received chest radiation, total body irradiation, or both. The cumulative incidence of lung fibrosis at 20 years after diagnosis was 3.5%, and the incidence continued to increase from diagnosis up to 25 years. An increased risk for other pulmonary conditions such as supplemental oxygen use, recurrent pneumonia, chronic cough, and pleurisy was also seen in this population.[54]

***Etiology.*** Important factors in determining whether the lungs are damaged include the volume of tissue irradiated, the dosage and its fractionation, the relative biologic effectiveness of the therapy employed, and the use of concomitant chemotherapy. Several chemotherapy agents are known to increase the risk of radiation pneumonitis and/or long-term lung damage.[58,59] Radiation-induced lung injury is typically categorized temporally as early pneumonitis (1–6 months) and late pulmonary fibrosis (>6 months).[60]

***Imaging.*** Radiographic changes, if present, usually appear a few months after the cessation of radiation therapy. The radiographic appearance initially is that of an ill-defined alveolar process. CT typically shows ground-glass opacity in a sharply defined zone not conforming to anatomic boundaries. As the process evolves, it becomes more interstitial in appearance until changes recognized as radiation fibrosis appear. CT is more sensitive than chest radiography in showing these findings. If the mediastinum has been irradiated, a central perimediastinal, sharply delineated area of linear increased opacity corresponding to the radiation portal is typically seen (e-Fig. 57.15).[57,60]

***Treatment and Follow-up.*** Corticosteroids are sometimes used for managing acute radiation-induced pneumonitis, and long-term treatment is aimed at control of symptoms.[60] Choice of follow-up imaging is largely determined by clinical factors. CT is more sensitive to identify subtle findings of fibrosis.

## Inhalation Injuries

### Overview

Children are rarely exposed to the industrial gases, chemicals, and particulates that adult workers may encounter. Secondhand smoke exposure is by far the most common inhalation injury in children, known to cause increased incidence of respiratory illnesses such as asthma, bronchitis, and pneumonia.[61,62] Acute inhalation injury in children is usually secondary to substances encountered in the home, the most common of which is smoke from house fires. Other far less common causes of acute inhalation injury include chlorine gas (pool disinfectant), talcum powder, and household cleaning agents.[43]

***Etiology.*** Pulmonary damage in pediatric fire victims can be related to heat-mediated upper airway injury but is more commonly due to chemical irritation of the peripheral airway and parenchyma from the products of combustion. From 20% to 30% of patients with burn injuries will have concomitant smoke inhalation injury.[63,64] Heat-related airway injury should be suspected in those with burns in the head-and-neck area, blackened sputum, and respiratory symptoms. Inhalation injury with its associated pulmonary complications increases the morbidity and mortality rates from burn injuries at least threefold.[64] Typically, pulmonary burns progress through three distinct clinical stages: (1) bronchospasm (1–12 hours after the burn), (2) pulmonary edema (6–72 hours), and (3) bronchopneumonia (after 60 hours) (Fig. 57.16). Bacterial pneumonia is very frequent (approximately two-thirds of patients) after the third or fourth day of injury and should be anticipated.[43,64]

Inhalation injury from chlorine gas has been reported in children. This irritant gas is found in swimming pool disinfectants and household cleaning agents. It reacts with the water in tissue to produce hydrochloric acid, which leads to mucosal necrosis. Irritation of the upper respiratory tract, cough, and wheezing are early findings.[43,65]

Inhalation injury may occur in infants caused by inhalation of the small (approximately 5 micrometers) particles of hydrous magnesium silicate present in talcum powder. Inhaled talc produces airway obstruction and impairs ciliary action, which leads to inflammation. Symptoms of cough and respiratory distress are rapid after exposure.[66]

Secondhand smoke exposure is associated with an increased rate of respiratory illness in infancy and childhood. The frequency of reactive airways disease is increased in exposed infants.[67,68]

***Imaging.*** Chest radiographs are most often normal or show hyperinflation early after smoke inhalation, but diffuse or focal patchy opacities or pulmonary edema may be noted (see Fig. 57.16). CT at hospital admission has been used to grade lower airway injury in adult patients.[69] Diffuse opacities on radiographs usually appear after a latent period of 12 to 48 hours and may clear slowly. Rapid appearance of total or subtotal lung consolidation has been described in up to 10% of burned children and is associated with high early mortality. ARDS is a serious and common complication of inhalation injuries and burns.[43]

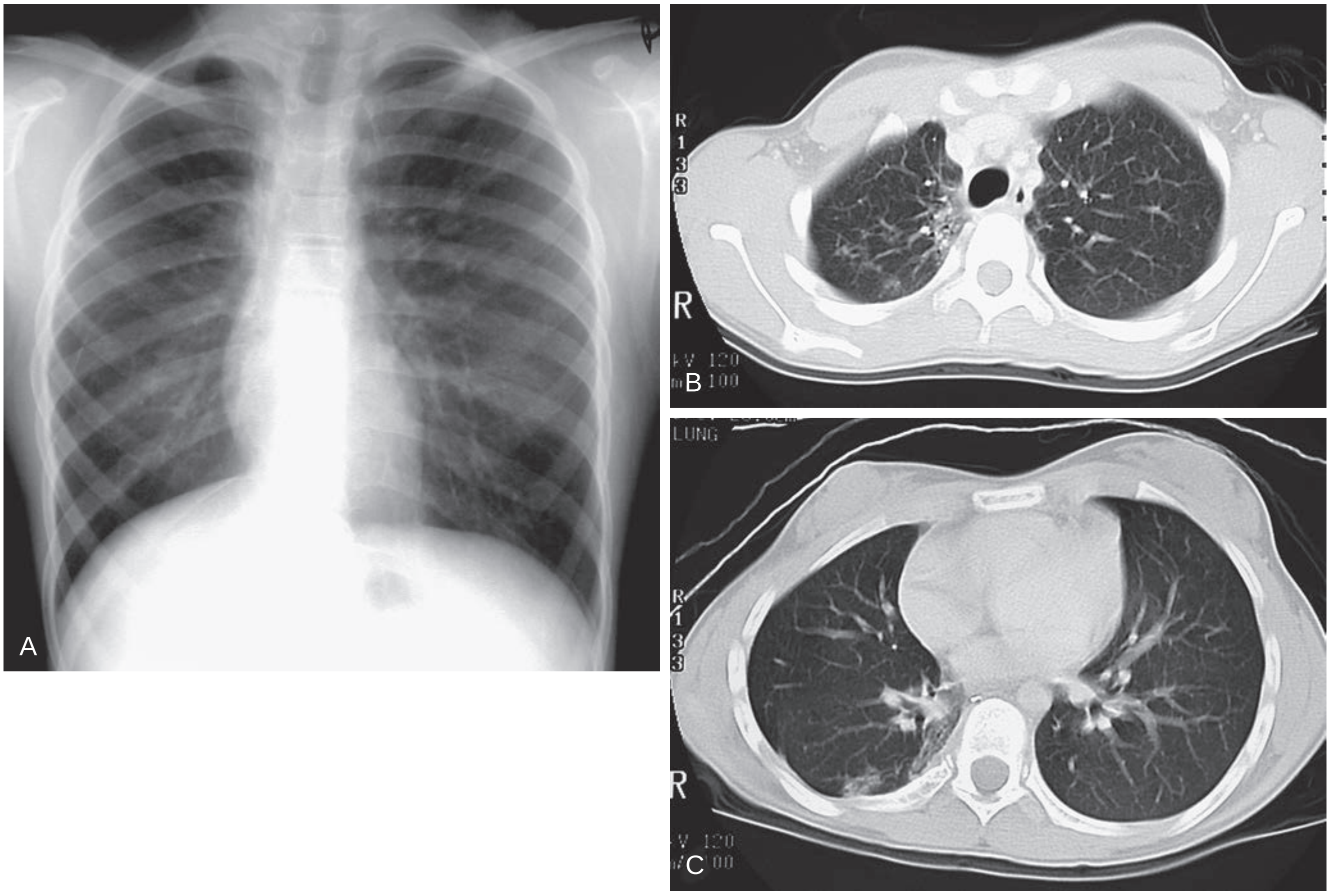
With chlorine gas inhalation, the onset of pulmonary edema is often rapid. The chest radiograph may be normal or may show hyperinflation or pulmonary edema.[65,66] With talcum powder inhalation, the chest radiograph may show hyperinflation and patchy opacities.[66]

***Treatment and Follow-up.*** Treatment, as for noncardiogenic pulmonary edema, is primarily supportive. Late sequelae, including severe bronchiectasis, asthma, and bronchiolitis obliterans, may be noted after smoke inhalation.[43] Follow-up radiographs are adequate if the patient shows clinical improvement. CT may be needed if clinical symptoms persist in a delayed setting.

## Hydrocarbon Pneumonitis

### Overview

Hydrocarbon pneumonitis occurs in 40% of children after ingestion of hydrocarbons such as lamp oil, lighter fluid, cleaning fluid, furniture and floor polishes, kerosene, and gasoline.[70] Because of



**e-Figure 57.15. Effects of radiation therapy in a 12-year-old girl 2 years after intense radiation therapy for a right paraspinal primitive neuroectodermal tumor.** (A) Chest radiograph shows a smaller right hemithorax and mild rightward mediastinal shift. (B and C) CT images show a smaller right lung, rather sharp-edged changes of lung opacity along the medial aspect of the right upper lobe, and a few scattered peripheral opacities.

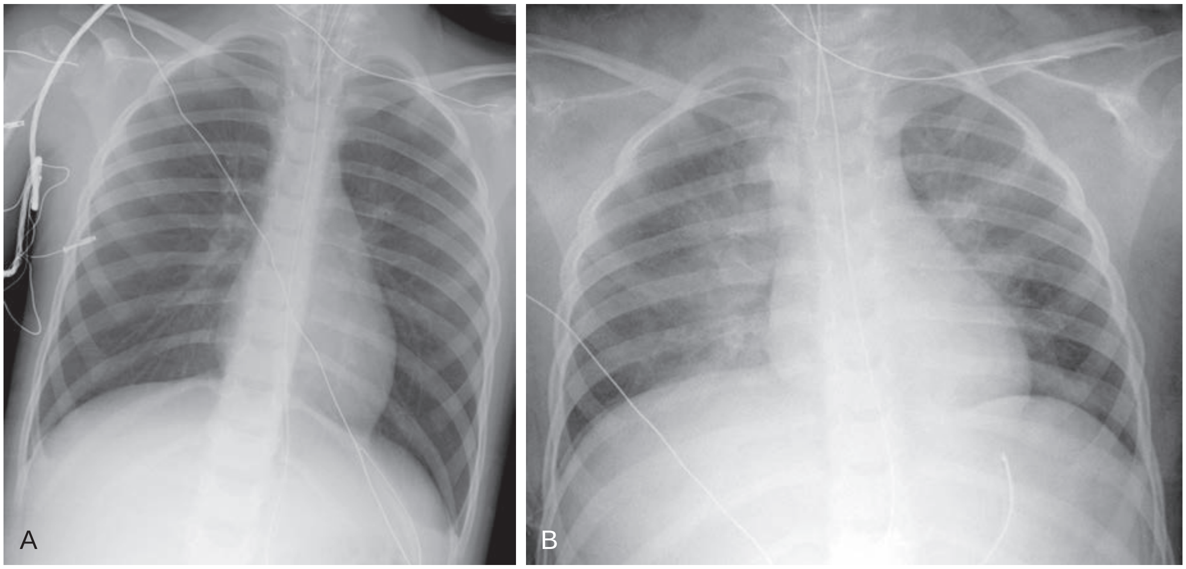


**Figure 57.16. Smoke inhalation injury.** A 4-year-old girl rescued from a house fire. (A) Portable anteroposterior chest radiograph at admission shows clear lungs and hyperinflation. (B) One day later, bilateral pulmonary edema has developed and lung volumes are lower.

their low viscosity, these substances are aspirated when ingested. In the United States, such exposures continue to account for 12% to 25% of lethal poisonings in children less than 5 years old.[43]

***Etiology.*** Aspirated or inhaled material usually results in an intense chemical pneumonitis causing damage to the respiratory epithelium and development of cyanosis through displacement of alveolar gas by the hydrocarbon.[43]

***Imaging.*** Although changes may be evident on the chest radiograph as early as 30 minutes after aspiration, the findings may be delayed several hours; virtually all affected children with lung disease have abnormal chest radiographs by 12 hours (e-Fig. 57.17).[43] The typical pattern of hydrocarbon pneumonitis is one of patchy airspace consolidation and alveolar edema involving predominantly the medial basilar portions of the lungs bilaterally. Pneumatoceles are a well-known complication of hydrocarbon aspiration but reportedly only develop in 10% of children.[70]

***Treatment and Follow-up.*** Treatment is supportive. Resolution of the radiographic changes usually lags behind clinical improvement and may take weeks or months. CT may be performed if improvement does not progress as expected.

### Lipoid Pneumonia

#### Overview

Oral administration of mineral oil for constipation is the most common cause of exogenous lipoid pneumonia. In a study of affected children in Brazil, 79% of patients were less than 24 months of age.[71]

***Etiology.*** Lipids aspirated during oral administration of mineral oil may result in an insidious chronic process that produces an intense lung response and severe lung injury. The current diagnostic method of choice is by analysis of bronchoalveolar lavage fluid, which is reported to show a milky white appearance, sometimes with floating fat globules, and also contains lipid-laden macrophages.[71]

***Imaging.*** The typical radiographic pattern of lipoid pneumonia is perihilar and basilar airspace opacities. CT shows areas of ground-glass opacity or more confluent airspace disease (Fig. 57.18 and e-Fig. 57.19). The airspace consolidation measures as fat attenuation on CT in up to 71% of these children and should alert the radiologist to the diagnosis.[72] However, in some cases the associated inflammation masks the low-density lipid. In adults and children with lipoid pneumonia, the crazy paving pattern has also been noted on thin-section CT.[71-73]

***Treatment and Follow-up.*** Cessation of exposure and clearing of the oil by multiple bronchoalveolar lavages is usually followed by slow clearing of lung opacities and clinical improvement.[72,74] CT and chest radiography are usually used for follow-up.

### Near-Drowning

#### Overview

Drowning is the second most frequent cause of accidental death in children, after motor vehicle accidents. The most common site for a near-drowning episode is the backyard swimming pool. Accidental submersion injuries demonstrate a bimodal age peak of 6 months to 4 years and 18 to 24 years.[43]

***Etiology.*** Submersion time, volume of water aspirated, severity of acidosis, and length of delay in cardiopulmonary resuscitation all correlate directly with morbidity and mortality. Most submersion victims aspirate a small amount of water that may contain vomitus or a variety of contaminants. Laryngospasm then occurs, which may prevent further aspiration.[43]

***Imaging.*** The radiologic pattern of near-drowning is that of pulmonary edema, and the severity depends predominantly on the amount of water aspirated. A significant delay, sometimes as long as 24 to 48 hours after near-drowning, may occur before the appearance of edema (Fig. 57.20). Opacities are usually bilateral and symmetric. Many episodes of near-drowning progress to ARDS.[43]

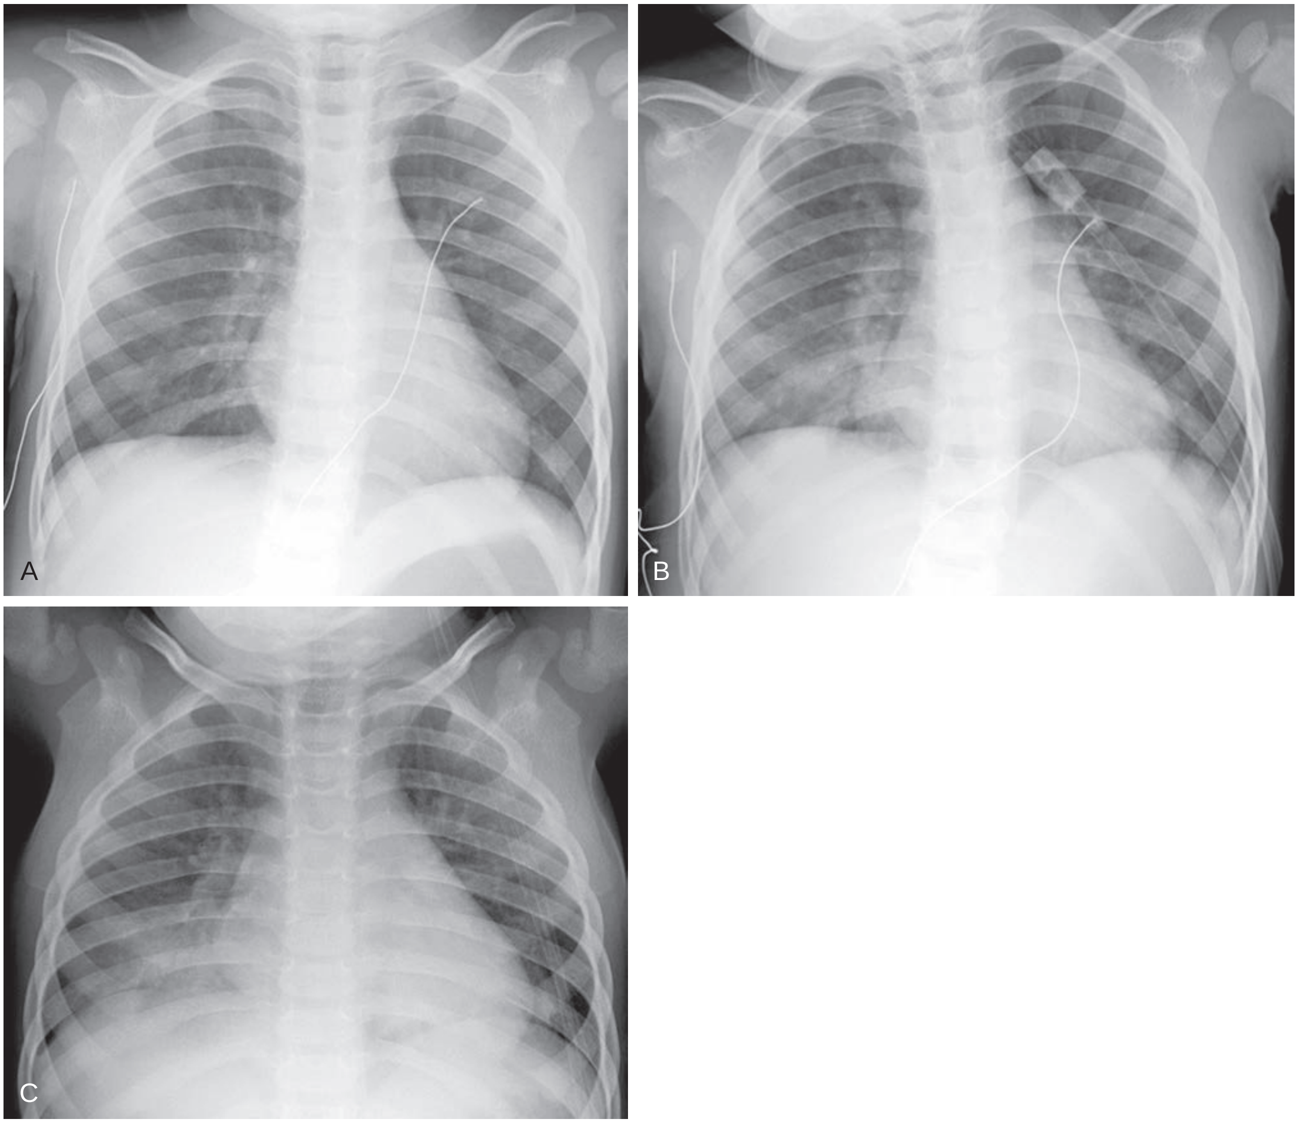
***Treatment and Follow-up.*** Treatment is primarily supportive with ventilatory support, if needed, in cases of severe respiratory distress. Radiography is usually adequate for imaging follow-up.

## CONDITIONS WITH PULMONARY CALCIFICATIONS

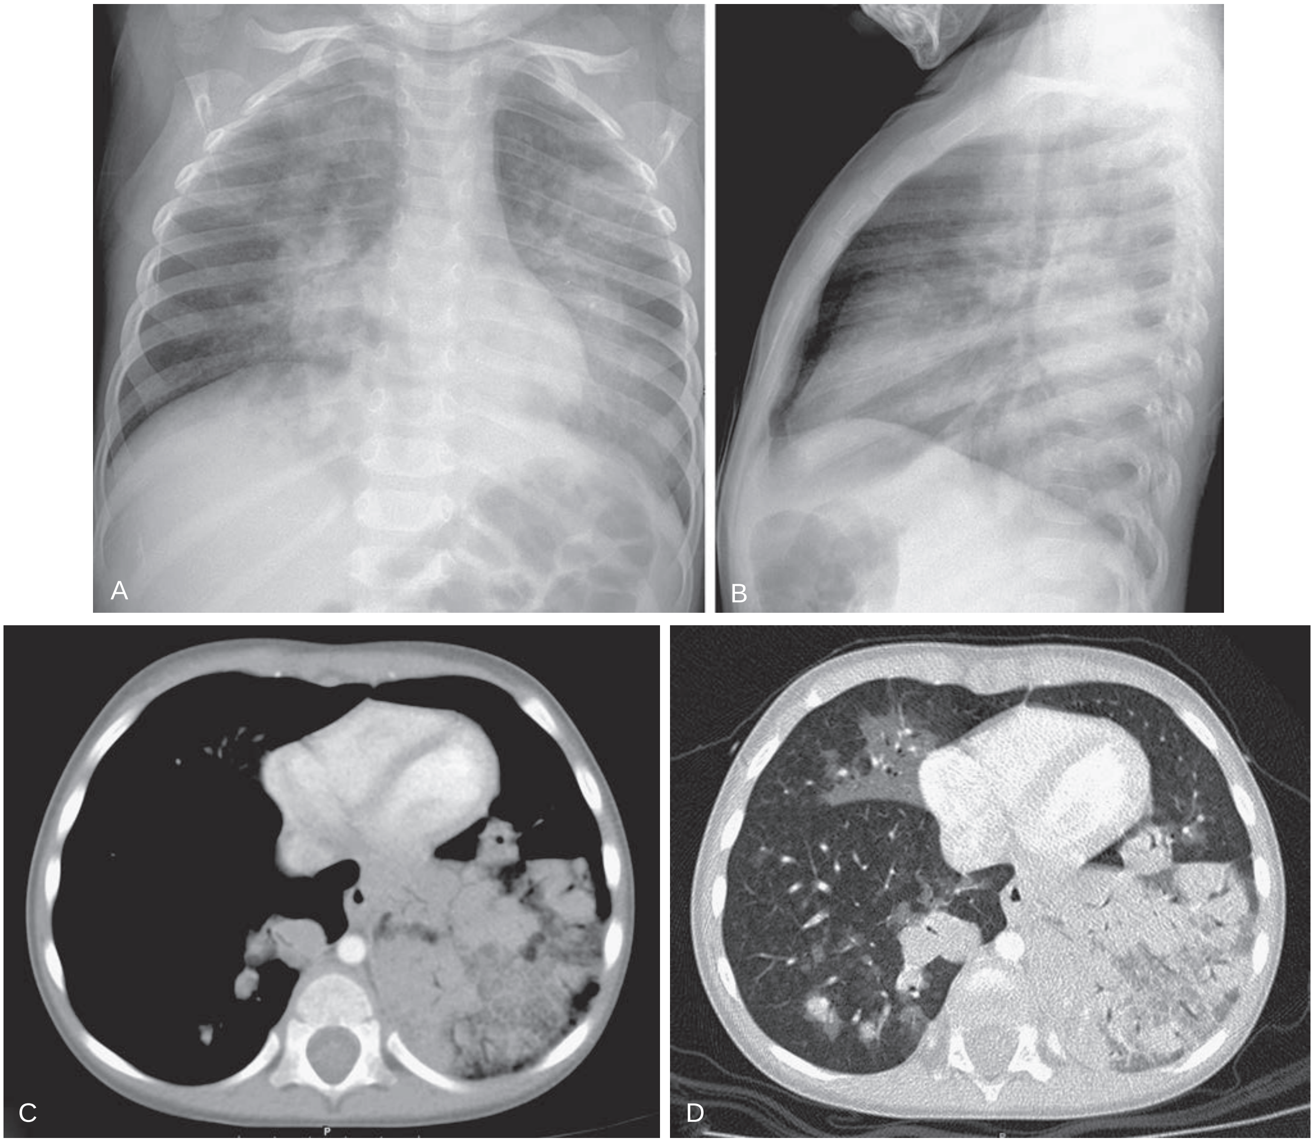
### Pulmonary Alveolar Microlithiasis

#### Overview

Pulmonary alveolar microlithiasis (PAM) is a rare disease characterized by the presence of innumerable calcium phosphate microliths



**e-Figure 57.17. Hydrocarbon aspiration in a 23-month-old girl who ingested lighter fluid.** (A–C) Chest radiographs at presentation, 6 hours later, and 2 days later, respectively. The initial radiograph is normal, but subsequent radiographs show delayed development of bibasilar airspace disease.



**e-Figure 57.19. Lipoid pneumonia.** This 19-month-old boy had persistent fevers despite antibiotic treatment. He had been ingesting mineral oil as a treatment for constipation. (A) Frontal and (B) lateral chest radiographs show bilateral patchy areas of airspace disease. (C and D) Mediastinal (C) and lung window (D) axial CT images obtained using controlled ventilation technique show partial low-attenuation airspace disease in the left lower lobe with some degree of the crazy paving pattern. Patchy areas of airspace disease, some with ground-glass attenuation, are also seen in the right middle lobe and right lower lobe.

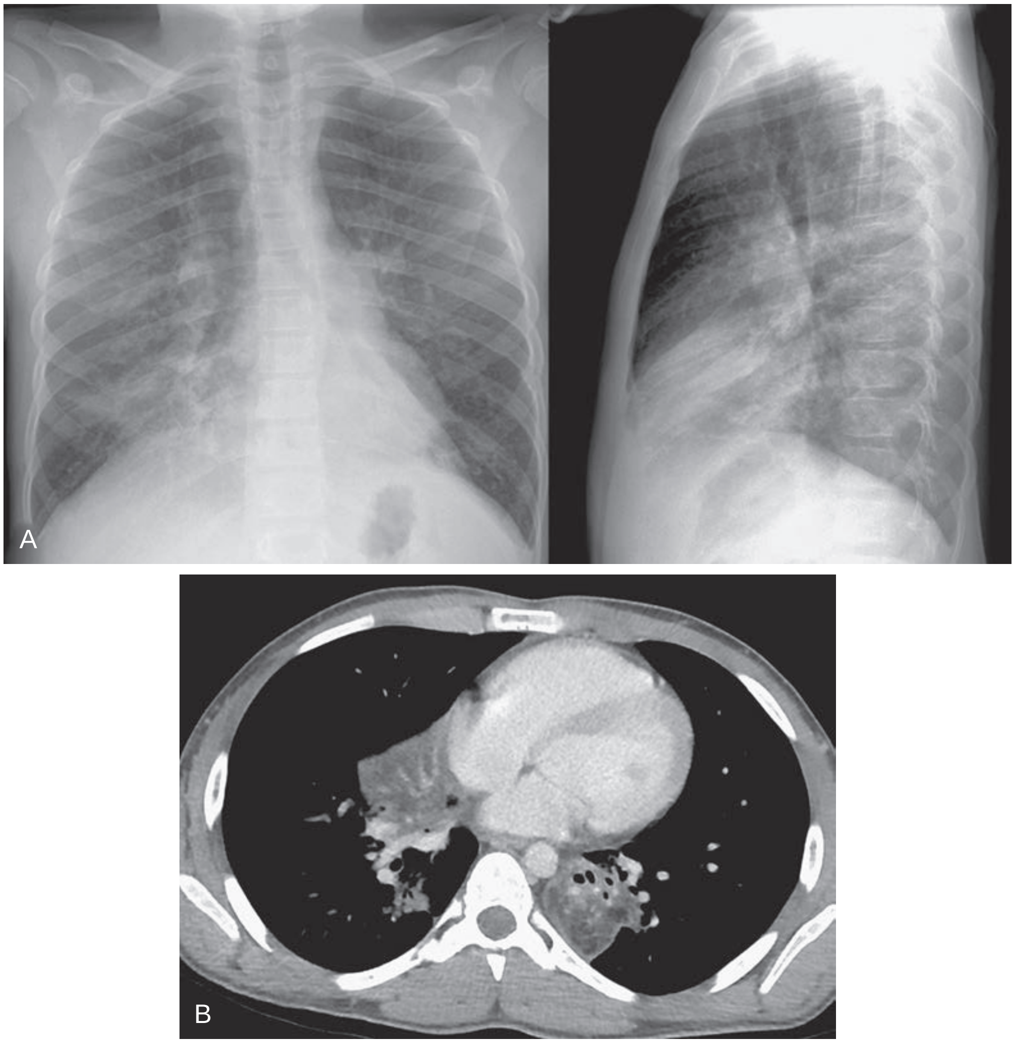


**Figure 57.18. Lipoid pneumonia.** This 11-year-old boy presented with chronic cough and drainage, with recent-onset difficulty breathing. He had a history of being treated for constipation with oral mineral oil. (A) Bilateral airspace opacities are noted predominantly in the lung bases on the initial posteroanterior and lateral chest radiographs. (B) Axial CT image shows focal consolidation with fat attenuation in the left lower lobe and right middle lobe.

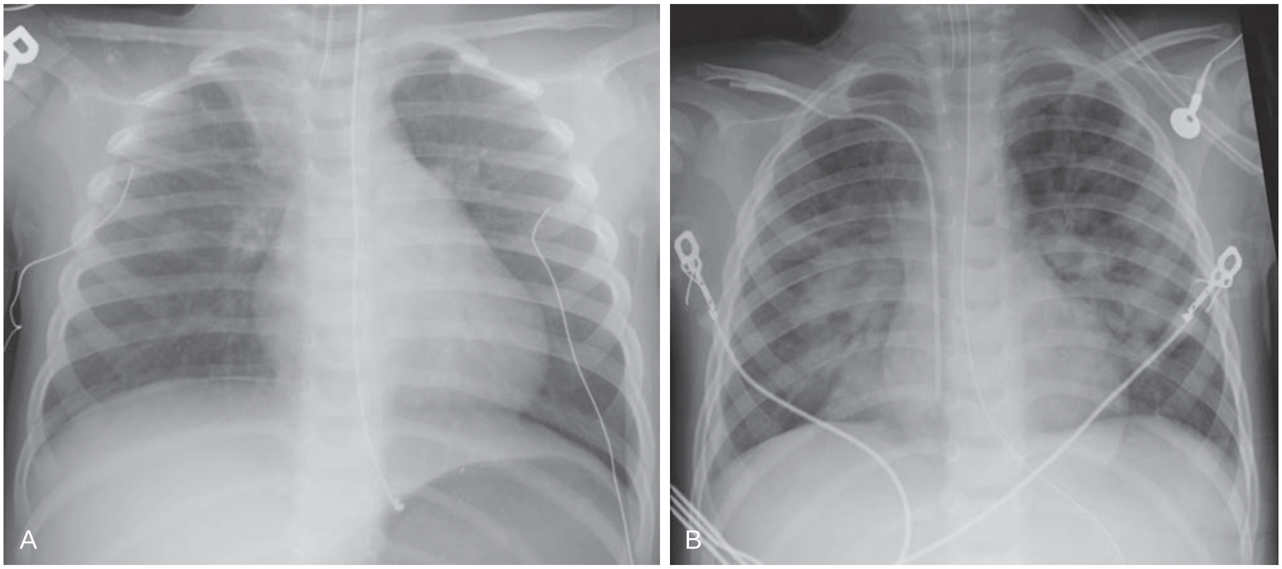

**Figure 57.20. Near-drowning.** This 3-year-old boy suffered a near-drowning episode in a creek. (A) Chest radiograph at presentation is near normal except for atelectasis at the medial right apex. (B) Chest radiograph 2 days later shows development of perihilar airspace disease consistent with noncardiogenic pulmonary edema.

in the alveoli. Many cases are familial and inherited as an autosomal recessive trait.[75] In one review, 17% of affected patients presented at 12 years of age or younger.[76]

***Etiology.*** This disorder is related to a gene mutation associated with a defective cellular phosphate transporter mechanism that leads to the inability of alveolar type II cells to clear phosphorus ions. This then likely causes the accumulation of the characteristic calcium phosphate microliths.[32] The tiny stones in the alveoli consist of concentric calcium rings, which measure from 0.01 to 3 mm in size, and are similar to bone histologically, radiographically, and metabolically. The number and size of the calculi and the amount of interstitial reaction increase with the age of the patient and the duration of the disease.[75,76]

***Imaging.*** On chest radiographs in children with PAM, diffuse ground-glass opacities were more common findings than nodular calcific densities. HRCT shows ground-glass opacities and interstitial septal thickening. Additionally, calcifications are seen in tiny lung nodules, as well as in the pleura and interlobar septae.[77,78] The calcified lung lesions demonstrate an avidity for bone scintigraphy agents.[76]

***Treatment and Follow-up.*** Virtually all types of treatment for PAM have been ineffective except lung transplantation.[76] CT or chest radiography may be used for follow-up, but CT shows the distribution and size of the calcifications more reliably.

## Miscellaneous Pulmonary Calcifications

### Overview

A wide variety of clinical conditions may be associated with pulmonary calcifications.

***Etiology.*** Focal pulmonary calcifications in childhood are usually the result of granulomatous infection, most commonly tuberculosis or histoplasmosis. Diffuse calcifications are probably dystrophic (calcification caused by tissue damage) and are most commonly seen after varicella infection. Metastatic calcification (calcification in normal tissue) is caused by abnormal calcium and phosphorous metabolism, usually in one of the following clinical situations: chronic renal failure with secondary hyperparathyroidism, acute renal failure, after renal transplantation, and after cardiac surgery.[79]

***Imaging.*** Initially, plain radiographs show airspace consolidation or nonspecific nodular opacities, which may demonstrate a progressive increase in density over time. These opacities may not be recognized as representing calcifications and be mistaken for an infectious process such as pneumonia. CT more accurately shows the nature of the opacities as containing calcification.[79]

***Treatment and Follow-up.*** Besides treatment for a discovered active granulomatous process, no treatment or follow-up is needed for the majority of pulmonary calcifications.

### KEY POINTS

- The most common radiologic findings of vasculitis are best delineated by HRCT and include nodules (often cavitary), ground-glass opacities, and airspace opacities.
- Common thoracic findings of CVD are pleural and pericardial effusions. CVD is rarely associated with interstitial lung opacities in children, but this finding would be best demonstrated by HRCT.
- Lung involvement with LCH is virtually always associated with multisystem disease and shows mostly cysts and nodules predominantly in the upper lobes and may progress to honeycombing.
- Subtle radiographic findings of interstitial pulmonary edema in infants and children include peribronchial cuffing, perihilar vascular haziness, fissural thickening, septal lines, hyperinflation, and small pleural effusions. These findings may be mistaken for airway disease.
- Only 10% of pediatric patients with hydrocarbon pneumonitis develop pneumatoceles despite the widely recognized association of this complication.
- Exogenous lipoid pneumonia is usually caused by mineral oil ingestion for constipation and is associated with fat attenuation opacities on CT.

# PART 4 Mediastinum

# 58

# The Mediastinum

*Gerald G. Behr, Ricardo Restrepo, and Edward Y. Lee*

A variety of congenital and developmental anomalies, inflammatory and infectious diseases, and benign and malignant neoplasms occur in the mediastinum in the pediatric population. Up-to-date knowledge and a practical diagnostic approach combined with a clear understanding of the characteristic imaging appearances of these conditions can facilitate prompt diagnosis and optimal patient management. This chapter reviews the underlying etiology, imaging findings, treatment, and follow-up of commonly encountered congenital and acquired anomalies and abnormalities that occur within the mediastinum in the pediatric population.

## SPECTRUM OF MEDIASTINAL ANOMALIES AND ABNORMALITIES

### Pneumomediastinum

#### Overview

Pneumomediastinum occurs more frequently in infants than in older children.[1,2] Affected pediatric patients may present with a sensation of retrosternal fullness, dysphagia, sore throat, chest pain, or dyspnea.

***Etiology.*** Pneumomediastinum may be spontaneous or iatrogenic. Spontaneous pneumomediastinum results from a sudden forceful increase in intraalveolar pressure such as forceful inhalation or the Valsalva maneuver. In this instance, an alveolus can rupture, allowing gas under pressure into the low-pressure pulmonary interstitial compartment. Subsequently, the air then travels via the peribronchovascular space medially toward the hilum, which opens into the mediastinum.[3,4] Occasionally, the air dissects along the lymphatics as well and extends to the visceral pleura, where a concomitant pneumothorax may occur. Iatrogenic pneumomediastinum may result from chest, abdominal, and cardiac surgery; endotracheal intubation; or cardiac catheterization. Secondary pneumomediastinum can occur after foreign body ingestion, trauma to the neck or chest, or any disruption of the tracheobronchial tree or esophagus (e.g., Boerhaave syndrome).[2]

It is not uncommon for pneumomediastinum and pneumothorax to coexist.[5] This phenomenon sometimes can be attributed to a common mechanism of air leak, or the pneumothorax may arise as a result of a pneumomediastinum. In addition, anatomic communications between the mediastinum and the peritoneal cavity exist. As such, intraabdominal air can dissect superiorly into the mediastinum and vice versa.[6] Rarely, air within the mediastinum can enter the spinal canal, termed *pneumorrhachis*.[7]

***Imaging.*** Air within the mediastinum typically displaces the pleura and lung laterally (Fig. 58.1). It may decompress into the superior mediastinum and dissect along fascial planes into the subcutaneous tissues of the neck and retropharynx (e-Fig. 58.2). In infants and younger children, air within the mediastinum can displace the thymus superiorly to produce the “spinnaker sail” sign (see Fig. 58.1).

Occasionally, only a sliver of curvilinear radiolucency is seen adjacent to the cardiac border, often on the left, outlining the aortic arch and descending aorta. When air is adjacent to the pulmonary artery (typically on the right), the “ring around the artery” sign is seen on the lateral view.[6,8] The “continuous diaphragm sign” results from air interposed between the pericardium and the diaphragm.[8] Although pneumomediastinum is usually anterior in location, posterior mediastinal air collections can also occur, typically toward the right in the infra-azygous space (e-Fig. 58.3). Posterior pneumomediastinum may occur secondary to barotrauma but should raise concern for iatrogenic and especially tracheal or esophageal injury.[9,10]

A large pneumomediastinum may be confused with a pneumothorax, especially when viewed on a supine radiograph. When equivocal, a decubitus radiographic view may be helpful because the mediastinal air does not move, whereas the pneumothorax rises nondependently.[5]

Pneumomediastinum may mimic pneumopericardium. In contrast to pneumomediastinum, pneumopericardium does *not* lift the thymus or outline the aortic arch as the air is contained by pericardium. Pneumopericardium is almost always seen in association with pneumomediastinum except after open-heart surgery.[5]

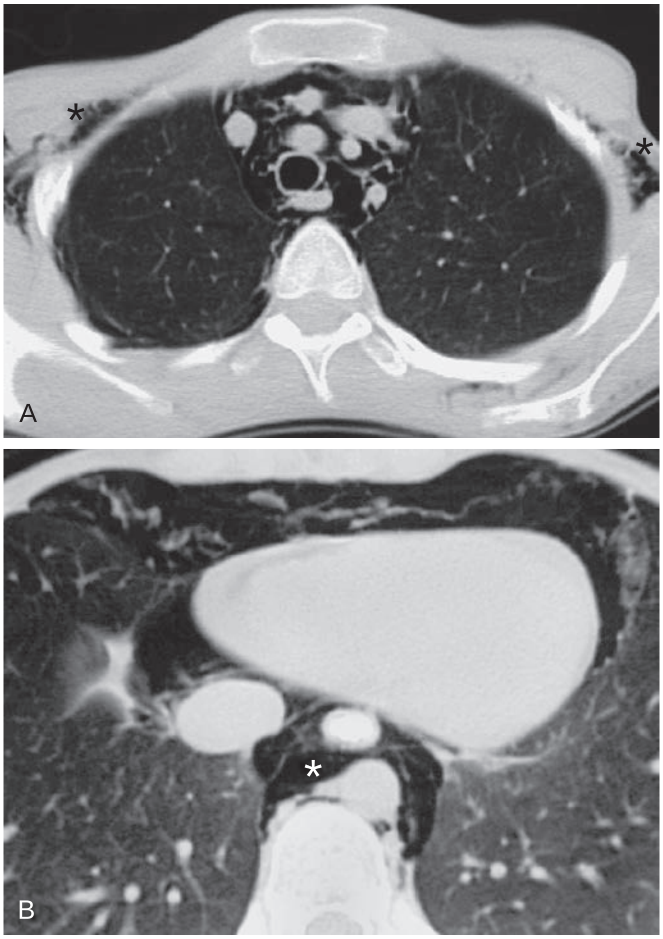
***Treatment and Follow-up.*** Treatment of pneumomediastinum is aimed at its underlying cause.[11] In most cases, management is supportive.[2] If there is concern for esophageal rupture, an esophagram using water-soluble contrast may be performed, and surgical consultation should be obtained.[12,13] However, esophageal rupture in children is rare and, in most uncomplicated cases of pneumomediastinum, no further imaging beyond the diagnostic chest x-ray is necessary.[13,14] Very rarely, pseudotamponade, laryngeal compression, tension pneumomediastinum, tension pneumothorax, or mediastinitis occur and require surgical intervention.

### Mediastinal Hemorrhage

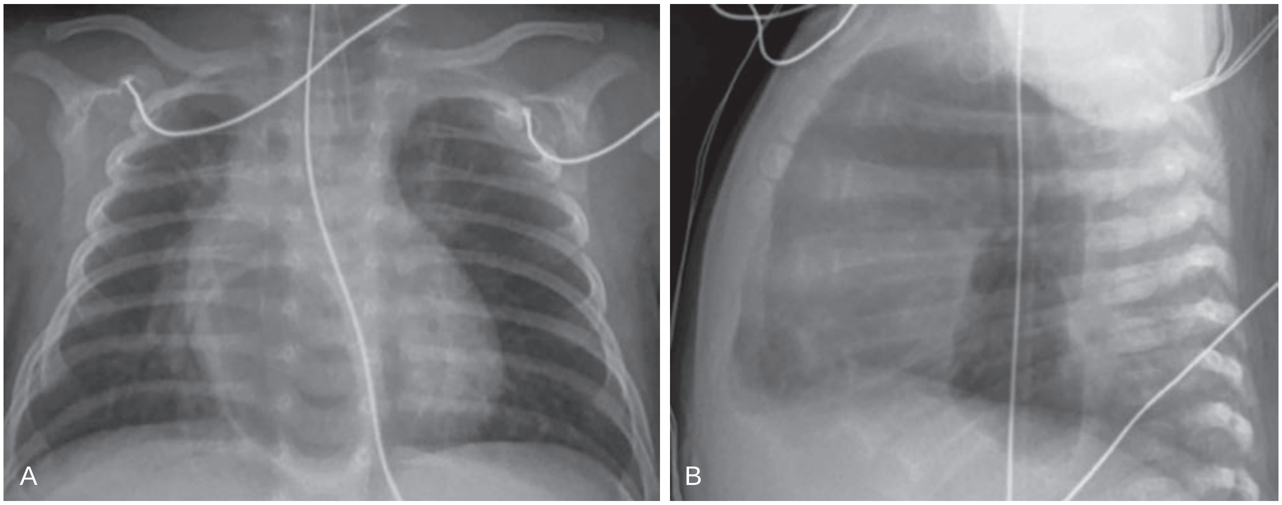
***Etiology.*** Mediastinal hemorrhage in children may occur as a result of blunt trauma (usually venous bleeding)[5] or iatrogenic causes related to central catheter placement or cardiothoracic procedures. However, mediastinal hemorrhage in children may occur spontaneously in the context of hemophilia, in which case the hemorrhage may be retropharyngeal and dissect into the mediastinum.[5,15] Rare cases of neonatal thymic hemorrhage have been reported, possibly related to vitamin K deficiency.[16,17]

***Imaging.*** Although imaging findings may be nonspecific, the possibility of mediastinal hemorrhage should be considered when mediastinal widening, blurring of the aortic margin, deviation of a nasoenteric tube, and/or left apical “capping” are present on chest radiographs. When evaluating mediastinal widening on chest radiographs, careful attention must be paid to the technique. For example, a portable anteroposterior chest radiograph may exaggerate the size of the mediastinum. Therefore in equivocal cases, confirmation with a posteroanterior view or a cross-sectional imaging study such as computed tomography (CT) may be necessary. On CT, mediastinal fluid with a Hounsfield unit greater than water (approximately 20–80 HU) suggests mediastinal hemorrhage (Fig. 58.4).

***Treatment and Follow-up.*** When mediastinal hemorrhage is considered on chest radiographs, further imaging studies such as echocardiography and/or contrast-enhanced CT using CT angiographic technique with multiplanar and three-dimensional reconstruction is warranted. With rapid clinical deterioration, urgent surgical exploration is an option to avoid delaying proper treatment.



**e-Figure 58.2. Pneumomediastinum in a 2-year-old girl.** (A) Axial lung window CT image at the level of the superior mediastinum shows mediastinal air that outlines major vessels and fascial planes. Air has dissected through the soft tissues and is seen bilaterally in the axilla *(asterisks).* (B) Axial lung window CT image at the level of the lower thorax demonstrates further caudal extent of the mediastinal air *(asterisk).*



**e-Figure 58.3. Infra-azygos pneumomediastinum in a 5-week-old after repair of an H-type tracheoesophageal fistula.** Frontal (A) and lateral (B) chest radiographs show a large posterior mediastinal lucency due to an infra-azygos pneumomediastinum concerning for an esophageal leak. *(Courtesy of Dr. Beverley Newman, Stanford Children's Hospital, Stanford University. From Pearls and pitfalls in pediatric radiology: variants and other difficult diagnoses, eds Daldrup-Link H, Newman B. Cambridge University Press, 2014. Fig. 20.2.)*

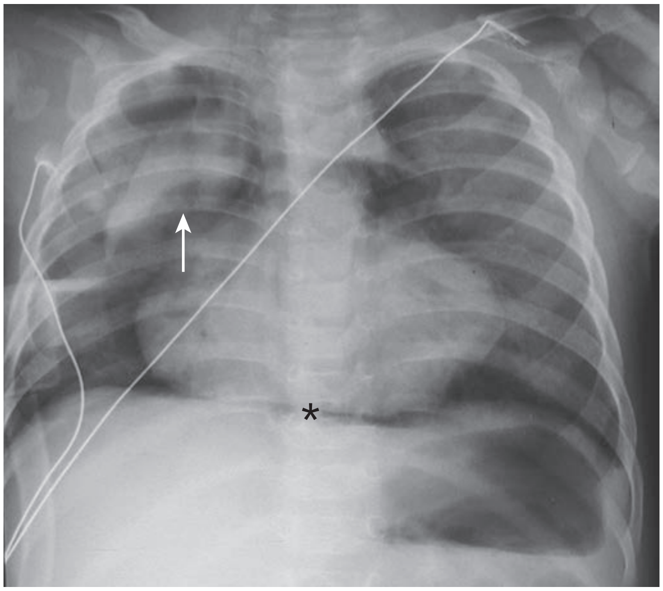


**Figure 58.1. Pneumomediastinum in a 6-month-old boy.** Frontal chest radiograph demonstrates a lifted thymic shadow *(arrow),* the so-called "spinnaker sail sign." Mediastinal air *(asterisk)* also is interposed between the central diaphragm and pericardium, and lucency is seen surrounding the heart.

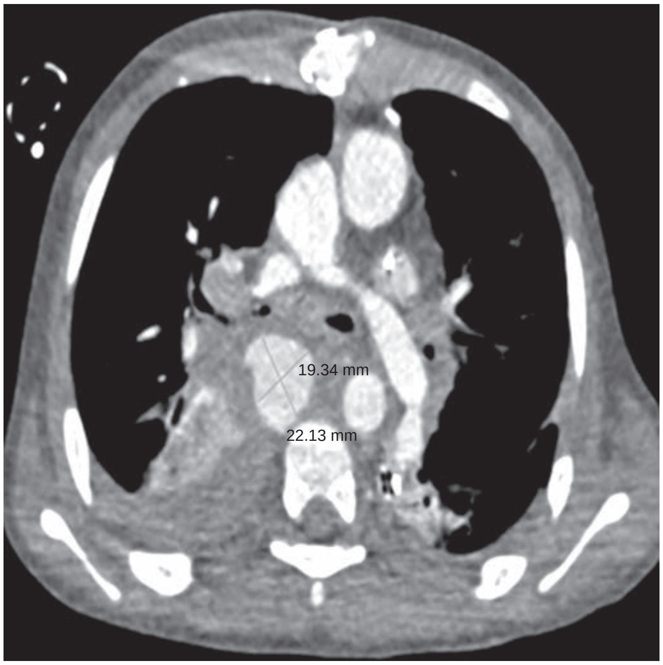

**Figure 58.4. Mediastinal hemorrhage in a 7-year-old boy with congenital heart disease.** Axial contrast-enhanced CT image demonstrates high density fluid in the middle and posterior mediastinum (measurement bars) due to postoperative hemorrhage. *(Courtesy of Dr. Aurelio Secinaro, Bambino Gesù Children's Hospital, Rome, Italy.)*

## Mediastinal Infection

### Overview

Infections arising de novo in the mediastinum are rare in the pediatric population. Mediastinal infections can be classified into acute infection and chronic fibrosing mediastinitis.

### Acute Mediastinitis

***Etiology.*** Acute mediastinal infection in children is most often iatrogenic, related to endoscopic surgery, esophageal instrumentation, and cardiac surgery.[18-20] Chronic fibrosing mediastinitis typically results from tuberculosis or *Histoplasmosis* infections in the pediatric population.[21-23]

In the past, esophageal perforation and spread of infection from other sites into the mediastinum were relatively more common. Affected pediatric patients typically present with chest pain, fever, and an elevated white blood cell count.

***Imaging.*** Plain radiographic findings of acute mediastinitis are nonspecific. However, mediastinal widening, obliteration of normal mediastinal contours, and displaced or narrowed trachea should suggest acute mediastinitis in the appropriate clinical setting. The more specific radiologic imaging finding of acute mediastinitis is the presence of gas within the mediastinum, which can be better evaluated with CT. CT also can show complications from acute mediastinitis such as mediastinal abscess formation or empyema (Fig. 58.5).

***Treatment and Follow-up.*** Acute mediastinitis is treated aggressively with a combination of antibiotics and surgical irrigation. Localized mediastinal abscess formation can be managed with either surgical or percutaneous abscess drainage. Recently, a combination of continuous irrigation and vacuum-assisted postthoracotomy closure has been used and shown to be safe in children.[24-27]

### Chronic Fibrosing Mediastinitis

***Etiology.*** Chronic fibrosing mediastinitis, also known as sclerosing mediastinitis, is rare in the pediatric population. It is a condition characterized by abnormal proliferation of dense acellular collagen and fibrous tissue.[28,29] Although it is most frequently attributed to the sequelae of granulomatous infection such as *Mycobacterium tuberculosis* or *Histoplasmosis* infection, it also can arise as an idiopathic condition or as the sequelae of autoimmune disease, radiotherapy, or drugs such as methysergide and metoprolol.[26,30] Chronic fibrosing mediastinitis is also associated with retroperitoneal fibrosis, sclerosing cholangitis, and Riedel thyroiditis.[31] Affected pediatric patients often present with respiratory distress related to airway narrowing, dysphagia due to esophageal compromise, and/or facial and neck swelling resulting from obstruction of the superior vena cava.

***Imaging.*** Widening of the mediastinum with a lobular paratracheal and/or subcarinal mass that may be calcified is a typical finding on chest radiographs. CT imaging findings of chronic fibrosing mediastinitis can be categorized into two patterns: focal or diffuse.[28,32] The focal form is more likely to calcify (Fig. 58.6). The diffuse type demonstrates a more diffusely infiltrating appearance without calcification.

***Treatment and Follow-up.*** Although no consensus or widely accepted guidelines currently exist for the treatment of chronic fibrosing mediastinitis, systemic antifungal or corticosteroid treatment, surgical resection, and local therapy for complications are the current management options. Surgical resection may be necessary for symptomatic pediatric patients who have extensive chronic fibrosing mediastinitis that results in either obstruction or compression of mediastinal structures such as central airways, the esophagus, or large vessels.

## Mediastinal Masses

### Overview

The mediastinum is the most common location of chest masses in the pediatric population. Mediastinal masses in infants and children can be benign or malignant neoplasms, congenital anomalies, infections, vascular malformations, or pseudomasses. As with adult

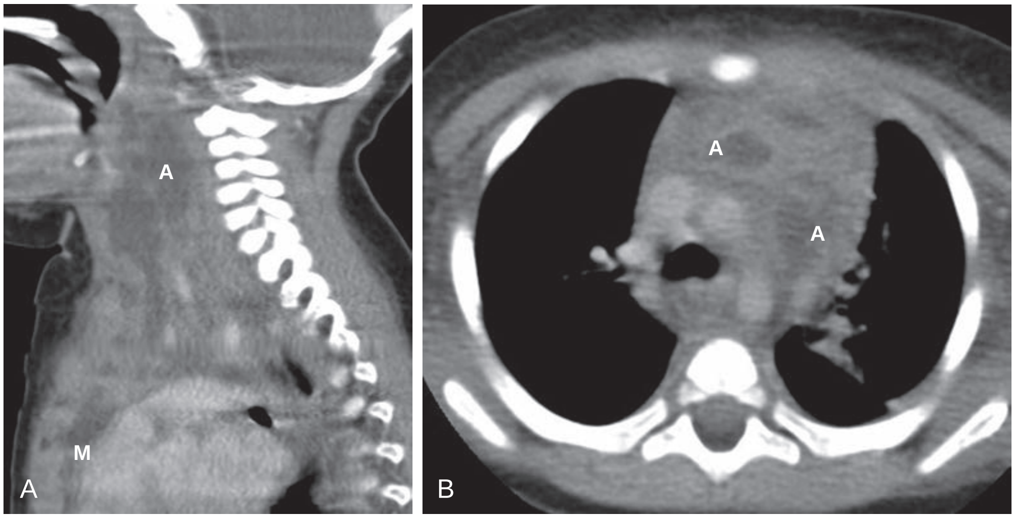

**Figure 58.5. Acute mediastinitis resulting from a retropharyngeal abscess in a 1-year-old boy.** (A) Sagittal reconstruction contrast-enhanced CT image through the neck shows a large, complex fluid collection *(A)* extending caudally into the mediastinum *(M).* (B) Axial contrast-enhanced CT image obtained at the level of the aortic arch demonstrates two of the better defined abscesses *(A)* in the anterior mediastinal compartment embedded in an inflamed and heterogeneous thymus.

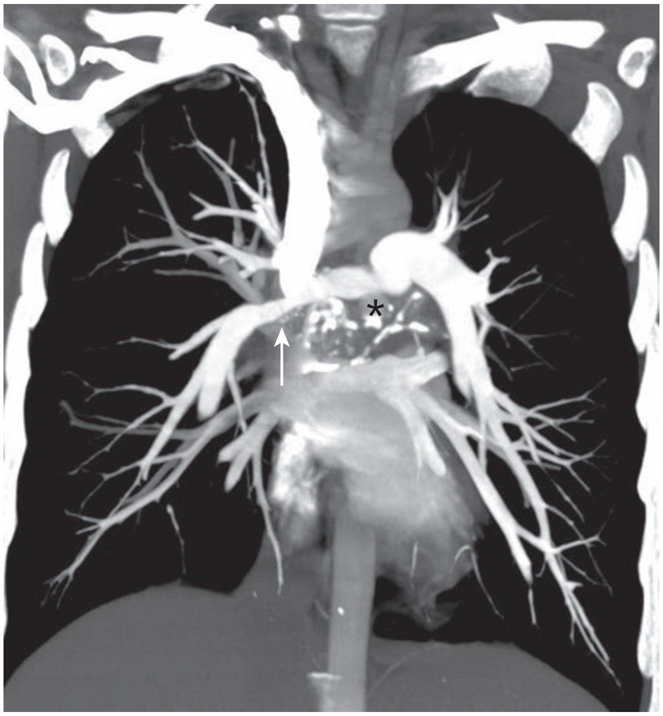

**Figure 58.6. Chronic fibrosing mediastinitis in a 17-year-old girl.** Coronal maximum intensity projection CT image of the chest shows a middle mediastinal ill-defined mass that narrows the right pulmonary artery *(arrow).* Also note the calcifications *(asterisk). (From Daltro PA, Santos EN, Gasparetto TD, et al. Pulmonary infections.* Pediatr Radiol. *2011;41(Suppl 1):S69–S82.)*

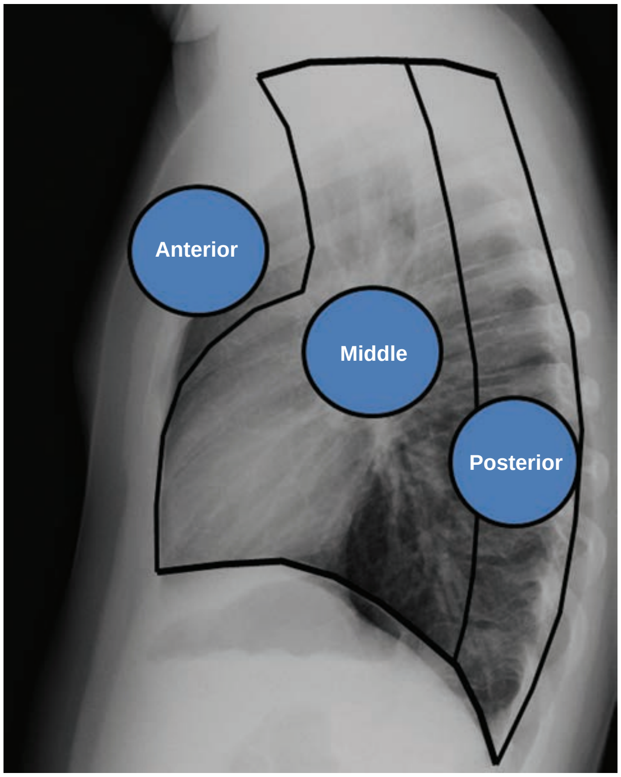

**Figure 58.7. Anatomic landmarks demarcating the anterior, middle, and posterior compartments of the mediastinum on a lateral chest radiograph.** *Anterior* indicates the anterior mediastinal compartment. *Middle* indicates the middle mediastinal compartment. *Posterior* indicates the posterior mediastinal compartment.

patients, it is useful to localize the mediastinal mass to one of three mediastinal compartments (anterior, middle, or posterior) (Fig. 58.7). However, such a system of compartmentalizing the mediastinum may have shortcomings. Specifically, the borders of the anterior, middle, and posterior mediastinum, which are defined by anatomic landmarks as assessed on a lateral radiograph of the chest, do not have true fascial planes. Recently, the International Thymic Malignancy Interest Group has published a similar three compartmental approach but is based on CT anatomy, allowing for anatomic delineation defined, in part, by pericardial and pleural reflections.[33,34] Regardless of the technique or specific classification used, the practice of assigning a mediastinal mass to a specific mediastinal compartment is useful by enabling one to formulate a manageable differential diagnosis, and effectively to direct further imaging workup.

## Anterior Mediastinal Masses

The most common anterior mediastinal masses in children are thymic lesions, lymphoma, lymphatic malformations, and germ cell tumors.

### Congenital Abnormalities of the Thymus

***Etiology.*** Arising from the third pharyngeal pouch, the thymus serves as the site of T-cell maturation. It begins a process of caudal and ventromedial elongation during the seventh and eighth week of gestation whereby the two sides fuse at about the level of the aortic arch. Absence or hypoplasia of the thymus is a component of DiGeorge syndrome,[35] with an incidence of 1 per 2,000 to 4,000.[36-38]

***Imaging.*** The appearance of the thymus on frontal chest radiographs is variable and dependent on the age of the patient (Fig. 58.8).[5,39-41] The thymus is normally prominent, with a quadrilateral shape and convex margins during infancy (e-Fig. 58.9). After approximately the fifth year of life, the thymus becomes more triangular, with straight margins (e-Fig. 58.10). By 15 years, its margins are either straight or concave (e-Fig. 58.11). After puberty, the organ undergoes involution and fatty replacement. Absent thymic tissue in pediatric patients with DiGeorge syndrome is usually evident on chest radiographs in infants and young children. However, an atrophic thymus due to stress response may appear similar.[42,43] The clinical context is often helpful in distinguishing these two conditions. After the stressor is removed, the thymus regains its size, so-called *thymic rebound.*[43,44]

***Treatment and Follow-up.*** Treatment of DiGeorge syndrome is targeted to the associated abnormalities such as hypocalcemia, frequent infections, and conotruncal cardiac defects.

### Normal Variants of the Thymus

***Etiology.*** Partial failure of thymic descent may result in ectopic thymic tissue in the neck or superior mediastinum. The two most common anatomic variants of the thymus are superior and posterior extension. The thymus may extend superiorly to the level of the lower neck[45,46] or posteriorly to the middle or posterior mediastinal compartment.[47,48] The posterior extension of the thymus typically is posterior to the superior vena cava on the right or the aortic arch on the left.

***Imaging.*** An ectopic thymus rarely presents as a mass and is most commonly discovered incidentally as thymic tissue extension on cross-sectional imaging (e-Figs. 58.12 and 58.13). Occasionally, however, ectopic thymus may be mistaken for a mediastinal or neck mass on radiographs. Normal or ectopic thymic tissue can often be identified sonographically, obviating the need for other imaging. The tissue exhibits homogenous echotexture with internal bright specular reflections, similar to the orthotopic thymus and is often in continuity with the rest of the gland.[49]

The appearance of rebound thymus on chest radiographs may be impressive in terms of degree and rapidity of development. Any displacement or compression of adjacent airway or vessels by the thymus should raise suspicion for a neoplasm.

***Treatment.*** Treatment for ectopic thymic tissue or rebound thymus is not necessary. However, its diagnosis is important to avoid unnecessary procedures.

### Thymic Cyst

***Etiology.*** A thymic cyst is a rare, fluid-filled lesion typically representing a remnant of the thymopharyngeal duct.[43,50] Although a thymic cyst can occur anywhere from the pyriform sinus to the anterior mediastinum, it is most commonly found in the lateral infrahyoid neck.[51] When large, affected pediatric patients present with a slowly enlarging neck mass that may be associated with respiratory compromise, dysphagia, or vocal cord paralysis. Although most unilocular thymic cysts are derived from a remnant of the thymopharyngeal duct, multilocular thymic cysts occasionally occur in patients with the human immunodeficiency virus, in various rheumatologic conditions,[52] and in pediatric patients with Langerhans cell histiocytosis.[53,54] Cysts in the latter group may feature small calcifications.[55]

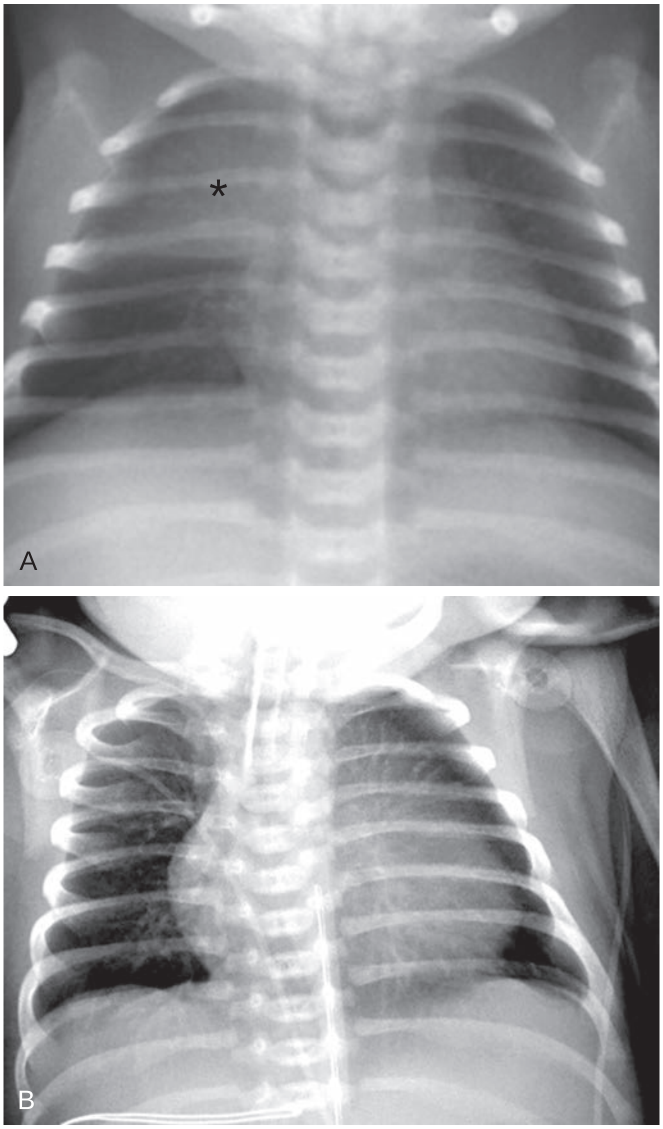

**Figure 58.8. Normal thymus in a female neonate.** (A) Frontal chest radiograph shows a thymic sail sign, which is created by the right lobe of the thymus *(asterisk)* abutting the minor fissure. (B) Frontal chest radiograph in a different neonate depicts a prominent superior mediastinum consistent with a normal thymus. A subtle but sharp contour demarcation—the "thymic notch" is often seen.

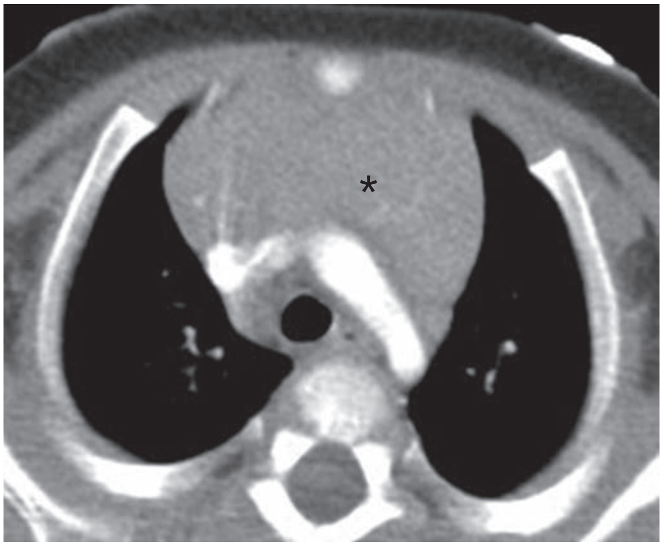
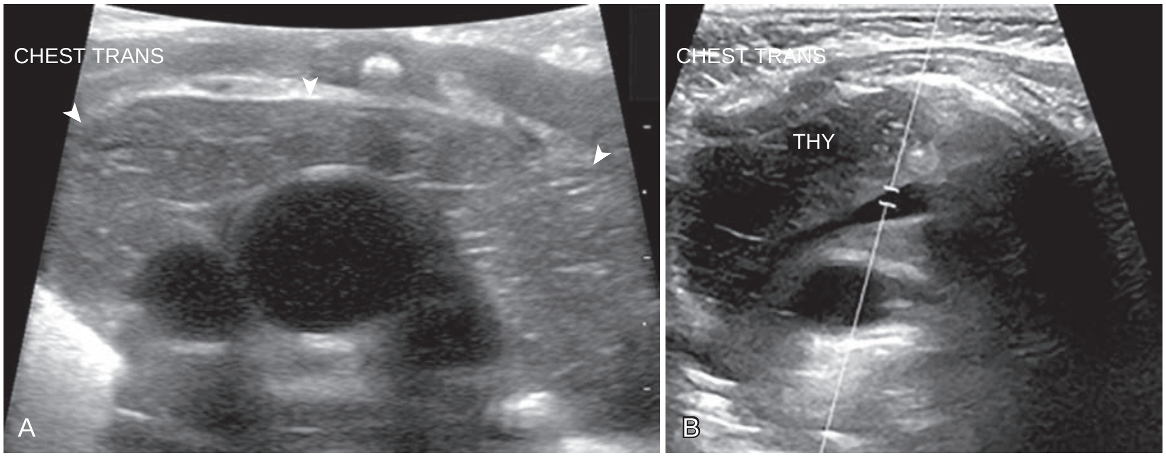
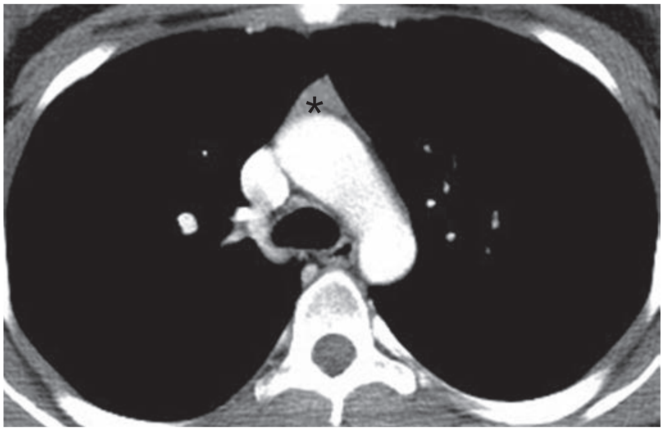
***Imaging.*** Thymic cysts appear as a spherical, fluid-filled lesion or as multilocular cystic spaces with a thin wall. They are usually occult on chest radiographs. In infants and young children, ultrasound may confirm the fluid-filled nature of the mass. On CT and magnetic resonance imaging (MRI), thymic cysts typically present as a nonenhancing cystic mass (e-Fig. 58.14). The MRI signal of a thymic cyst is variable depending on whether the contents are proteinaceous and/or hemorrhagic. The differential diagnosis



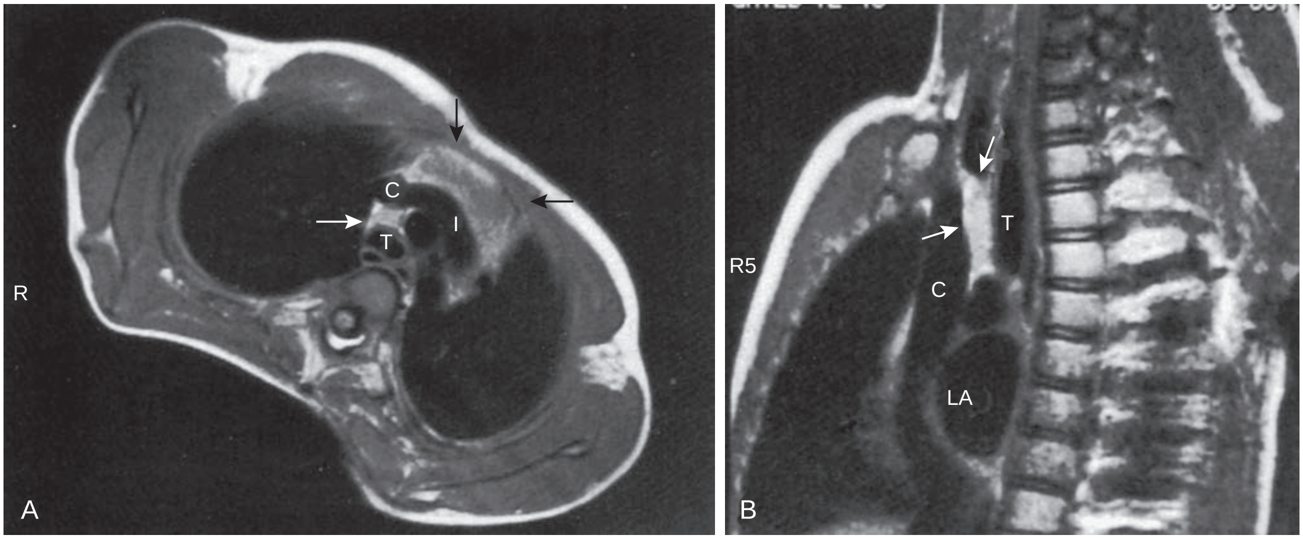
**e-Figure 58.9. Normal thymus in a 5-month-old girl.** Axial contrast-enhanced CT image at the level of the aortic arch shows the expected appearance of the thymus *(asterisk)* in the anterior mediastinal compartment at this age. The thymus has a quadrilateral shape and a convex margin. It is homogeneous in attenuation without any associated cystic, calcific, or fat component.



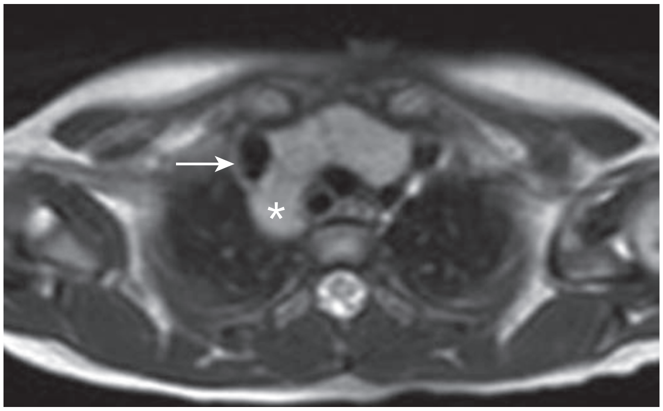
**e-Figure 58.10. Normal thymus in a female neonate.** (A) Ultrasound depicts the superficial structure in the anterior mediastinum with a dot-dash appearance—consistent with normal thymic tissue. (B) The brachiocephalic vein runs deep to the thymus (depicted by the Doppler interrogation gate) and should not be compressed or displaced.



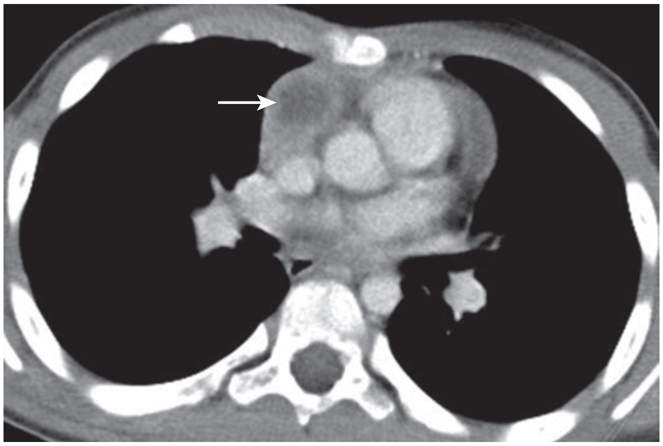
**e-Figure 58.11. Normal thymus in an adolescent boy.** Axial contrast-enhanced CT image at the level of the aortic arch shows the expected appearance of the thymus *(asterisk)* in the anterior mediastinal compartment at this age. The thymus is much smaller with a triangular shape with a straight margin.



**e-Figure 58.12. Normal superior extension of thymic tissue into the neck.** On this gated axial (A), oblique (B), mildly T1-weighted MRI sequence, the thymus is clearly distinguished from vessels. It is of intermediate signal intensity—less than fat but greater than muscle. Note how far cephalad to the innominate vein *(I)* the thymic tissue extends *(arrows). C,* Superior vena cava; *LA,* left atriu; *T,* trachea;.



**e-Figure 58.13. Posterior thymic extension as a normal variant in a 1-year-old boy.** Axial T2-weighted MRI at the level of the brachiocephalic vein shows posterior extension *(asterisk)* of the thymus behind the superior vena cava *(arrow).*



**e-Figure 58.14. Thymic cyst in a 2-year-old girl.** Axial contrast-enhanced CT image at the level of the main pulmonary artery shows a round hypoattenuating lesion *(arrow)* consistent with a cyst in the thymus. Surgical pathology confirmed the diagnosis of a thymic cyst.

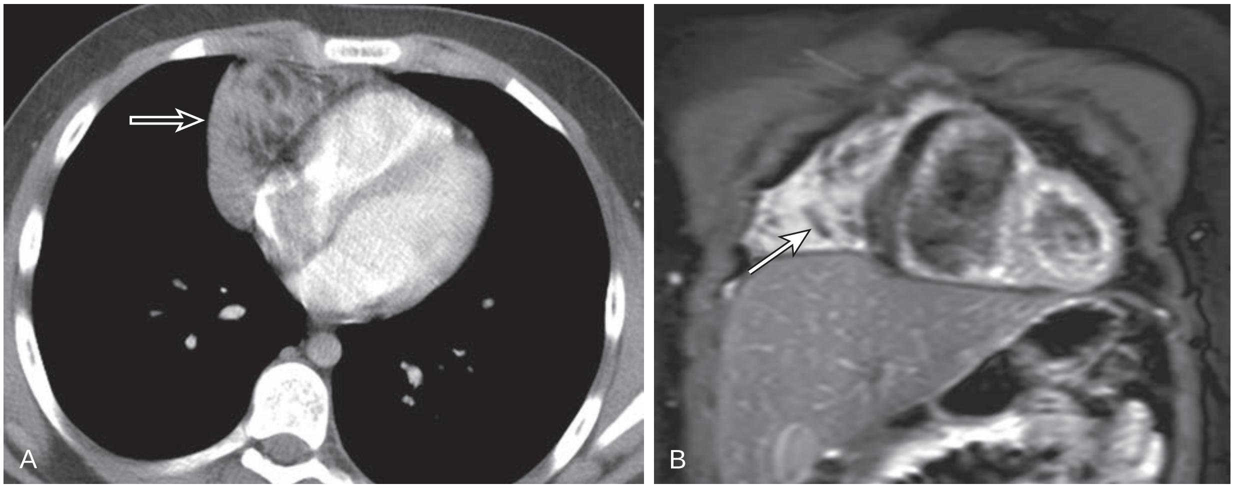


**Figure 58.15. Thymolipoma in an 8-year-old girl.** (A) Axial contrast-enhanced CT image at the level of the mid heart shows an anterior mediastinal mass *(arrow)* with whorls of low attenuating regions consistent with fat. (B) Coronal fluid-sensitive fat-saturated MRI shows the linear low signal fatty striations *(arrow)* through the mass.

includes a branchial cleft cyst, lymphatic malformation, thyroglossal duct cyst, dermoid cyst, bronchogenic cyst, and teratoma.

***Treatment.*** The current choice for managing a thymic cyst, particularly in symptomatic pediatric patients, is surgical resection, which is associated with an excellent prognosis.

### Thymolipoma

***Etiology.*** Thymolipoma is an uncommon benign thymic mass composed of both thymic and adipose tissue. Thymolipomas account for approximately 2% to 9% of all thymic neoplasms.[43,56] The presumed underlying etiologies include a variant of a thymoma, hyperplasia of mediastinal fat, and a neoplasm of mediastinal fat that encases thymic tissue.[56,57] Affected patients typically are asymptomatic.

***Imaging.*** On chest radiographs, a thymolipoma may present as a low-density lesion because of its underlying fatty component. On cross-sectional imaging studies, thymolipomas are characterized by an enlarged thymus with areas of low attenuation on CT, and high signal intensity on T2-weighted MRI, in a whorled pattern representing the underlying fatty component (Fig. 58.15).

***Treatment and Follow-up.*** Although thymolipoma is not malignant, surgical resection often is undertaken because the diagnosis may be uncertain solely on the basis of imaging. Interestingly, there is evidence of association with autoimmune etiologies and paraneoplastic phenomena in adults.[58]

### Thymoma

***Etiology.*** Thymomas arise from the thymic epithelial cells and account for approximately 1% to 2% of anterior mediastinal masses in the pediatric population.[51,59] Thymomas traditionally are classified into two types: noninvasive and invasive, depending on the presence of well-defined margins without extension through its fibrous capsule. Because thymomas may be locally invasive but typically do not metastasize, many authorities prefer the term *invasive thymoma* rather than *malignant thymoma*. From 15% to 30% of affected pediatric patients present with myasthenia gravis.[54,60,61] Other associated autoimmune conditions include pure red cell aplasia and hypogammaglobulinemia.[60,61]

***Imaging.*** On chest radiographs, a thymoma appears as an ovoid anterior mass that occasionally is associated with thin peripheral capsular calcification. Pleural lesions may be seen in patients with invasive thymoma. Cross-sectional imaging studies show an enlarged and homogeneous anterior mediastinal soft tissue mass, sometimes associated with an area of low attenuation representing underlying cystic necrosis (Fig. 58.16).[51] Findings suggestive of invasive-type thymoma include irregular margins, obliterated adjacent mediastinal fat planes, or extension to the pleura or chest wall. A search for these imaging features is particularly important, because the histology between invasive and noninvasive type thymoma overlaps, apart from surgical evidence of capsular extension.

Larger, more coarse-appearing, intralesional calcifications have been rarely encountered in both adults and children with thymomas and have been shown to represent osseous metaplasia. To date, this very rare entity has been exclusively reported in females.[62]

***Treatment and Follow-up.*** All thymomas that are deemed surgically resectable are removed. In addition, most thymomas require radiation therapy and/or chemotherapy.

### Thymic Carcinoma

***Etiology.*** A thymic carcinoma is an aggressive epithelial neoplasm of the thymus, characterized by cellular atypia and are extremely rare in children. Affected pediatric patients most often present with chest pain and constitutional symptoms.[51] Paraneoplastic phenomena such as myasthenia gravis are uncommon with a thymic carcinoma, in contradistinction to a thymoma.[63,64] Metastatic disease or invasion is detected in most new diagnoses.[64,65] Prognosis is poor.

***Imaging.*** Thymic carcinoma typically presents as a large anterior mediastinal mass with irregular margins, heterogeneous contrast enhancement, and local invasion of adjacent mediastinal structures (Fig. 58.17). Calcification and areas of necrosis are common,[66] but their presence has been shown to have limited diagnostic and prognostic value.[67] Although differentiation from a thymoma is difficult, features such as local invasion of adjacent structures, lymphadenopathy, and metastasis favor the diagnosis of a thymic carcinoma.

***Treatment.*** Because of the rarity of such tumors, proposed treatment guidelines are just beginning to emerge.[68] These have included various combinations of neoadjuvant chemotherapy, surgery, and postoperative radiation therapy.[69]

### Lymphoma

***Etiology.*** Lymphoma results from an abnormal proliferation of lymphocytes and is the most common cause of a mediastinal mass in children. It is the third most common group of malignancies after leukemia and central nervous system tumors in the pediatric population[5] and accounts for approximately 46% to 56% of all mediastinal masses.[5] Lymphoma is traditionally classified into non-Hodgkin lymphoma and Hodgkin lymphoma. These two

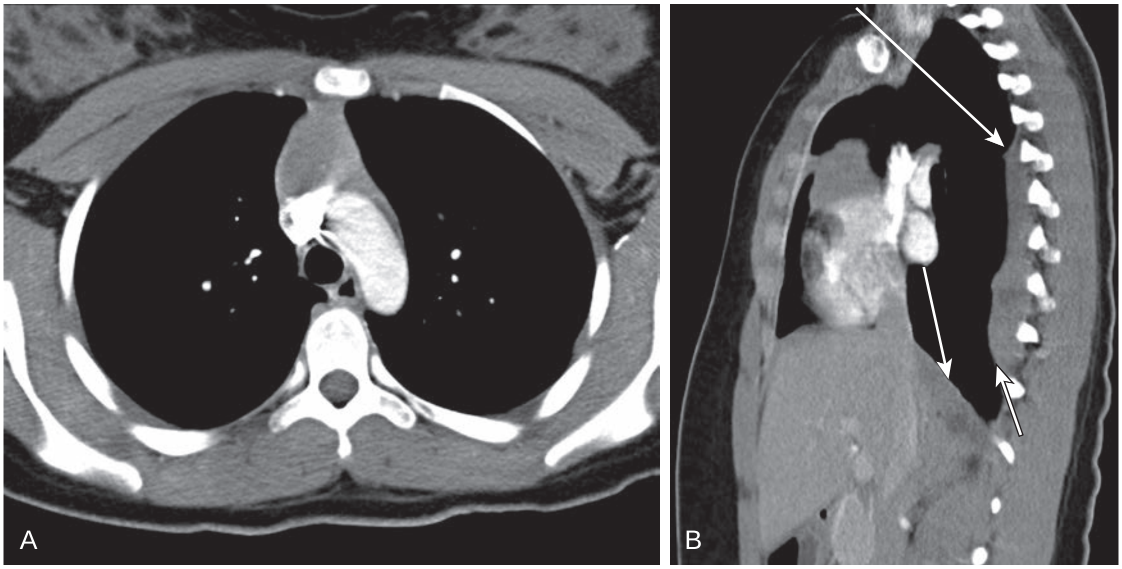

**Figure 58.16. Invasive thymoma in a 15-year-old girl.** Axial (A) and sagittal (B) reformation contrast-enhanced CT images demonstrate an anterior mediastinal mass (in A). It is heterogeneous with lobulated borders unlike normal thymus. There is prominent pleural extension of tumor (*arrows* in B).

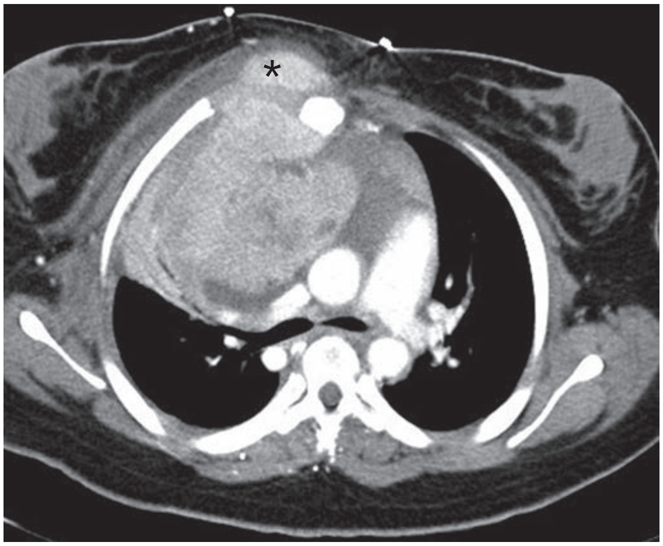

**Figure 58.17. Thymic carcinoma in a 14-year-old girl.** Axial contrast-enhanced CT image at the level of the carina shows an anterior mediastinal mass with poorly defined areas of low attenuation. Note the anterior chest wall invasion by the mass *(asterisk).*

subtypes have many similarities, including their appearance on imaging, but because of their many important differences, especially in clinical behavior, they are discussed separately in the following sections. Pulmonary involvement by lymphoma is discussed in Chapter 55.

Non-Hodgkin lymphoma typically occurs in boys who are younger than 5 years. The four main types of non-Hodgkin lymphoma are (1) lymphoblastic or T cell (the most common); (2) Burkitt; (3) non-Burkitt; and (4) large cell or histiocytic. Pediatric patients with lymphoblastic lymphoma commonly present with a mediastinal mass at initial diagnosis. Large cell or histiocytic types may involve either the thorax or the abdomen, and Burkitt and non-Burkitt types nearly always present in the abdomen. Pediatric patients often present with clinical symptoms related to obstruction or compression of adjacent mediastinal airways and vascular structures.

Hodgkin lymphoma is rare in younger children and occurs with increasing frequency in children older than 5 years.[5] It more frequently affects boys than girls by a ratio of 2 : 1.[5] Hodgkin lymphoma is divided into four main types based on the relative amounts of lymphocytes and Reed-Sternberg cells and the type of connective tissue proliferation: (1) nodular sclerosing; (2) mixed cellularity; (3) lymphocyte depletion; and (4) lymphocyte predominant. Among these four, the nodular sclerosing type (the most common subtype) accounts for approximately 75% of all mediastinal masses in children.[5,70] The majority of affected patients present with chest pain and discomfort. Shortness of breath or wheezing should suggest underlying airway compression. More specific clinical symptoms of Hodgkin lymphoma include weight loss, night sweats, and unexplained fevers.

***Imaging.*** Both Hodgkin and non-Hodgkin lymphoma can arise from or infiltrate the thymus, which may be potentially confused with thymic rebound in young children. Differentiating imaging features include unusually lobular bulky borders, heterogeneity, and displacement of adjacent structures such as airway or vessels—features that are not present with normal thymic tissue.

Hodgkin lymphoma presents as bulky hilar nodes or an anterior mediastinal mass on chest radiographs (Fig. 58.18A and B) in over two-thirds of patients.[71] Contrast-enhanced CT of the chest should be performed to confirm the presence of a mass or enlarged nodes and to characterize its extent for disease staging (Fig. 58.18C).[72,73] Sedation/anesthesia should be avoided and flat supine positioning should be approached with caution because of concern for airway compression. Common nodes involved include the superior prevascular and pretracheal nodes and range from small nodes to large, conglomerate nodal masses. The presence of calcifications before treatment is rare.[51]

On MRI, the signal characteristics of Hodgkin lymphoma are variable but usually are intermediate on T1-weighted images and have increased signal on T2-weighted images. MRI has, to date, added little additional value in the diagnosis or workup of Hodgkin lymphoma, although recent work suggests added benefit in select clinical circumstances. These include follow-up of nodes, assessment of posttreatment fibrosis versus tumor, and the differentiation of thymic rebound from disease recurrence.[74,75] Positron emission

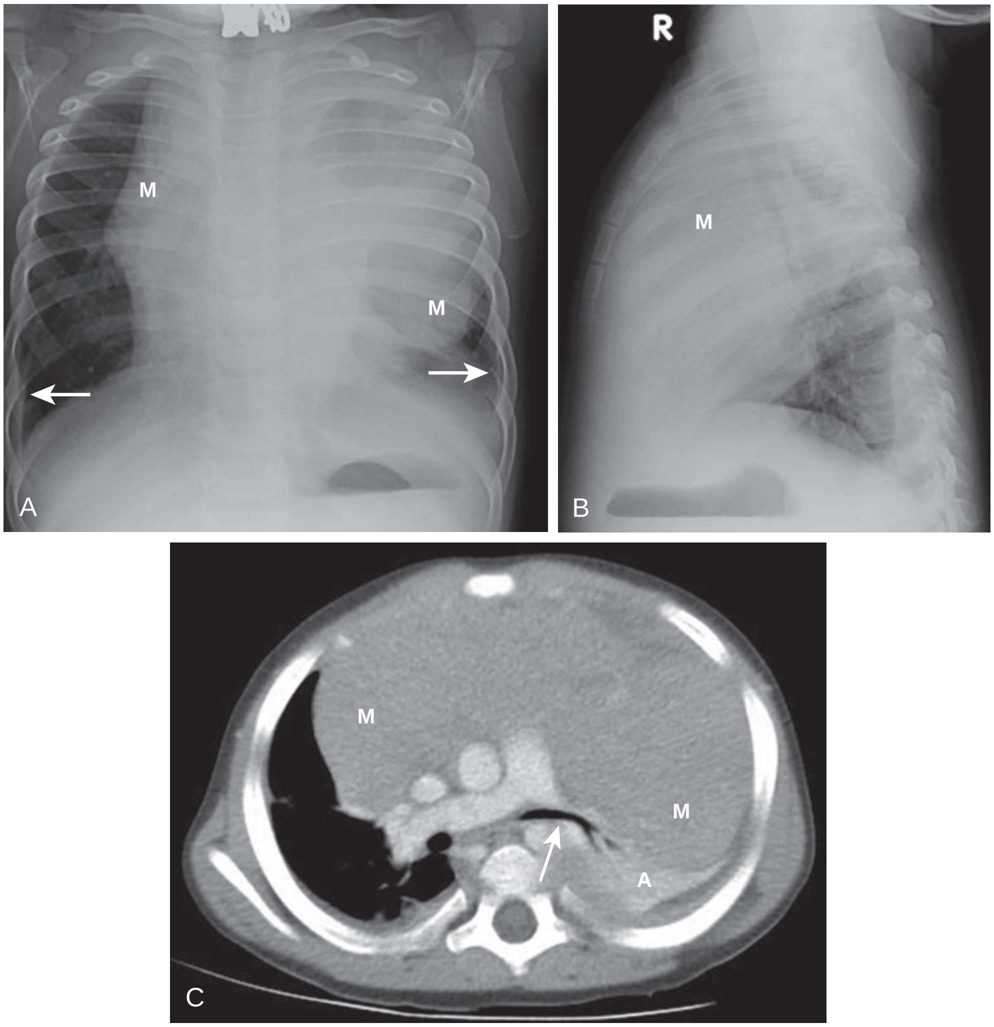

**Figure 58.18. Hodgkin lymphoma in a 2-year-old girl.** (A) Frontal chest radiograph shows a large mediastinal mass *(M)* with lobulated and bulky margins. Small pleural effusions *(arrows)* also are present. (B) Lateral chest radiograph confirms that the location of this mass *(M)* is within the anterior mediastinal compartment. (C) Axial contrast-enhanced CT image at the level of the right pulmonary artery shows a large anterior mediastinal mass *(M)* with compression of the left main-stem bronchus *(arrow)*. Left-sided atelectasis *(A)* is present.

tomography (PET) and/or PET/CT scans have been well validated in the literature in adult patients[76-78] and are now considered to be standard of care in the workup of children with Hodgkin disease.[79,80]

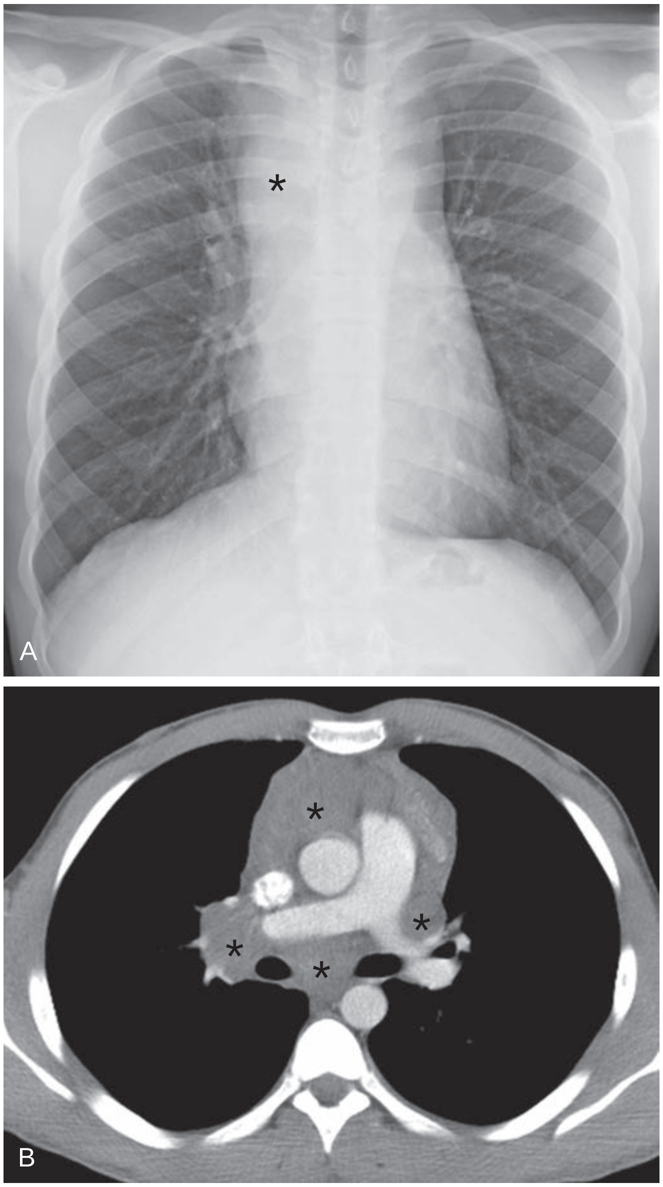
In contradistinction, non-Hodgkin lymphoma may arise in the abdomen, thorax, or head/neck regions. When non-Hodgkin lymphoma occurs in the thorax (in about 50% of cases[51]), its most common appearance is that of a large anterior mediastinal mass (e-Fig. 58.19A). As with any anterior mediastinal mass, such imaging findings should prompt a CT scan, which typically shows discrete or conglomerate mediastinal lymph nodes (e-Fig. 58.19B). After the administration of contrast, areas of heterogeneity and low-density necrosis are a frequent finding. Hilar, subcarinal, and posterior nodal chain involvement is frequent. In contradistinction to Hodgkin lymphoma, pleural disease may be present.[51]

MRI may be useful in the evaluation of sites beyond the anterior mediastinum, including the chest wall.[74] PET/CT can assist in staging; however, its role in children with non-Hodgkin disease has still not been firmly clarified.[81] PET is particularly helpful in discriminating viable tumor from scar, detecting active disease in normal-sized nodes on CT, and searching for extranodal disease. Interpretive pitfalls include increased physiologic metabolic activity in the normal thymus and brown fat.[82,83]

***Treatment and Follow-up.*** The prognosis of lymphoma in pediatric patients depends on two main factors: the type and stage. The prognosis of Hodgkin lymphoma, which has a cure rate of approximately 90%,[51,80,84] is better than that of non-Hodgkin lymphoma, for which the cure rate among pediatric patients is 80%.[85] Currently, multiple chemotherapeutic treatment regimens are used in combination with radiation therapy to treat pediatric patients with lymphoma. In pediatric patients with non-Hodgkin lymphoma, stem cell transplant is an option.

### Lymphatic Malformation

***Etiology.*** Lymphatic malformation represents a nonneoplastic congenital malformation of lymphatic channels, lined by single layer of endothelium.[86] It typically occurs in the cervical region (often posterior to the sternocleidomastoid muscle) but may extend caudally into the superior and/or anterior mediastinum. They can also occur in the middle and posterior mediastinal compartments, as well as the lung. Lymphatic malformations currently are classified into macrocystic and microcystic, although mixed lesions are



**e-Figure 58.19. Non-Hodgkin lymphoma in an 8-year-old girl.** (A) Frontal chest radiograph shows a mediastinal mass *(asterisk).* (B) Axial contrast-enhanced CT image at the level of the pulmonary artery shows a mediastinal mass *(asterisks)* located within the mediastinum. Note the anterior, subcarinal, and hilar components.

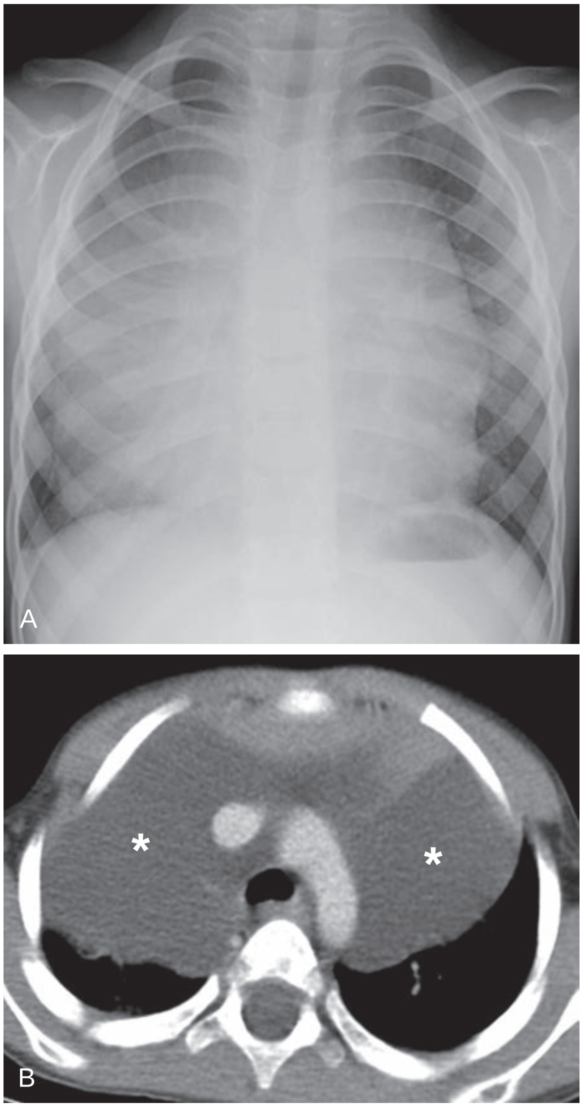


**Figure 58.20. Mediastinal lymphatic malformation in a 1-year-old boy.** (A) Frontal chest radiograph shows a large mediastinal mass. (B) Axial contrast-enhanced CT image at the level of the aortic arch shows a large, predominantly anterior mediastinal mass *(asterisks)* of fluid attenuation that crosses midline and extends laterally, consistent with a macrocystic lymphatic malformation.

common. Outdated terms include *cystic hygroma* and *lymphangioma* that should be avoided.[87] The term *lymphatic malformation* adheres to the nomenclature of the International Society for the Study of Vascular Anomalies (ISSVA).[88] Lymphatic malformations may enlarge as more lymph fills the sacs. They typically present early in life as a palpable, pliable soft tissue mass and grow commensurate with the patient's growth. Sudden enlargement also may occur if they undergo hemorrhage or become infected.

***Imaging.*** Plain radiographs have little role in the evaluation of lymphatic malformations. However, a lymphatic malformation may first be noted as a mediastinal opacity (Fig. 58.20A). CT can suggest the diagnosis but the density may be higher than expected for simple fluid due to internal complexity (Fig. 58.20B). MRI is the best imaging modality for the evaluation of lymphatic malformations because of its excellent capability for soft tissue characterization. The septa are particularly well visualized on MRI and may enhance after the administration of gadolinium. Because of proteinaceous debris and/or blood products, the magnetic resonance signal may be varied on both T1- and T2-weighted sequences. Fluid/fluid levels are common and strongly support the diagnosis of lymphatic malformation, but there should be no solid enhancing components. Calcification in lymphatic malformations is rare.

***Treatment and Follow-up.*** Because there is no known risk of malignant transformation of lymphatic malformation, some controversy exists with regard to treating smaller asymptomatic lesions. If treatment is elected, both percutaneous sclerotherapy and/or surgery currently are used in management.

### Germ Cell Tumor

***Etiology.*** Primitive germ cell rests may reside in the mediastinum and give rise to neoplasms.[89,90] Primary mediastinal germ cell tumors account for 6% to 18% of anterior mediastinal tumors in children,[73,91] and 60% of these tumors are teratomas.[51] Teratomas are divided into mature and immature types (the latter being malignant). Of all mediastinal germ cell tumors, 14% are malignant.[92] Infants with teratomas tend to present with airway compression, whereas older children often are asymptomatic[5] but may experience pain, dyspnea, or cough. The tumor can rupture into the tracheobronchial tree or pleural space with expectoration or deposition of its contents.[5,93]

***Imaging.*** On chest radiographs, germ cell tumors typically appear as round, sharply demarcated anterior mediastinal masses. Calcifications occur in approximately 25% to 53% of teratomas[5,50,51,94] and may be seen on radiographs. As for most anterior mediastinal masses, CT can better characterize their extent and may allow definitive diagnosis. Typically, teratomas (both mature and immature) demonstrate fat, fluid, and calcifications, which, when present, allow a confident diagnosis (Fig. 58.21). However, approximately 15% of mature teratomas display no fat or calcium on imaging.[5] Although calcifications may be difficult to detect on MRI, the intralesional fat and fluid are readily apparent. Invasion of adjacent structures suggests the immature type.

***Treatment and Follow-up.*** Surgical resection is the current management of choice for the benign teratomas with excellent prognosis if complete surgical excision can be achieved. However, immature teratomas generally require chemotherapy and radiation in addition to surgical excision.[95]

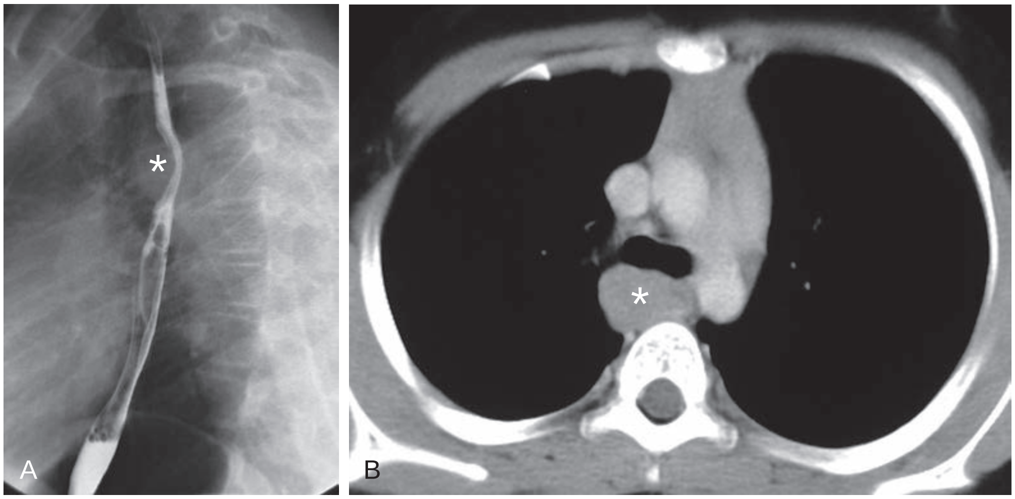
## Middle Mediastinal Masses

Masses arising from the middle mediastinum may be mainly categorized into vascular and nonvascular lesions. Most nonvascular middle mediastinal masses in the pediatric population are developmental malformations of the embryonic foregut or adenopathy resulting from underlying infection, primary neoplasm, or metastatic disease.

### Foregut Duplication Cysts

***Etiology.*** Foregut duplication cysts arise from developmental malformations of the embryonic foregut and include bronchogenic, esophageal, and neurenteric cysts. Bronchogenic cysts develop from errors in lung budding during development of the ventral foregut. Errors in development of the posterior division of the embryonic foregut may result in an esophageal duplication cyst. Neurenteric cysts arise from embryologic failure of separation of ectoderm from endoderm. The persistent communication is known as the canal of Kovalevsky and results in a form of spinal dysraphism. The extent of the persistent canal results in a range of abnormalities that includes the neurenteric cyst.[96] The distinction among these three types of foregut duplication cysts can be made histologically. Together, these three account for 11% of all mediastinal masses in children.[73]

***Imaging.*** Chest radiographs often reveal a rounded middle mediastinal mass (e-Fig. 58.22A). In cases of a neurenteric cyst, an accompanying vertebral anomaly also may be present (see also e-Figs. 96.16 and 96.17). The position of the cyst in the



**e-Figure 58.22. Esophageal duplication cyst in a 4-year-old boy.** (A) Lateral view of the esophagus obtained during a barium esophagram study shows a smooth-bordered focal anterior indentation consistent with an extraluminal mass *(asterisk)* centered between the trachea and esophagus. (B) Axial contrast-enhanced CT image at the level of the carina shows a fluid density middle mediastinal mass *(asterisk)*.

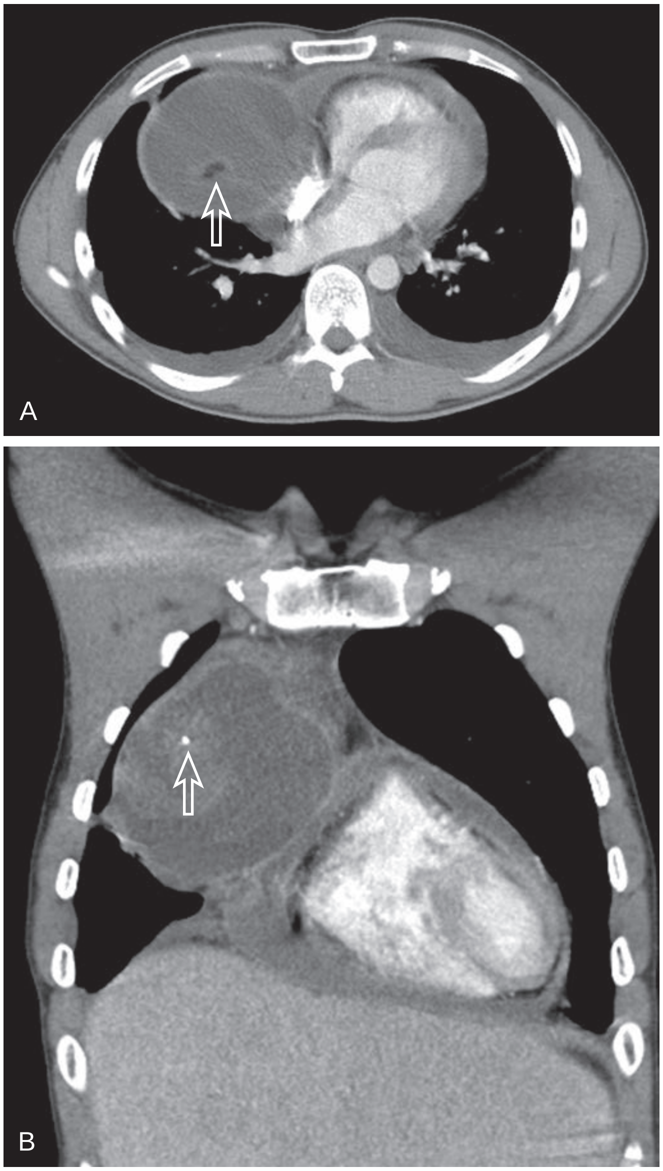


**Figure 58.21. Mediastinal teratoma in a 24-year-old man.** Axial (A) and coronal (B) reformation contrast-enhanced CT images reveal a large low-density mass in the anterior mediastinum. There is a small plug of fat attenuation (*arrow* in A) and punctate calcification (*arrow* in B), findings that are consistent with a teratoma.

mediastinum suggests its type. Bronchial duplication cysts typically are located within the middle mediastinum in close proximity to the airway. Esophageal duplication cysts are in the middle or posterior mediastinum. Neurenteric cysts most often are in the posterior mediastinum but are discussed here because they fall into the same differential. Cross-sectional imaging studies demonstrate a nonenhancing, fluid-filled cystic mass with well-marginated borders (e-Fig. 58.22B). Internal proteinaceous material can increase the Hounsfield units on CT and signal intensity on T1-weighted MRI. The high water content usually results in adequate T2 prolongation to reveal its cystic nature on T2-weighted MRI when CT density is equivocal. On both CT and MRI, foregut duplication cysts lack internal enhancement and appear homogeneous unless superimposed infection is present. Neurenteric cysts are typically associated with a regional vertebral anomaly, allowing differentiation.

***Treatment and Follow-up.*** The current management for a foregut duplication cyst is complete surgical resection, particularly in symptomatic pediatric patients. In some institutions, endoscopic ultrasound-guided fine-needle aspiration is used to preoperatively confirm the diagnosis.[97,98]

### Lymphadenopathy

***Etiology.*** Lymphadenopathy may occur in any mediastinal compartment but is most prevalent in the middle mediastinum. Most enlarged mediastinal lymph nodes in children are reactive and are often seen in children with cystic fibrosis. Particularly prominent hilar lymph nodes may be seen in the setting of granulomatous diseases.

As discussed elsewhere in this chapter, lymphoma is the most common cause of a primary mediastinal neoplastic mass that presents as a conglomeration of lymph nodes. Although nodes commonly are found in the anterior mediastinum, they may extend or arise in the middle mediastinum, particularly in non-Hodgkin lymphoma. Although less common, mediastinal lymphadenopathy also may be seen as a result of metastatic disease from tumors such as Wilms tumor, Ewing tumor, and osteosarcoma.

***Imaging.*** Lymphadenopathy often is first detected on chest radiographs. The presence of hilar involvement, bilaterality, and calcification should be investigated carefully. Unless acute infection is the suspected cause, a CT scan with intravenous contrast material should be obtained for further evaluation after chest radiographs. MRI may be helpful in selected cases but is seldom required. On T1-weighted MRI sequences, nodes are isointense to muscle and are hyperintense on T2-weighted sequences and are easily distinguished from adjacent vessels.

Calcified lymph nodes suggest a history of treated lymphoma or the presence of granulomatous disease. Low-density or centrally necrotic nodes should suggest *Mycobacterium tuberculosis* (Fig. 58.23)[99] or *Mycobacterium avium-intracellulare*.[100,101] Sarcoidosis is rare in children. Large hilar lymphadenopathy also has been described in persons with lymphoma, infectious mononucleosis, and Castleman disease (angiofollicular lymphoid hyperplasia) (e-Fig. 58.24).

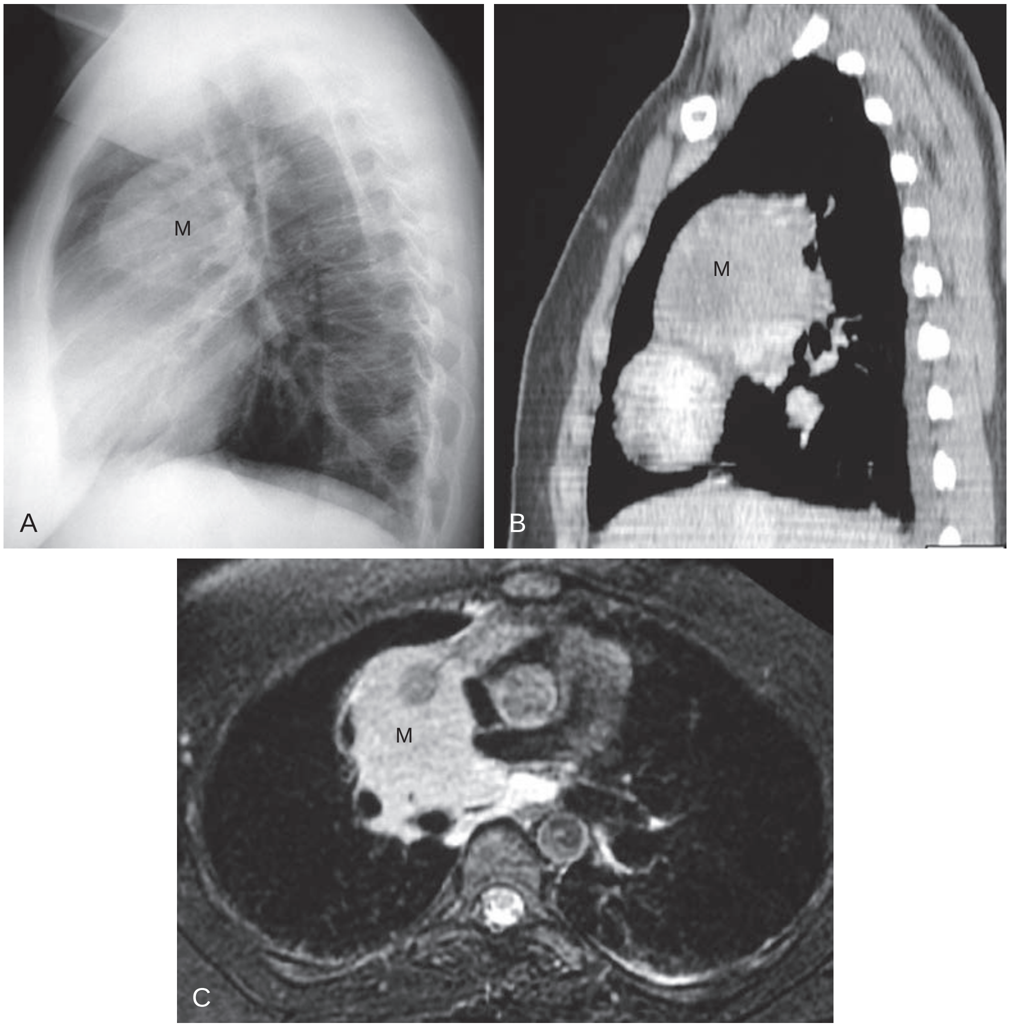
## Posterior Mediastinal Masses

### Neurogenic Tumors

***Etiology.*** The vast majority (88%) of masses arising in the posterior mediastinum are of neurogenic origin and together account for about 34% of all mediastinal masses in children.[73] Ganglion cells in the paravertebral sympathetic chain and peripheral nerve sheaths are responsible for most posterior mediastinal neurogenic masses. Sympathetic chain tumors are more common than nerve sheath tumors in the pediatric mediastinum.

Tumors arising from the sympathetic chain include neuroblastoma, ganglioneuroblastoma, and ganglioneuroma, in order of increasing cellular differentiation and increasing age of presentation. These tumors are related by their structure of origin but are distinguished by their underlying histologic cellular differentiation. The least differentiated (and most malignant) and most common of these tumors is neuroblastoma, which usually arises in children younger than 5 years. About 10% to 16% of all neuroblastomas arise in the mediastinum. Clinical manifestations include constitutional symptoms and several paraneoplastic syndromes. Presentations that are unique to the mediastinal location of neuroblastoma include Horner syndrome if the mass involves the superior mediastinum. Still, many children with thoracic neuroblastoma present with incidentally discovered masses on chest or abdominal radiographs. Seventy-six percent of thoracic neuroblastomas are positive for urinary catecholamines.

The two most common nerve sheath masses are neurofibromas and schwannomas, both of which are benign tumors composed of spindle cells and myxoid stroma. Plexiform neurofibromas



**e-Figure 58.24. Castleman disease in a 17-year-old girl.** (A) Lateral chest radiograph shows a large middle mediastinal mass *(M).* (B) Sagittal contrast-enhanced CT image demonstrates a homogeneously enhancing middle mediastinal mass *(M).* (C) Axial T2-weighted MRI shows a middle mediastinal mass *(M)* with homogeneously high signal intensity.

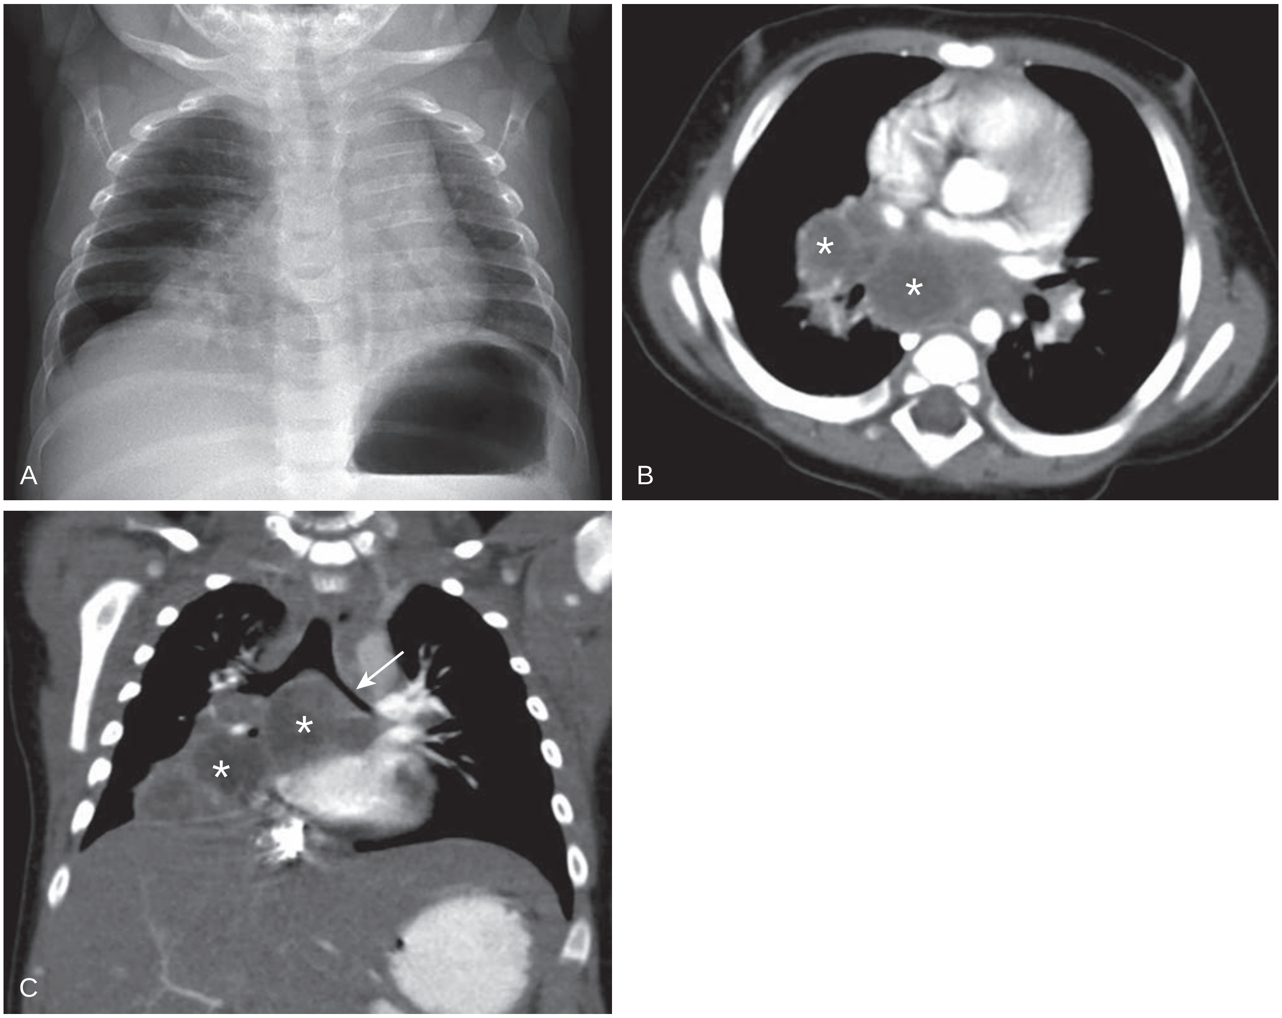


**Figure 58.23. Primary *Mycobacterium tuberculosis* in a 2-year-old boy.** (A) Frontal chest radiograph shows right hilar and infrahilar opacity. In addition, the distal trachea has a slight leftward deviation, suggesting displacement by the mass. (B) Axial contrast-enhanced CT image demonstrates low attenuation hilar, infrahilar, and subcarinal lymphadenopathy *(asterisks).* (C) Coronal contrast-enhanced CT image shows a narrowing of the left main-stem bronchus *(arrow)* as a result of a large mediastinal lymphadenopathy *(asterisks).* The sputum culture confirmed the diagnosis of *Mycobacterium tuberculosis* infection.

commonly are seen in children with neurofibromatosis type 1. These tumors tend to arise in the superior/posterior mediastinum and are usually bilateral. Posterior mediastinal schwannomas are more often seen in adults.

***Imaging.*** Most posterior mediastinal neurogenic tumors are first detected on chest radiographs as a soft tissue opacity (Figs. 58.25 and 58.26). Associated adjacent bone destruction or scalloping and silhouetting of posterior mediastinal structures such as the descending aorta are additional findings. Detection of calcification suggests a sympathetic chain tumor such as a neuroblastoma as opposed to a nerve sheath tumor. Approximately 40% of neuroblastomas in the posterior mediastinum show speckled or curvilinear calcification.[5]

On CT, posterior mediastinal neurogenic tumors typically present as soft tissue masses with a varying degree of contrast enhancement (see Figs. 58.25 and 58.26). Further characterization and differentiation among different types of posterior mediastinal neurogenic tumors with CT is limited.

MRI is currently the best imaging modality for evaluating posterior mediastinal tumors in pediatric patients because of its high sensitivity for detecting the intraspinal (extradural) extension and its lack of ionizing radiation.[73] Moreover, MRI offers exquisite soft tissue contrast resolution, which is an advantage when assessing a region such as the posterior mediastinum with similar soft tissue densities and minimal fat. Finally, MRI is sensitive for assessing bone marrow involvement.

The sympathetic chain tumors have a similar appearance on all imaging studies. These masses appear as T2-hyperintense, well-circumscribed, sausage-shaped structures in a paraspinal distribution along the expected region of the sympathetic chain. Intraspinal extension is common with widening of the neural foramina. After intravenous administration of contrast material, variable, heterogeneous enhancement occurs. A metaiodobenzylguanidine scan can confirm the diagnosis of neuroblastoma and assess for distant sites of disease with a reported sensitivity between 90% and 95%.[102]

Nerve sheath tumors appear as sharply demarcated, rounded, paravertebral masses. Nerve sheath tumors are localized to one or two levels, as opposed to the typically more extensive neuroblastomas. However, plexiform neurofibromas can involve multiple

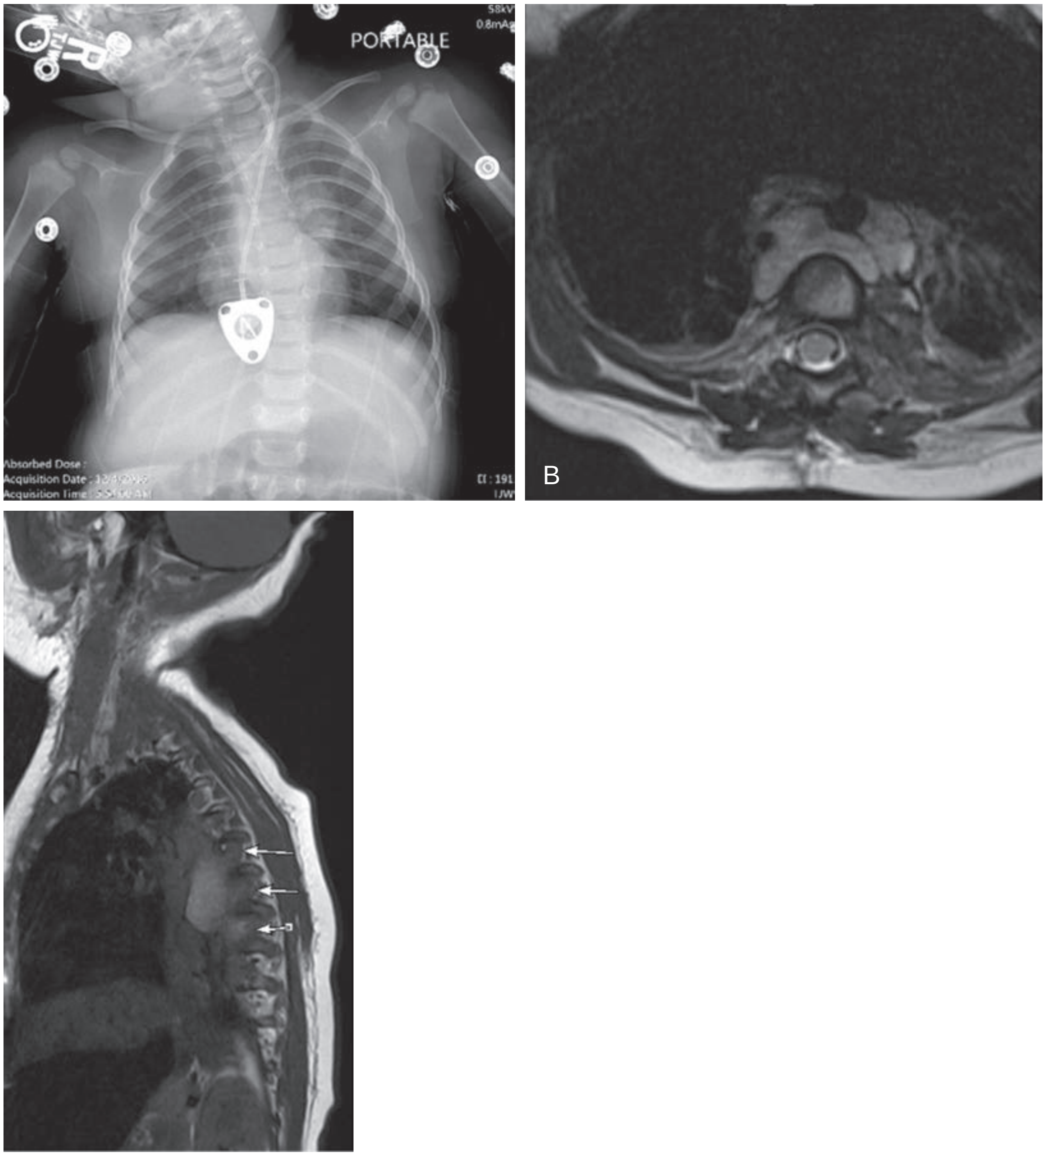

**Figure 58.25. Neuroblastoma in a 10 month old girl.** (A) AP chest radiograph shows a right paraspinal soft tissue convexity *(arrow)*. (B) axial T2 weighted MRI through the thorax shows a posterior mediastinal mass encasing the descending aorta and azygous vein. (C) T1 weighted sagital MRI demonstrates a posterior mediastinal, paraspinal mass with neural foraminal involvement *(arrows)*.

levels and extend into the middle mediastinum. On T2-weighted MRI, plexiform neurofibromas have a distinct high signal periphery with an intermediate signal centrally—the so-called target appearance (Fig. 58.27). Associated findings include thoracic dural ectasia and scalloping of the posterior vertebral bodies.

***Treatment and Follow-up.*** Sympathetic chain neurogenic tumors are treated entirely differently from nerve sheath tumors because the sympathetic chain tumors are considered malignant (although to a varying degree depending on their cellular differentiation). Chemotherapy usually is initiated after a histologic diagnosis is rendered and surgical resection is performed for sympathetic chain neurogenic tumors. Radiation therapy generally has no role.[5] The prognosis depends on the patient's age. Younger patients (particularly infants) have a far better prognosis than older children. Overall, patients with a thoracic neuroblastoma have a better prognosis than patients with retroperitoneal disease.[51] Patients with benign nerve sheath tumors such as neurofibromatosis type 1 do not undergo routine resection of their masses. However, imaging surveillance may be used because of risks of malignant transformation and other tumors arising de novo.

### Other Posterior Mediastinal Lesions and Lesions Simulating Posterior Mediastinal Masses

***Etiology.*** Benign masses and even lung parenchymal processes may mimic more sinister posterior mediastinal masses. For example, extramedullary sites of hematopoiesis include the posterior mediastinal paravertebral space.[103] Rarely, the posterior mediastinum may be the site of herniated bowel loops or kidney relating to diaphragmatic defects. Ectopic thymic extension into the posterior mediastinal compartment was discussed previously. Cystic structures in the posterior mediastinum may be a neurenteric cyst, esophageal duplication cyst (both of which are discussed in the section on middle mediastinal masses), lymphatic malformation (discussed earlier), or meningocele, which usually are associated with

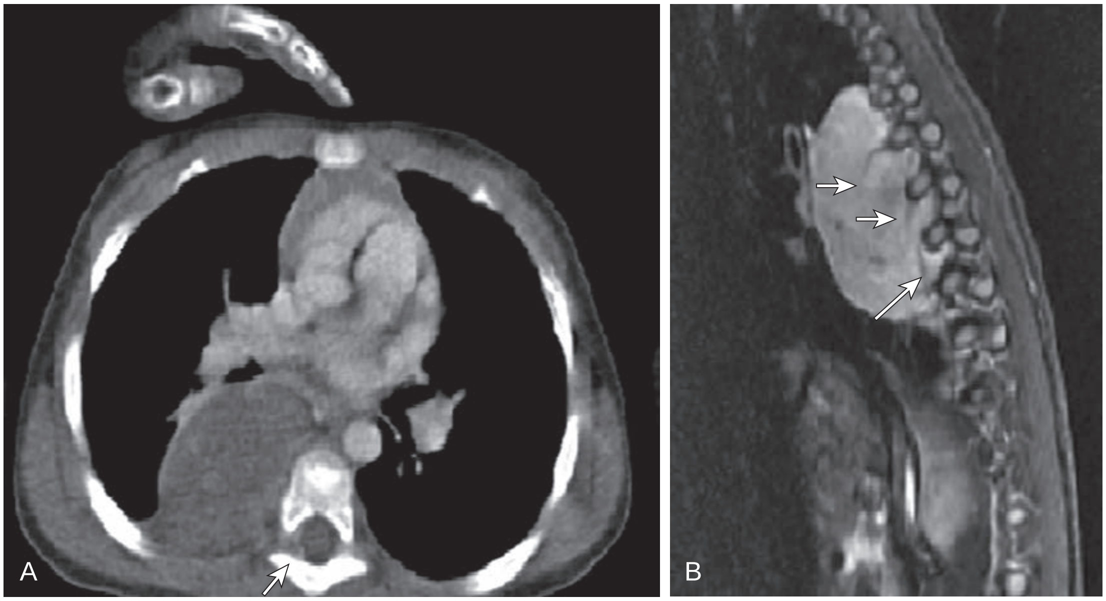

**Figure 58.26. Ganglioneuroma in a 3-year-old.** (A) Axial contrast-enhanced CT image demonstrates a large right paravertebral, posterior mediastinal mass. Neural foraminal extension is present *(arrow).* (B) Sagittal STIR MRI is far superior in its depiction of the neural foraminal extent *(arrows).*

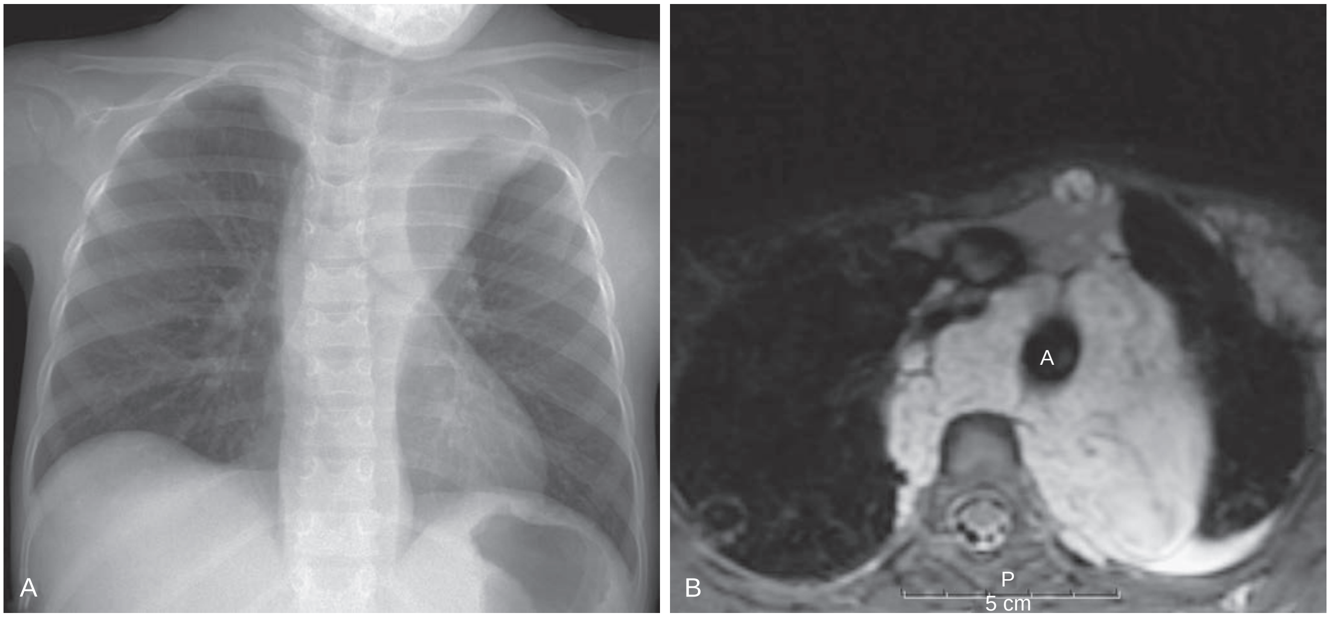

**Figure 58.27. Neurofibromatosis type 1 in a 6-year-old boy who presented with cough.** (A) Frontal chest radiograph shows a large left apical and paraspinal mass that cascades down each side of the spine. (B) Axial T2-weighted MRI demonstrates the "target sign" (central low signal within lesion lobules) and the lobulated shape of the plexiform neurofibromas. *A,* Aorta; *P,* paraspinal muscle.

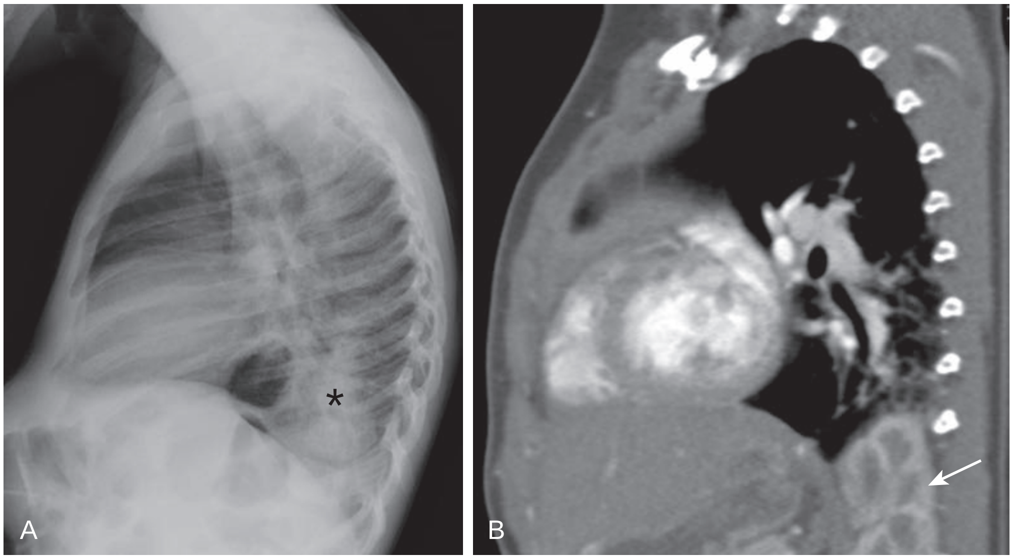
neurofibromatosis type 1. Finally, pulmonary airspace disease, which is seen through the mediastinal structures on chest radiographs, may mimic a mediastinal mass or vice versa.

***Imaging.*** A focus of hematopoietic tissue is most often seen in a paravertebral position as abnormal smooth or lobulated soft tissue. Other clues such as bone marrow reconversion or evidence of sickle cell disease may suggest the diagnosis. An airspace consolidation such as that seen with pneumonia may mimic a posterior mediastinal mass, particularly when it is in the lower lobe medially and obscures posterior mediastinal structures such as the descending aorta and/or azygoesophageal fissure on a frontal chest radiograph. Conversely, a posterior mediastinal mass such as a neuroblastoma may be confused with lung consolidation, particularly when it is located superiorly. The presence of a diaphragmatic hernia is usually obvious, particularly if air-filled loops of bowel are present. In confusing cases, coronal reformatted CT or MRI that can delineate the entire diaphragm are helpful for confirmation (e-Fig. 58.28).

***Treatment and Follow-up.*** Treatment and follow-up of posterior mediastinal lesions other than neoplasms are dictated entirely by the nature of the underlying lesion. As such, determination of the etiology is essential.



**e-Figure 58.28. Bochdalek hernia with superior herniation of a kidney into the chest in a 1-year-old boy.** (A) Lateral chest radiograph shows an opacity *(asterisk)* with obscuration of the posterior left hemidiaphragm. (B) Sagittal contrast-enhanced CT image demonstrates that the opacity seen on the lateral chest radiograph (A) is caused by upward herniation of the kidney *(arrow)* through a Bochdalek hernia.

## KEY POINTS

- Pneumomediastinum is most often attributed to alveolar rupture. Elevation of the thymus is a very helpful imaging clue for pneumomediastinum in neonates and infants on chest radiographs.
- The mediastinum is the most common location of chest masses in the pediatric population.
- The thymus is variable in size and shape, particularly among pediatric patients, and it changes dramatically over time for each patient. Variations of the thymus should be considered when an anterior mediastinal mass is suspected. Many anterior mediastinal neoplasms arise in or infiltrate the thymus.
- Most nonvascular middle mediastinal masses in the pediatric population are developmental malformations of the embryonic foregut or adenopathy as a result of underlying infection, a primary neoplasm, or metastatic disease.
- Most masses arising in the posterior mediastinum are of neurogenic origin and together account for about 34% of all mediastinal masses in children.

# PART 5 Chest Wall, Pleura, and Diaphragm

# 59 The Chest Wall

Ricardo Restrepo and Edward Y. Lee

The chest wall provides support and protection to the various thoracic vascular and nonvascular structures. In addition, it allows the important physiologic motion of the lungs and airways. The chest wall is less rigid and more cartilaginous in children than in adults and consists of several fundamental structural components, including bones (ribs, sternum, and vertebrae), nerves, muscles, vessels, and subcutaneous soft tissues.[1] Within these structural components, a wide variety of localized or systemic processes (e.g., congenital and developmental anomalies, inflammatory and infectious diseases, benign and malignant neoplasms, and traumatic lesions) can occur in pediatric patients.[1-3]

## CONGENITAL AND DEVELOPMENTAL ANOMALIES

### Overview

During childhood, congenital and developmental anomalies of the thorax typically manifest as deformities or anterior chest wall defects that can be isolated or part of a syndrome. Most of these anomalies cause only cosmetic problems. However, pediatric patients with severe congenital or developmental anomalies of the chest wall may present with pain, respiratory distress, or cardiovascular compromise. Imaging can provide a road map for the surgeon in evaluating the anatomy and associated anomalies if reconstructive surgery is contemplated.[4]

### Deformities of the Anterior Chest Wall

***Etiology.*** Most asymptomatic palpable anterior chest wall lesions in pediatric patients are normal anatomic osseous or cartilaginous variants, most commonly a prominent anterior convexity of a solitary rib, costal cartilage, or sternal tilt (Fig. 59.1).[5,6] These normal anatomic variations occur in approximately one-third of children.[5] Symptoms that may raise concern and require further evaluation are focal pain and rapid growth of the mass.[3,5]

***Imaging.*** In the case of a palpable but otherwise asymptomatic anterior chest wall lesion in children, a chest radiograph with a BB marker is usually adequate to exclude a potentially aggressive or malignant underlying condition. When chest radiographic findings are equivocal, ultrasound can be performed.[7] To minimize ionizing radiation exposure, computed tomography (CT) should be reserved for situations in which further characterization is still necessary after radiographic and ultrasound evaluation.[3,6] Magnetic resonance imaging (MRI), which is not associated with ionizing radiation exposure, is a particularly helpful imaging modality for confirming and characterizing congenital and developmental chest wall lesions.

***Treatment and Follow-up.*** If the diagnosis of an anterior chest wall developmental variant can be made confidently by imaging studies in asymptomatic infants and children, no further treatment or follow-up is necessary.[5]

### Pectus Deformity

***Etiology.*** Two of the most common abnormalities of the chest wall are pectus excavatum and pectus carinatum, with the former being the most common congenital deformity of the sternum and the most common sternal deformity requiring surgery. The current leading theory for the development of pectus excavatum is a misdirected, rapid growth of the lower costal cartilages. Such abnormal growth of the lower costal cartilages, which often intensifies during growth spurts, displaces the sternum either inward or outward, resulting in pectus deformity.[8] Pectus excavatum occurs in between 1 in 400 and 1 in 1,000 live births.[9] In children with pectus excavatum, the inferior aspect of the sternum is depressed inward, resulting in varying degrees of anterior chest wall concavity and anterior protrusion of the costochondral junctions. Although most cases of pectus excavatum are isolated, approximately 45% of cases are familial.[10,11]

Pectus carinatum is a less common chest wall deformity that occurs in approximately 1 in 1,500 live births and has a familial occurrence of approximately 25%.[9] In children with pectus carinatum, outward displacement of the sternum occurs, with secondary abnormal protrusion of the ribs.

Pectus deformities may occur in association with scoliosis (more frequently with pectus excavatum), Marfan syndrome, Ehlers–Danlos syndrome, Poland syndrome, and congenital heart disease. In addition to cosmetic issues, severe pectus deformities also can cause chest pain, dyspnea, palpitations, and restrictive lung disease.[3]

***Imaging.*** On frontal chest radiographs, the sternal depression of pectus excavatum may cause a pseudoinfiltrate over the right side of the heart and various degrees of leftward cardiac shift. On the lateral chest radiograph, the sternal depression causes narrowing of thoracic anteroposterior (AP) diameter (Fig. 59.2). Pectus carinatum usually is diagnosed on a lateral chest radiograph, which shows an increased AP diameter of the thoracic cavity and an extended retrosternal space (Fig. 59.3).[3,8]

The Haller or pectus index is used to estimate the severity of pectus excavatum. It is calculated from an axial CT image by dividing the maximum transverse dimension of the thorax from the inner aspect of the ribs by the AP dimension of the thoracic cavity at its narrowest point (Fig. 59.4). A pectus index greater than 3.25 in symptomatic pediatric patients typically initiates corrective surgery, whereas an index less than 2.56 is considered normal.[12] Recent studies have advocated the use of chest radiographs instead of CT to preoperatively evaluate the severity of the deformity.[13] In more severe cases, the use of a limited, low-dose CT scan with selective five to seven axial CT images through the deformity can be obtained to generate the pectus index.[14] When the primary purpose of imaging is to assess the Haller index, axial MRI can be used to avoid ionizing radiation.[15]

***Treatment and Follow-up.*** Severe pectus deformity requires surgical correction, particularly in symptomatic pediatric patients. The Ravitch procedure for pectus excavatum includes resection of deformed cartilages and correction of the sternum by a wedge osteotomy in the upper sternal cortex. In the Nuss procedure, a convex metal bar is placed behind the sternum, pulling the sternum anteriorly. The Nuss procedure has a 4% to 11% complication rate (infection and dislocation of the metallic bar are most common),[16-18] and thus follow-up imaging is necessary to monitor the implanted bar and its complications. Corrective surgery for

## Abstract:

The chest wall consists of several fundamental structural components, including bones (ribs, sternum, and vertebrae), nerves, muscles, vessels, and subcutaneous soft tissues. Within these structural components, a wide variety of localized or systemic processes (e.g., congenital and developmental anomalies, inflammatory and infectious diseases, benign and malignant neoplasms, and traumatic lesions) can occur in pediatric patients and will be discussed in this chapter.

mesenchymal hamartoma
Ewing sarcoma family of tumors

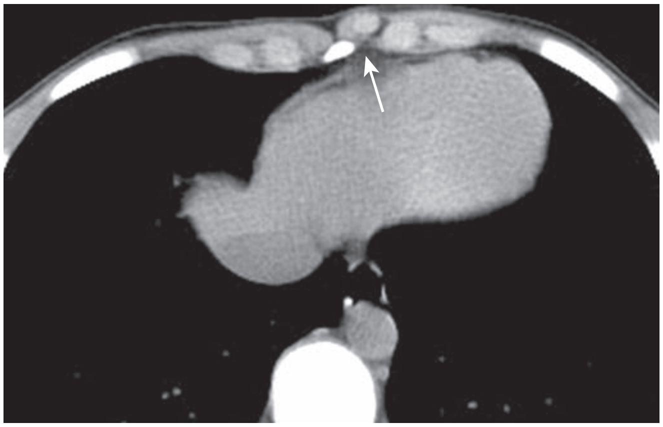

**Figure 59.1. Chondral nodule in an adolescent boy who presented with a focal, palpable, painless lump in the anterior chest wall.** Axial CT image shows a small, round, well-defined structure *(arrow)* protruding anteriorly in the chest wall to the left of the sternum with the same density as the adjacent costochondral junctions.

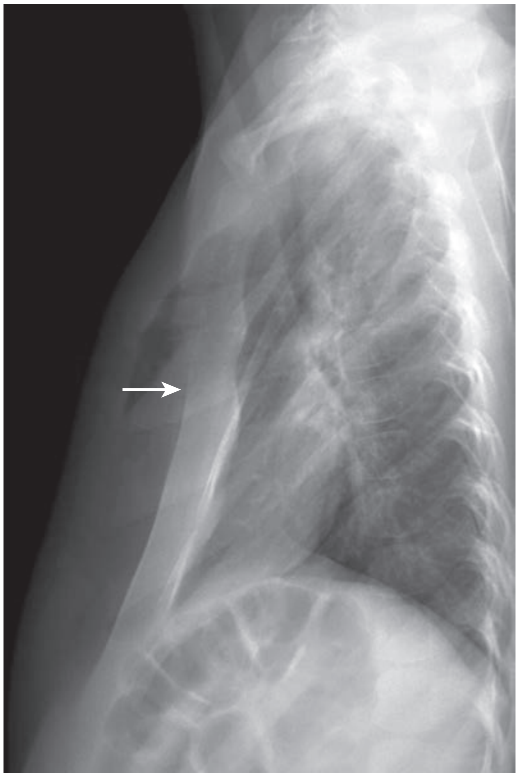

**Figure 59.2. Pectus excavatum in an 8-year-old girl.** Lateral chest radiograph shows the sternal depression *(arrow)* causing narrowing of the anteroposterior diameter of the thorax.

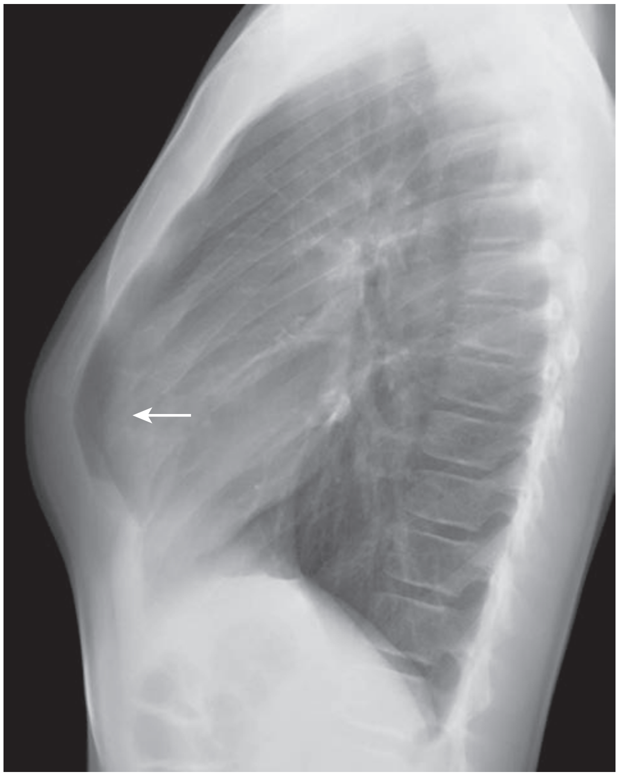

**Figure 59.3. Pectus carinatum in an adolescent boy.** Lateral chest radiograph demonstrates an increased anteroposterior diameter of the thoracic cavity and extended retrosternal space *(arrow).*

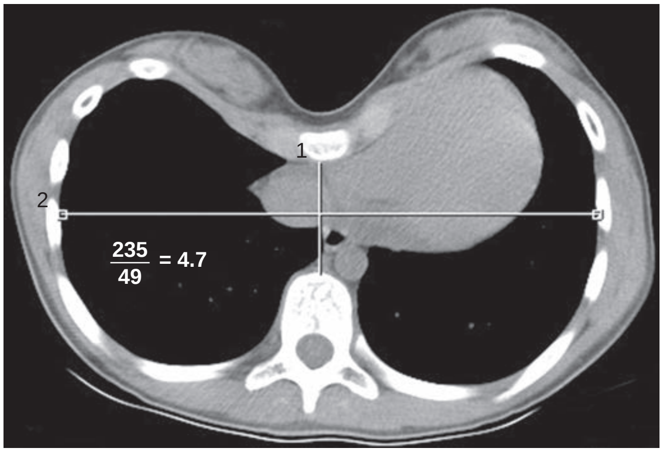

**Figure 59.4. Pectus index.** Axial CT image shows severe anterior depression of the sternum that is compressing and displacing the heart. The pectus index is 4.7.

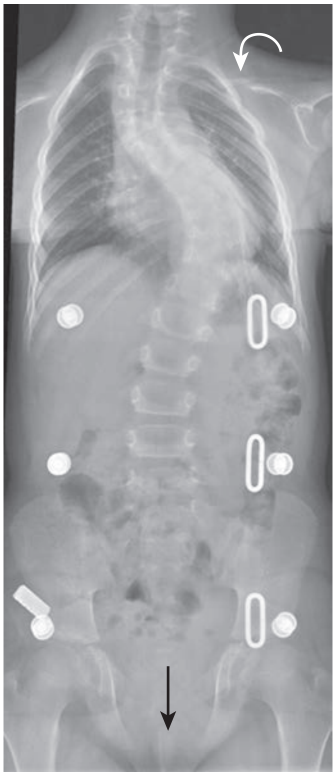
pectus carinatum also requires costochondral resection and a wedge osteotomy, but the sternum is pushed inward.

## Cleidocranial Dysostosis

***Etiology.*** Cleidocranial dysostosis is a rare syndrome usually caused by an autosomal dominant gene mutation *(CBFA1)* with a high degree of penetrance and variable expression. The triad of partial or complete absence of the clavicles, supernumerary or impacted teeth, and delayed fontanel closure is highly suggestive of this syndrome. Other features include midface hypoplasia, short stature, and pelvic and distal phalangeal hypoplasia that causes brachydactyly.[19-21]

***Imaging.*** Typical chest radiographic findings include a bell-shaped thorax, short ribs, and either complete or partial absence of the clavicles (e-Fig. 59.5). When the clavicle is partially absent, the distal portion of the clavicle usually is involved. Scoliosis may be present. Because many of the characteristic manifestations only become evident during adolescence, early clinical diagnosis may be difficult and often requires a skeletal survey. Other features of the syndrome can support the diagnosis.[19-21]



**e-Figure 59.5. Cleidocranial dysostosis in an adolescent boy.** A chest and abdominal radiograph shows absence of the right clavicle and hypoplasia of the distal half of the left clavicle *(curved arrow).* Diastasis *(straight arrow)* of the symphysis pubis also is present. The patient has scoliosis and is wearing a brace.

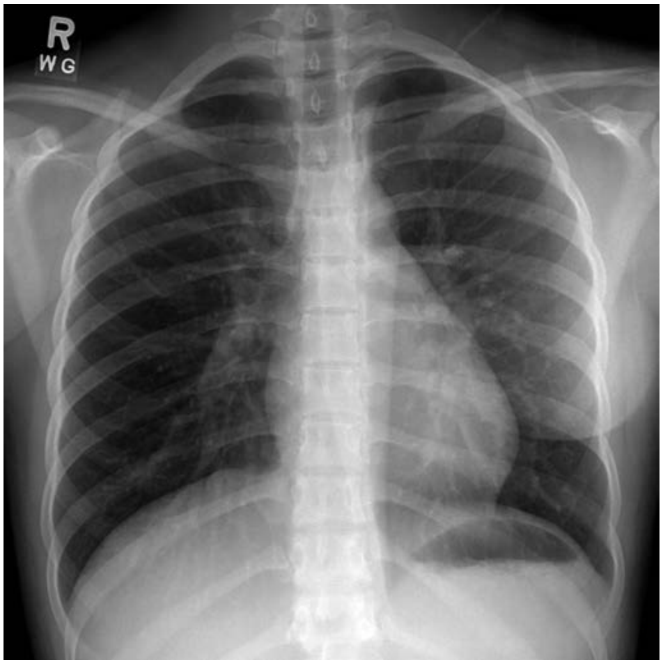


**Figure 59.7. Poland syndrome in an adolescent girl.** Frontal chest radiograph shows a hyperlucent right lung as a result of the absence of right chest wall soft tissues, including the breast.

***Treatment and Follow-up.*** Multidisciplinary management by a team of specialists including pediatricians, geneticists, and orthodontists is the optimal approach for patients with cleidocranial dysostosis. Genetic counseling is recommended. No imaging follow-up is required once the diagnosis has been made.[19]

## Poland Syndrome

***Etiology.*** Poland syndrome is a form of chest wall and breast hypoplasia that occurs in 1 in every 20,000 to 30,000 live births.[22] The syndrome includes absence of the pectoralis muscles and ipsilateral syndactyly. Other associations include rib aplasia, amastia/athelia, and absence of axillary hair. Poland syndrome typically is unilateral and (more often) sporadic and occurs more frequently in boys than in girls, with a ratio of 2 : 1 to 3 : 1.[23] The tendency toward unilaterality (with the right side affected more frequently than the left side) has raised the hypothesis that this anomaly is perhaps a result of interrupted or insufficient blood supply during limb bud development in the sixth week of gestation.[23] Poland syndrome is diagnosed clinically by the apparent asymmetry of the chest wall (e-Fig. 59.6) and syndactyly. Cardiopulmonary impairment and functional deficiency of the shoulder, although rare, also can be present.[3,22,23]

***Imaging.*** On chest radiographs, hyperlucency of the affected hemithorax is usually apparent in unilateral cases because of the absent pectoralis muscle and breast (Fig. 59.7). Because the extent of involvement is difficult to assess with clinical examination or chest radiographs, cross-sectional imaging with CT or MRI is useful (Fig. 59.8). Furthermore, it is imperative to preoperatively assess the presence of all of the chest wall and anterior abdominal wall muscles, because muscle flaps are used in surgical reconstruction.[2,22]

***Treatment and Follow-up.*** Corrective surgery often is performed for cosmetic reasons, particularly in girls. Such surgery includes (1) restoration of the structural integrity of the rib cage and (2) improvement in the appearance of the chest by performing transposition of musculocutaneous flaps (most commonly with latissimus dorsi and rectus abdominis muscles), as well as concomitant breast implants in female patients.[8,22,23]

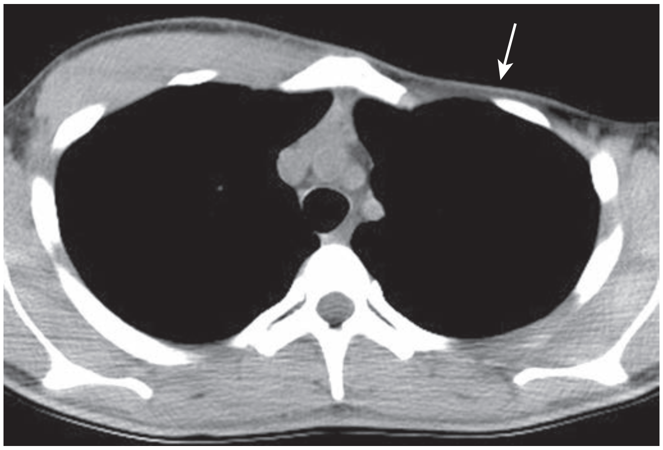

**Figure 59.8. Poland syndrome in an adolescent boy.** Axial CT image demonstrates complete absence of the left pectoralis muscles *(arrow)*, causing asymmetry of the anterior chest wall.

# INFECTIOUS DISEASES

## Overview

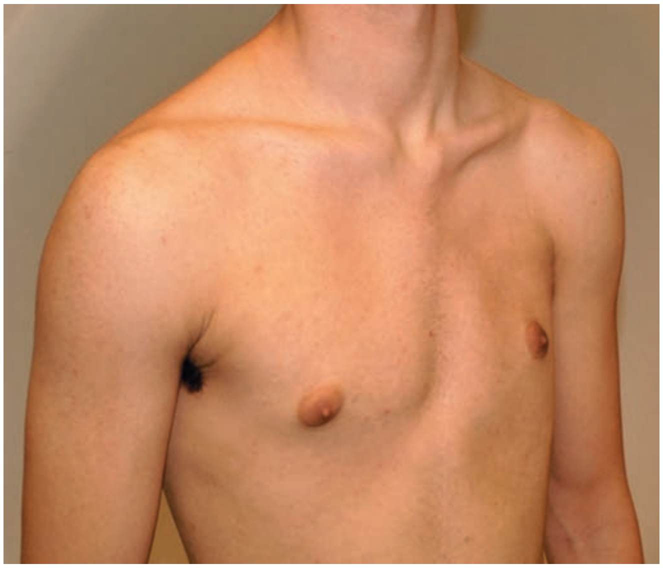
Chest wall infections are relatively rare in children. Chest wall infections occur either by direct extension or, less frequently, by hematogenous spread. Such infectious processes can involve the soft tissues, cartilage, and osseous structures. Chest wall infections can be the result of bacterial, mycobacterial, or fungal infections. They range from superficial cellulitis to deeper infections, which include myositis, abscess, necrotizing fasciitis, and osteomyelitis.[24,25]

## Bacterial Infection

***Etiology.*** Bacterial infections of the chest wall are rare in children. The common organisms that cause bacterial infections of the chest wall are *Staphylococcus aureus* and *Salmonella* species in persons with sickle cell disease. Sternal osteomyelitis may occur in patients with an underlying disease, such as immunodeficiency and hemoglobinopathies.[11] Rib osteomyelitis is most commonly acquired by direct spread from an adjacent pneumonia or empyema. Empyema necessitans is a rare complication of empyema characterized by the extension of the infection from the pleural space into the chest wall. Pediatric patients with a bacterial chest wall infection often present with focal soft tissue erythema, edema, and pain. Additionally, other signs of infection, such as leukocytosis and elevated erythrocyte sedimentation rate, often are present.[3,11,26,27]

***Imaging.*** Chest radiographs may reveal localized soft tissue edema in cases of cellulitis or fasciitis. Bone changes such as periosteal reaction or lytic or sclerotic lesions can be present, particularly in the late stage of disease. Concomitant pulmonary consolidation, empyema, and subcutaneous emphysema also may be present. Ultrasound, CT, and MRI are more sensitive than chest radiographs in detecting and characterizing chest wall infections. Ultrasound should be reserved for superficial and more localized chest wall infections because of the limited field of view (Fig. 59.9A). The extent of the chest wall infection is best demonstrated on CT or MRI. For evaluation of chest wall abscess and bone marrow edema in the earlier stage of osteomyelitis, MRI is the most sensitive imaging modality (Fig. 59.9B). CT is the imaging modality of choice for evaluating concomitant pulmonary parenchymal infection.[2,11,26-28]

***Treatment and Follow-up.*** Antibiotics are administered to treat bacterial chest wall infections. In cases of abscesses localized to the chest wall or empyema, drainage may be necessary to relieve the focus of infection and avoid further spread. Prolonged antibiotic



**e-Figure 59.6. Poland syndrome in an adolescent boy.** Asymmetry of the chest wall is apparent because of a lack of soft tissue on the left side.

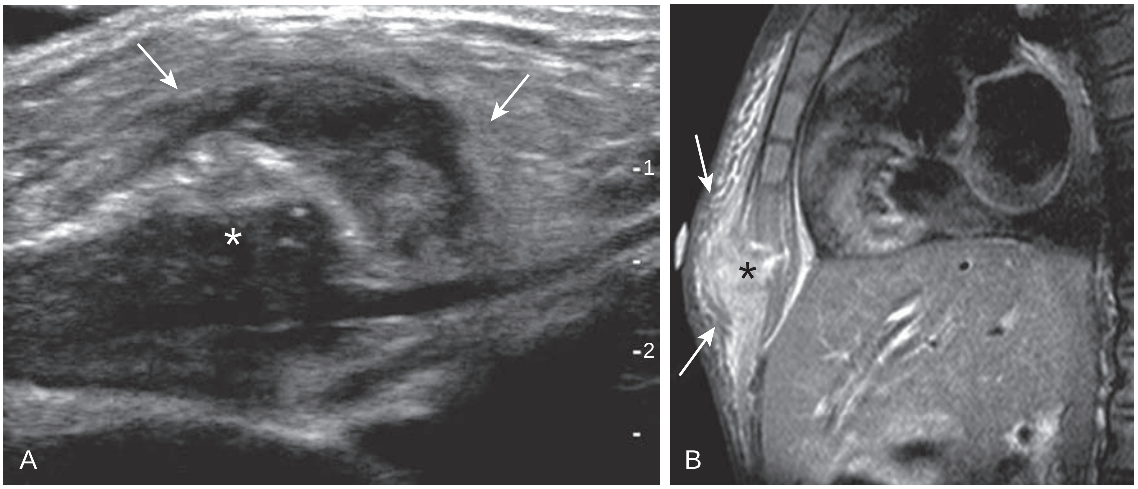


**Figure 59.9. Sternal osteomyelitis in a 6-year-old girl who presented with prolonged fever and a painful, palpable, and erythematous sternal lump.** (A) Longitudinal sonogram of the inferior aspect of the sternum *(asterisk)* shows marked surrounding soft tissue edema and swelling *(arrows).* (B) Sagittal contrast T1-weighted MRI of the chest with fat saturation demonstrates focal destruction of the distal ossification center of the sternum *(asterisk)* with contrast enhancement and edema of the adjacent soft tissues *(arrows).*

therapy is necessary for cases of osteomyelitis.[27,29] Evaluation of response to treatment by monitoring C-reactive protein in pediatric patients with osteomyelitis has dramatically decreased both the average duration of therapy and the need for follow-up imaging.[30]

## Tuberculosis

***Etiology.*** Tuberculosis (TB) is a potentially deadly infectious disease caused by various strains of mycobacteria, usually *Mycobacterium tuberculosis* in humans. Tuberculosis infection of the chest wall often is a result of the hematogenous spread of pulmonary TB infection.[31] However, tuberculosis of the chest wall also can occur as an isolated primary infection with no evidence of pulmonary disease, although this presentation is rare.[32] Skeletal TB infection accounts for 10% to 20% of extrapulmonary cases and 1% to 2% of all TB infection cases.[33] Affected patients present with a slow-growing soft tissue chest wall mass, often without associated pain or fever. Respiratory symptoms may be present in cases of lung involvement.[32,34]

***Imaging.*** TB infection can involve any bone of the chest wall; however, the ribs are most commonly affected. On radiographs, osseous TB infections are usually lytic and sharply marginated. Associated periosteal reaction is a relatively rare finding.[35] On CT or MRI, TB chest wall infections usually present as a rim-enhancing chest wall mass. CT and MRI can play an important role in demonstrating bone involvement from a chest wall TB infection that may not be seen on radiographs.[32] Expansion and destruction of the bone with an adjacent soft tissue mass from a TB infection of the chest wall may mimic an underlying malignancy.[31,33,34]

***Treatment and Follow-up.*** Treatment of chest wall TB infection currently is not well established. Some advocate at least 6 months of antituberculous medication, whereas others suggest more aggressive management consisting of surgical excision of affected bones and soft tissues, in addition to preoperative and postoperative antituberculous medication regimens.[32,36]

## Actinomycosis

***Etiology.*** In humans, actinomycosis is most commonly caused by *Actinomyces israelii*, a branching gram-positive, facultative anaerobe. Actinomycosis infection typically affects the cervicofacial region in patients with dental caries. Pulmonary and chest wall involvement of actinomycosis in children is less frequent without underlying predisposing pulmonary conditions. Actinomycosis infection initially involves the lungs and then usually spreads to the adjacent soft tissues. Clinically, affected patients present with cough, intermittent fever, and weight loss. Pain develops once the microorganism invades the pleura and chest wall.[37,38]

***Imaging.*** On a chest radiograph, the classic radiologic appearance of actinomycosis infection is a chronic lung consolidation that crosses the fissures with a pleural effusion. Because actinomycosis infection does not respect tissue boundaries, it tends to invade the surrounding tissues with fistulous tracts and abscess formation that are best seen on CT or MRI. Rib periostitis, pulmonary cavitation, and diaphragmatic invasion also may occur in more advanced cases and are very suggestive of actinomycosis infection.[38,39] Advanced actinomycosis infection of the chest wall may mimic TB or a malignancy of the Ewing sarcoma family of tumors (ESFT).[37]

***Treatment and Follow-up.*** A definite diagnosis of actinomycosis of the chest wall requires either microscopic visualization of the typical sulfur granules representing the colonies of the microorganism or recovery of the *Actinomyces* organisms in an anaerobic culture. The standard treatment of actinomycosis is long-term, high-dose penicillin. In cases with an abscess, image-guided percutaneous drainage may help expedite recovery and isolate the organism.[37,38]

# TUMORS OF THE CHEST WALL

## Overview

Because the chest wall is composed of several different types of tissues, a wide variety of both benign and malignant tumors may occur, including vascular, cartilaginous, osseous, muscular, or adipose tumors. Imaging evaluation plays a pivotal role in (1) initial detection, (2) assessment of the extent of disease, (3) guidance for tissue sampling, (4) evaluation of the response to treatment, and (5) surveillance for recurrence.[7,25]

## Benign Tumors

### Soft Tissue Tumors

#### Infantile Hemangioma

***Etiology.*** Infantile hemangiomas are benign vascular tumors of abnormally proliferating endothelial cells that follow a predictable course. Infantile hemangiomas are the most common tumor of childhood, with a reported incidence of approximately 10% in the general population.[40-42] The etiology of hemangiomas currently is unknown. Several proposed theories include placental emboli, somatic mutation, and clonal expansion of progenitor stem cells.[43,44] Infantile hemangiomas are more common in premature white children, with female predominance ratios ranging from 1.4 : 1 to 3 : 1.[41] Hemangiomas can involve any part of the body, including the chest wall and breast bud. At birth, these lesions frequently are underdeveloped, with only a macule or discoloration representing a "precursor" lesion. Soon after birth, infantile hemangiomas grow during the so-called proliferative phase and become raised and red in color. Around the first year of life, they begin to involute, eventually leaving a fibro-fatty scar. Multiple lesions are found in 15% to 30% of patients.[41,44,45]

***Imaging.*** Ultrasound is the first imaging modality of choice, especially for evaluating localized, superficial hemangiomas. For large and extensive lesions with a deep soft tissue component, MRI often is necessary for a complete evaluation. Although CT can be used when MRI is not available, it is less preferable because of the associated radiation and inferior soft tissue characterization. The imaging appearance of infantile hemangiomas may change according to the stage of disease. On ultrasound, hemangiomas are well-defined, lobulated, hyperechoic masses that become more heterogeneous during the involuting phase. Increased vascularity, containing arteries, veins, and even evidence of shunting, often is seen on color Doppler, especially during the proliferative phase (e-Fig. 59.10). On MRI, infantile hemangiomas are isointense or slightly hyperintense compared with muscle on T1-weighted images, and hyperintense on T2-weighted images, containing flow voids that represent arteries or rapid venous flow. Hyperintense fatty elements may be seen on T1-weighted images. The pattern of contrast enhancement also varies according to the stage of disease. Marked contrast enhancement usually is seen during the proliferative phase, whereas heterogeneous contrast enhancement is observed during the involuting phase. On CT, hemangiomas present as well-defined soft tissue masses that are isodense to muscle with marked postcontrast enhancement.[44,46-49]

***Treatment and Follow-up.*** Most infantile hemangiomas require no treatment because they typically involute. A pulsed dye laser can be used for the cosmetic management of superficial lesions.[30] Propranolol is the drug of choice in the treatment of hemangiomas with minor complications, such as hypoglycemia and hypotension.[50-52]

### Lymphatic Malformation

***Etiology.*** Lymphatic malformations are a subtype of slow-flow vascular malformations.[42] These lesions are fully developed at birth and grow commensurate to the patient's growth. Lymphatic malformations, although congenital and not true neoplasms, are discussed in the tumor section. Lymphatic malformations consist of dilated lymphatic channels and spaces, with walls lined by mature endothelium that have normal rates of endothelial cell turnover. These lesions occur anywhere in the body, but the cervicofacial, axillary, and chest regions are the most common locations. Lymphatic malformations have no sex predilection. Except for very small lesions, these lesions present as a mass that usually is discovered at birth. The lesions have normal overlying skin and often display transillumination. With superimposed hemorrhage or infection, a sudden increase in the lesion size is typical.[3,53]

***Imaging.*** Plain radiography plays no role in the evaluation of lymphatic malformations in the chest wall of pediatric patients. The imaging workup of lymphatic malformations includes ultrasound and MRI, with the former more commonly used for localized and superficial lesions. More extensive lesions are better evaluated with contrast-enhanced MRI, with CT as an alternative imaging modality. On ultrasound, lymphatic malformations appear as multiloculated cystic lesions that are macrocystic or microcystic, depending on the size of the locules. No internal blood flow is seen on color Doppler imaging. With associated bleeding or superimposed infection, echogenic material, low-level echoes, or fluid-fluid levels can be observed (Fig. 59.11A). On MRI, the cystic lesions are hyperintense on T2-weighted images (Fig. 59.11B) and hypointense on T1-weighted images. Lymphatic malformations display no solid components and have minimal, if any, peripheral and septal enhancement, unless superimposed infection is present. Hyperintense elements on T1-weighted images suggest proteinaceous material, bleeding, or infection. Because of their pliable nature, lymphatic malformations typically insinuate and displace, rather than invade, adjacent structures.[3,46-48]

***Treatment and Follow-up.*** The treatment for lymphatic malformation is percutaneous sclerosis, surgical resection, or a

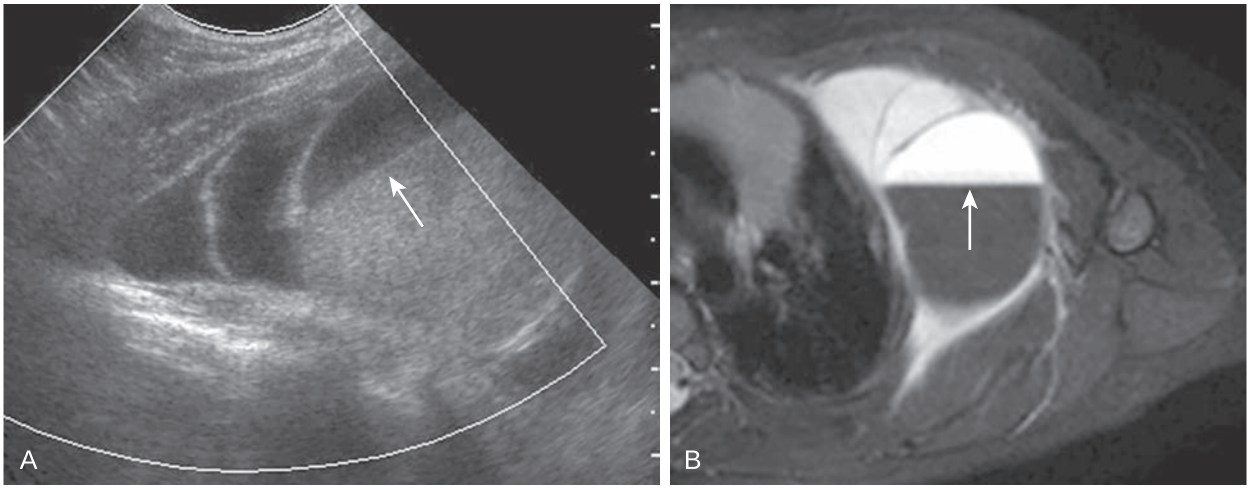

**Figure 59.11. Lymphatic malformation in a 2-year-old boy who presented with an enlarging chest wall lump after a fall.** (A) Longitudinal color Doppler sonogram shows a multiloculated avascular cystic mass in the anterolateral chest wall. Some of the locules are anechoic, but a fluid-fluid level *(arrow)* is present in the most dominant one, likely indicating recent bleeding. (B) Axial T2-weighted MRI of the chest demonstrates the multiseptated mass with hyperintense elements representing lymphatic fluid and hypointense elements with a fluid-fluid level *(arrow)* indicating recent bleeding. The patient has minimal, if any, adjacent soft tissue edema, and no soft tissue component is seen in the lesion.

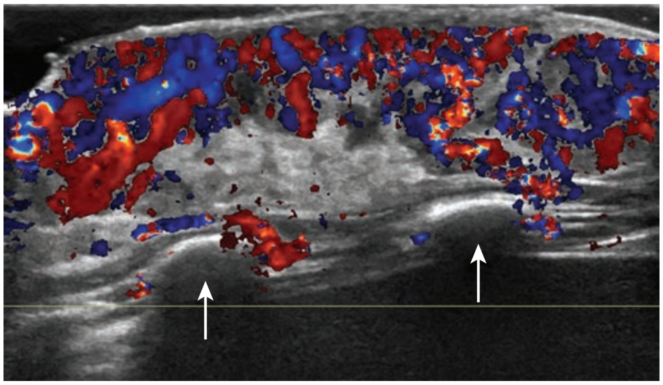

**e-Figure 59.10. Infantile hemangioma in a 6-week-old girl in whom a raised red cutaneous lesion developed in the anterior chest wall 3 weeks after birth.** Color Doppler sonogram shows a well-defined soft tissue mass confined to the subcutaneous soft tissues that insinuates along the ribs *(arrows)* and involves the dermis. The lesion has a hyperechoic and markedly vascular soft tissue component containing arteries and veins.

combination of both. Sclerotherapy is the preferred method for macrocystic lymphatic malformations. The treatment of microcystic lesions is more difficult and can include observation, sclerotherapy, and/or surgical resection.[46,48,53]

### Infantile Fibrous Hamartoma

***Etiology.*** An infantile fibrous hamartoma is a tumor of neonates, infants, and young children, with approximately 90% occurring in the first year of life.[54] They are more common in boys than in girls. The most common location is around the shoulder girdle. The tumor usually presents as a painless, mobile soft tissue mass. Histologically, an infantile fibrous hamartoma contains fibrocollagenous tissue, primitive mesenchyma, and mature fat.[54-56]

***Imaging.*** An infantile fibrous hamartoma is a well-defined lesion with a heterogeneous echotexture on ultrasound, attenuation on CT, and signal intensity on MRI because of different underlying tissue components. Hyperechoic elements seen on ultrasound and T1 hyperintensities seen on MRI represent the fatty elements, which is an important clue in the diagnosis. On MRI, the fibrous component of infantile fibrous hamartoma is seen as hypointense areas on T1- and T2-weighted images.[54,57]

***Treatment and Follow-up.*** Local surgical resection of infantile fibrous hamartoma is usually curative, with a low risk of recurrence. No metastatic disease from infantile fibrous hamartoma has been reported.[56,58]

## Osseous Tumors

### Fibrous Dysplasia

***Etiology.*** Fibrous dysplasia is a benign, intramedullary, fibro-osseous lesion thought to occur as a result of a developmental failure in the remodeling of primitive bone to mature lamellar bone, and failure of the bone to realign in response to mechanical stress.[59] The true incidence of fibrous dysplasia is difficult to estimate, but the lesions are not rare and typically are discovered before age 30 years. Fibrous dysplasia has been reported to represent 20% to 30% of chest wall masses, with the rib being the most commonly affected bone.[3,60] Fibrous dysplasia can be monostotic or polyostotic; however, monostotic disease does not progress to polyostotic disease. Although a focal mass or chest wall deformity can be seen, most cases of monostotic fibrous dysplasia are discovered incidentally when radiographs of the area are obtained for different reasons. Localized pain may be the presenting symptom in cases with pathologic fractures or mass effect on adjacent thoracic structures.[59,60]

***Imaging.*** The diagnosis of fibrous dysplasia usually is made with plain radiographs. Radiographic characteristics include a focal, well-defined, expansile, intramedullary lytic lesion with a lucent, ground-glass, or sclerotic matrix, causing cortical thinning and loss of trabecular definition (e-Fig. 59.12). Rarely, fibrous dysplasia can be cystic with fluid-fluid levels. Fibrous dysplasia is usually a radiographic diagnosis that requires no further imaging.[3,61] When seen on CT, amorphous calcification inside the lesion with bone expansion is usually present. MRI is helpful in assessing the extent of the disease. The lesions are isointense to muscle on T1-weighted images. On fluid-sensitive sequences, the lesions are predominantly hyperintense, with focal hypointense, isointense, or markedly hyperintense foci. The heterogeneous MRI signal is due to the presence of calcifications, fat, cystic changes, or septations. Fibrous dysplasia displays various contrast enhancement patterns that can be patchy, peripheral, or homogeneous.[61,62]

***Treatment and Follow-up.*** Fibrous dysplasia of the chest wall usually requires no treatment unless symptoms such as nerve or vascular compression develop. In such cases, resection of the affected bone can alleviate the symptoms.[63,64] In symptomatic polyostotic cases, bisphosphonates can be used because of their inhibitory effect on bone resorption. When the lesions are discovered incidentally and the radiographic features are characteristic, no biopsy is indicated; a follow-up study every 6 months to ensure stability currently is advised.[59]

### Osteochondroma

***Etiology.*** An osteochondroma is a benign cartilage-capped developmental lesion rather than a true neoplasm. It affects bones with epiphyses and apophyses. These lesions result from the separation of a fragment of epiphyseal growth plate cartilage, which subsequently herniates through the periosteal bone cuff normally surrounding the physis. An osteochondroma usually is diagnosed in the first 3 decades of life and may be inherited as a multifocal, familial, autosomal dominant disease. Solitary lesions have a male predilection; they occur in approximately 1% to 2% of persons undergoing radiographic evaluations and constitute 10% to 15% of all bone tumors.[65] Osteochondromas are the most common benign osseous neoplasm involving the chest wall.[3] Most solitary osteochondromas are asymptomatic. Symptomatic lesions tend to occur in younger patients, with 75% to 80% of those cases discovered before age 20 years.[65] Lesions in the chest wall usually present with a palpable, painless mass or focal deformity. Pain may occur as a result of mechanical irritation, fracture, and nerve or vascular compression.[3,61,66]

***Imaging.*** Osteochondromas are usually diagnosed on plain radiographs. In patients with multiple osteochondromatosis, a skeletal survey usually is obtained to assess the overall extent of disease. In the chest wall, the lesions arise most frequently from the ribs or scapula (Fig. 59.13). They can be sessile or pedunculated, depending on whether a narrow or broad pedicle is located at the base. Corticomedullary continuity is the characteristic imaging

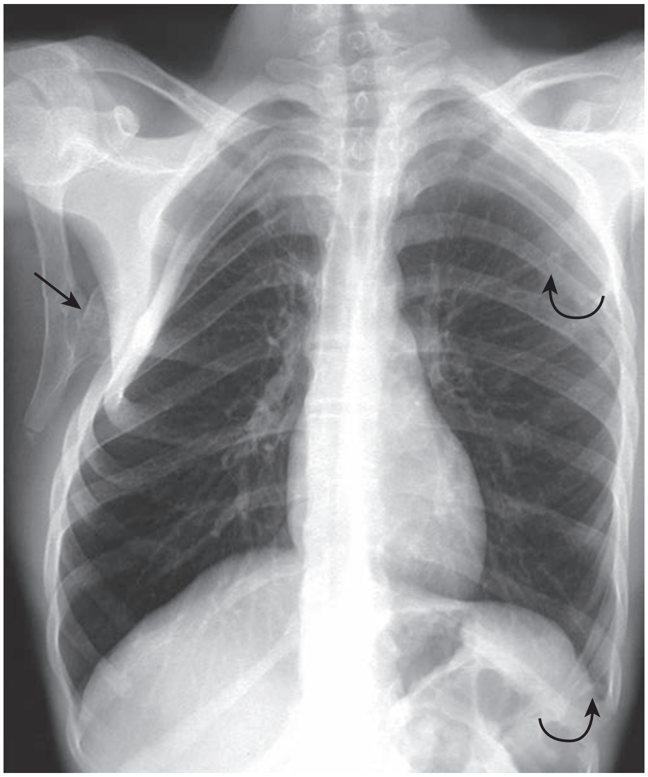

**Figure 59.13. Multiple osteochondromas in an adolescent boy with hereditary exostosis.** Frontal chest radiograph shows a large pedunculated osteochondroma *(straight arrow)* arising from the undersurface of the right scapula that is causing remodeling of the underlying right ribs and chest wall deformity. Smaller lesions *(curved arrows)* are seen in the left scapula and the tenth left rib at the mid axillary line, producing focal rib deformity.

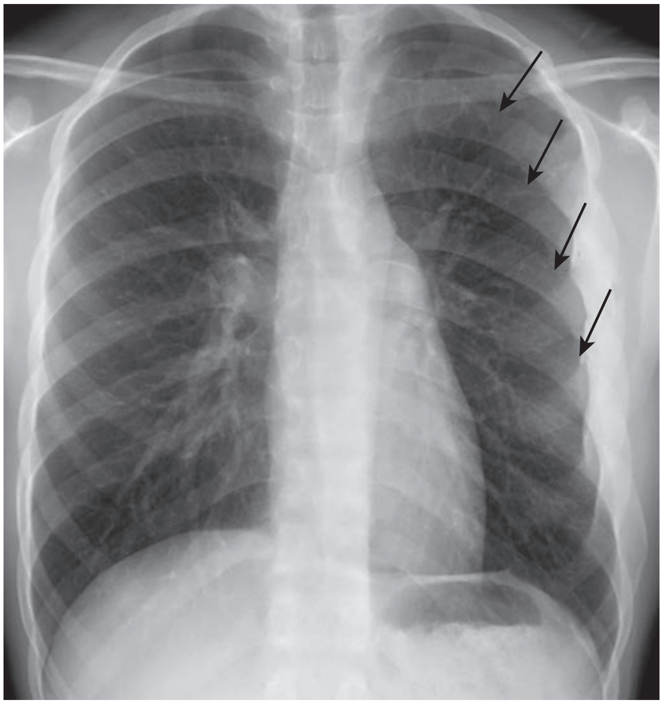

**e-Figure 59.12. Polyostotic fibrous dysplasia in an adolescent.** Frontal chest radiograph shows diffuse thickening of multiple left ribs *(arrows)* with a ground-glass matrix and an indistinct cortex.

finding of an osteochondroma, but this finding may be difficult to completely assess on radiographs. Although both CT and MRI demonstrate the corticomedullary continuity, MRI has an advantage over CT in evaluating the thickness of the cartilaginous cap that should be thin, uniform, and hyperintense on fluid-sensitive sequences. Additionally, MRI can be helpful in assessing the adjacent soft tissue edema and bursa formation that are indicative of the irritation often resulting from osteochondromas. It has been reported that CT with three-dimensional reconstructions can be valuable in preoperative planning.[27,61,65,66]

***Treatment and Follow-up.*** Indications for surgical resection of solitary osteochondromas include pain, cosmetic deformity, and nerve impingement. The treatment choice for multiple hereditary exostoses is more complicated and often is directed to correct bone deformity.[65,66] Malignant transformation of the cartilaginous cap into a chondrosarcoma occurs in fewer than 1% of solitary cases and in up to 25% of multiple hereditary exostoses.[65] The risk of malignant transformation is proportional to the size and number of lesions and only occurs in adulthood. Solitary osteochondromas in children do not require routine follow-up unless symptoms or rapid growth occur.[66] In cases of multiple lesions, close clinical and radiographic monitoring is required to evaluate the progression of deformities and the development of complications.[65]

### Mesenchymal Hamartoma

***Etiology.*** A mesenchymal hamartoma of the chest wall is a rare, benign lesion. It typically presents at birth as a large, extrapleural mass arising from a rib that causes chest wall deformity or respiratory distress because of mass effect. Mesenchymal hamartomas, which are not considered true neoplasms, are composed of maturing, proliferating normal skeletal elements with a prominent cartilaginous component and hemorrhagic cavities as a result of aneurysmal bone cyst (ABC) formation. To date, no instances of malignant degeneration of mesenchymal hamartoma of the chest wall have been reported.[67-69]

***Imaging.*** A mesenchymal hamartoma may have an ominous imaging appearance, despite its benign nature. On chest radiographs, it usually presents as a partially calcified extrapleural mass causing erosion of one or more ribs. A mass effect on the adjacent lungs and mediastinum often is present.[70] CT or MRI scans show a well-circumscribed lesion with solid and cystic components, the latter representing ABC, a feature specific to this lesion (Fig. 59.14). Cortical bone partially surrounding the lesion and mineralization also can be seen. In one series, mineralization was present in 100% of cases and hemorrhagic cystic areas of aneurysmal bone cyst were present in more than half of patients.[67] On MRI, the signal intensity of mesenchymal hamartoma is variable. Hyperintense areas on fluid-sensitive sequences represent ABC formation and chondroid elements, whereas areas of low signal on T1 and fluid-sensitive sequences represent areas of mineralization.[67,71] Multifocal cases of mesenchymal hamartoma also have been reported.[67,71]

***Treatment and Follow-up.*** Surgical excision of a mesenchymal hamartoma with rib resection and chest wall reconstruction is recommended if cardiorespiratory symptoms from mass effect or chest wall deformity are present. Smaller lesions can be monitored with chest radiographs and ultrasound because spontaneous regression of the lesion has been reported, and the lesions typically stop growing after age 1 year.[67,68,72]

### Other Osseous Tumors (Langerhans Cell Histiocytosis, Enchondroma, and Aneurysmal Bone Cyst)

***Etiology.*** Several other benign tumors can involve the chest wall in the pediatric population, including Langerhans cell histiocytosis (LCH), enchondroma, and ABC. These tumors can arise from any bone in the chest wall, including the ribs, scapula, and (less frequently) the sternum.

Langerhans cells are a type of histiocyte that originates from the bone marrow and play a role in the immune system. Abnormal clonal proliferation causes LCH, the most common form of which is a localized bone lesion (formerly called eosinophilic granuloma). In the chest wall, LCH most commonly affects the thoracic vertebral bodies causing vertebrae plana, but it can involve any bone. Bone destruction, pain, localized swelling, and a palpable mass often are present.[73,74]

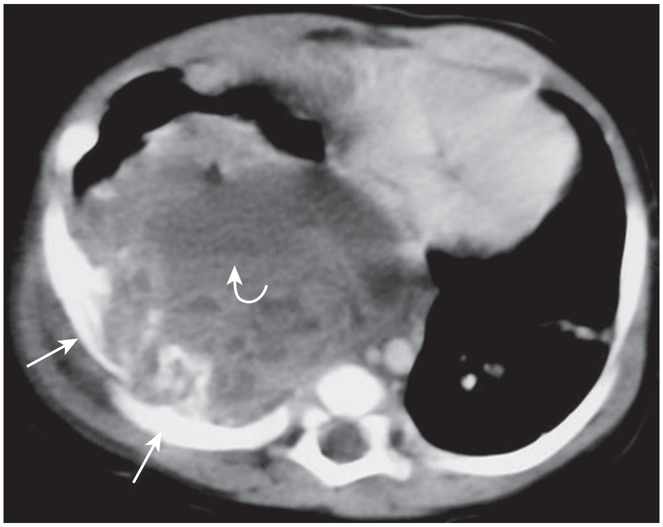

**Figure 59.14. Mesenchymal hamartoma in a newborn girl with respiratory distress and a palpable mass in the right chest wall.** Axial contrast-enhanced CT image shows a very large, round mass in the posterior right hemithorax with erosion of two consecutive ribs *(straight arrows).* The lesion has a heterogeneous parenchyma with a fluid-fluid level *(curved arrow)* corresponding to the aneurysmal bone cyst component.

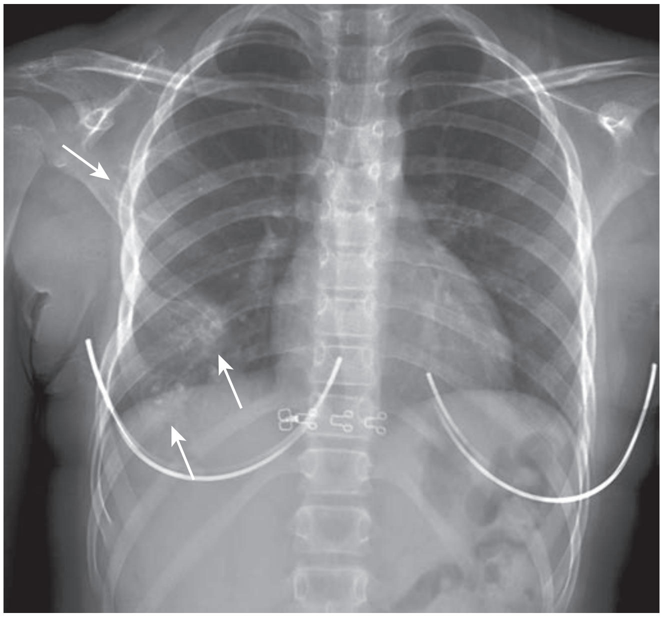
Enchondromas occur less frequently in children than osteochondromas and represent benign, mainly hyaline cartilage tumors arising from the medullary canal of a bone. Most enchondromas are solitary and usually are found incidentally; they also may be multiple, such as in patients with Ollier or Maffucci syndromes.[3,26,61,75]

ABCs are benign, expansile, osteolytic lesions that contain multiple blood-filled spaces of different sizes and are lined by fibroblasts and giant cells of the osteoclast type (see also Chapter 138). An ABC is a hyperplastic lesion reactive to a subperiosteal or intraosseous hemorrhage. Although they are benign, these lesions can grow rapidly, causing bone destruction and pathologic fractures that produce pain and a palpable mass. ABCs may be found either as primary osteolytic lesions or as a reactive process as part of another lesion. The primary ABC is found mostly in the second decade of life and more frequently in females, with a ratio of 2 : 1.[61,76] In the chest wall, the most common sites of involvement from ABCs are the posterior elements of the spine and the ribs.[61]

***Imaging.*** The classic imaging finding of an LCH lesion when it involves the thoracic spine is vertebrae plana, characterized by flattening of vertebral bodies. When it involves other bones of the chest wall, the radiographic appearance of LCH varies. In the acute phase of the disease, the lesion develops rapidly and has a more aggressive appearance. In this phase, the lesions typically are lytic with poorly defined borders (Fig. 59.15). Periosteal reaction occurs when the lesion involves the cortex. A soft tissue component of an LCH often is present and is best seen on CT or MRI. In the later phase of disease, the lesions can be lytic and sclerotic, and they may adopt a bubbly appearance and have sharp, sclerotic borders.[3,73,74]

Enchondromas arise from the medullary portion of bone with well-defined, lobulated borders and endosteal scalloping. Localized bone expansion and a chondroid matrix frequently are present in enchondromas (e-Fig. 59.16).[3,61,75] ABCs are well-defined, lytic, expansile, intramedullary lesions. In the short and flat bones, such



**e-Figure 59.16. Chest wall enchondromas in an adolescent girl with Ollier disease.** Frontal chest radiograph shows several well-defined lytic lesions involving the costochondral junction of the right sixth and seventh ribs and the mid aspect and superior border of the right scapular wing *(arrows).* Chondroid matrix is better identified in the rib lesions.

as the ribs, the cyst usually appears as an eccentric osteolytic area extending into the cancellous bone with overlying cortical thinning. Because of the rapid growth, a more aggressive appearance with cortical disruption also can be seen (Fig. 59.17A). On CT or MRI, ABCs are typically cystic, with multiple locules and fluid-fluid levels representing the underlying hemorrhagic nature of the lesion (Fig. 59.17B). ABCs do not have an associated soft tissue component.[61,76]

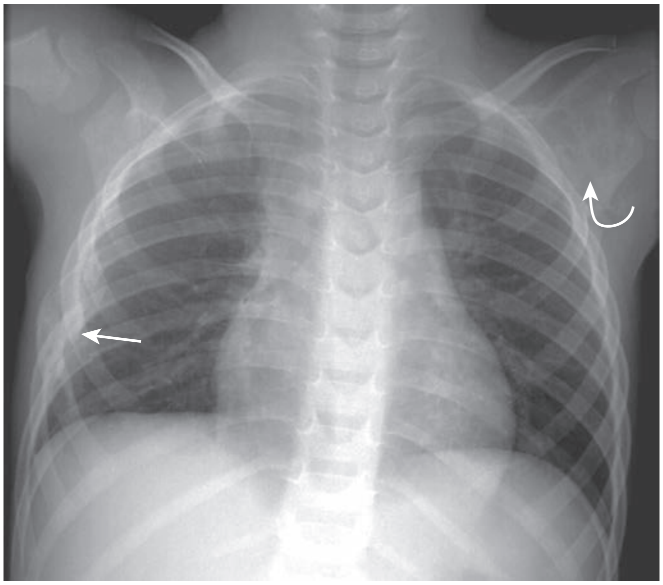


**Figure 59.15. Langerhans cell histiocytosis of a rib and left scapula in a young boy who presented with chest pain.** Frontal chest radiograph shows a lytic, slightly expansile lesion involving a segment of the right sixth rib *(straight arrow)* with cortical disruption. A second lytic lesion *(curved arrow)* with rather defined borders involves the left scapular neck.

***Treatment and Follow-up.*** LCH treatment is not standardized. Solitary LCH lesions initially can be managed conservatively with close radiographic follow-up, because some of these lesions may heal spontaneously with bone remodeling. Alternatively, the lesion can be treated with curettage and bone grafting. More disseminated disease may require systemic chemotherapy.[73,74] Incidental enchondromas, especially the solitary ones, require no treatment. For symptomatic lesions that often are associated with pathologic fractures, curettage and bone grafting usually are curative.[77] ABCs can be treated with selective arterial embolization, percutaneous sclerotherapy, or excision with bone grafting.[78,79] En bloc resection of ABC is recommended for small lesions located in the ribs. For large lesions, excision with bone grafting may be necessary.[76]

## Malignant Tumors

### Soft Tissue Tumors

**Rhabdomyosarcoma**

***Etiology.*** Rhabdomyosarcoma (RMS) tumors are the second most common primary malignancy that occurs in the chest wall in children.[80] RMS arises from primitive mesenchymal cells committed to develop into striated muscles. It can arise from any tissue anywhere in the body, except from cortical bone.[80] Tumors of the trunk account for 7% of all RMS tumors.[81] In children, the age-standardized annual incidence rate for RMS is 4 to 7 per million. In a study of 15 chest wall tumors out of 303 RMS tumors, the mean age of diagnosis was 16 years.[82] Affected children typically present with a painful and rapidly enlarging chest wall mass.[82,83]

***Imaging.*** On ultrasound, RMS presents as a heterogeneous soft tissue mass with increased internal vascularity. The outer margin of the tumor may be either well defined or ill defined. For a complete assessment of tumor extension, CT or MRI is necessary. Although CT is more sensitive than MRI for the evaluation of osseous abnormality and pulmonary metastatic disease, MRI is better than CT for assessment of the local extension of the tumor. On CT and MRI, chest wall RMS usually presents as

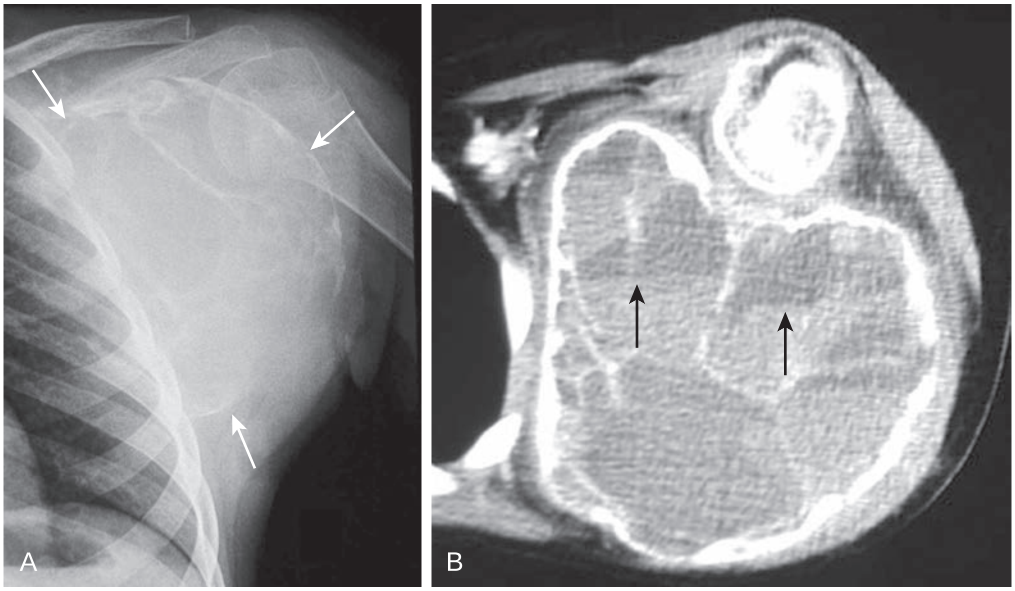

**Figure 59.17. Aneurysmal bone cyst in a patient with a slowly growing left shoulder mass.** (A) Frontal radiograph of the left shoulder demonstrates a very large expansile lytic lesion *(arrows)* arising from the left scapular wing. Thin bony septations are seen inside the lesion. The inferior margin of the lesion is indistinct. (B) Axial contrast-enhanced CT image clearly shows the expansile lytic lesion containing multiple bony septae arising from the left scapular wing and its relationship with the rib cage and humerus. Several slightly hyperintense fluid-fluid levels are seen in some of the internal locules *(arrows).*

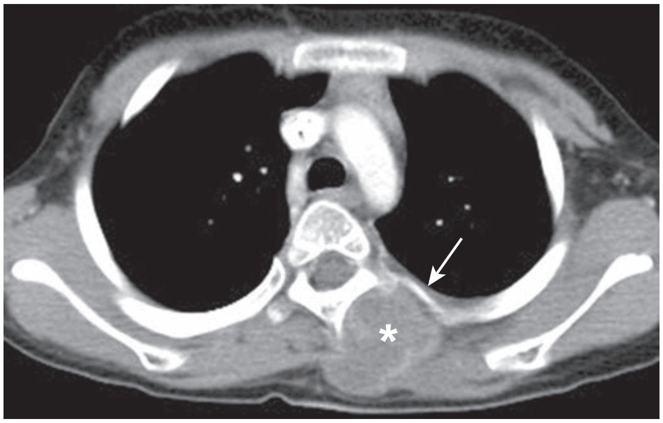

**Figure 59.18. Rhabdomyosarcoma of the left paraspinal musculature in a 14-year-old girl who presented with a painful, palpable, soft tissue lump.** Axial contrast-enhanced CT image shows a well-defined, slightly hypodense mass in the left paraspinal region *(asterisk).* The mass causes mild remodeling of the underlying bone but no destruction *(arrow).*

a large, heterogeneous, soft tissue mass with intrathoracic extension. The tumor tends to show a heterogeneously increased signal on T1 and fluid-sensitive MRI sequences. RMS mass typically displays enhancement that is heterogeneous contrast enhancement in cases of underlying tumor necrosis.[5,84-86] In comparison with Ewing sarcoma family of tumors (ESFT), bone involvement is much less frequent in children with an RMS, and if present, it tends to occur later in the course of the disease (Fig. 59.18).[84]

***Treatment and Follow-up.*** The current treatment of RMS tumors of the chest wall is chemotherapy to control local disease and reduce the size of the mass before surgical resection. Radiotherapy often is used if surgical resection margins are positive.[80,83] Because of its higher sensitivity in detecting residual, recurrent, or metastatic disease, CT positron emission tomography (PET) in conjunction with MRI currently is recommended as the follow-up imaging modality of choice.[87-89]

## Osseous Tumors

### Ewing Sarcoma Family of Tumors

***Etiology.*** The Ewing sarcoma family of tumors (ESFT) represent the most common primary chest wall malignancies in children and young adults.[90] They comprise the classic Ewing sarcoma, atypical Ewing sarcoma, primitive neuroectodermal tumor, and Askin tumor. These tumors belong to the small, round, blue cell tumors that originate from unique mesenchymal cells capable of multilineage differentiation. Based on their varied but similar underlying neural differentiation, their immunohistochemical, cytogenetic, and molecular uniformity, and their identical response to Ewing-based chemotherapy regimens, tumors such as ESFT are regarded as being related to sarcomas. A common chromosomal translocation (t11; 22) (q24; q12) has been implicated in 80% to 95% of cases. ESFT lesions have been reported in all age groups, but most cases are diagnosed in the second decade of life, with a median age of 15 years.[91] It is more common in males, with a ratio of 1.3 : 1 to 1.5 : 1, and has a predilection for white persons.[91] Affected children usually present with a rapidly growing palpable chest wall mass that often is painful. In cases with pleural effusions and substantial mass effect on the lung, dyspnea can be the predominant symptom. Pediatric patients with a paraspinal ESFT may present with symptoms related to neurologic impairment. Systemic symptoms such as fever, and laboratory test abnormalities, including leukocytosis and an elevated erythrocyte sedimentation rate, may simulate infectious processes such as osteomyelitis.[83,91]

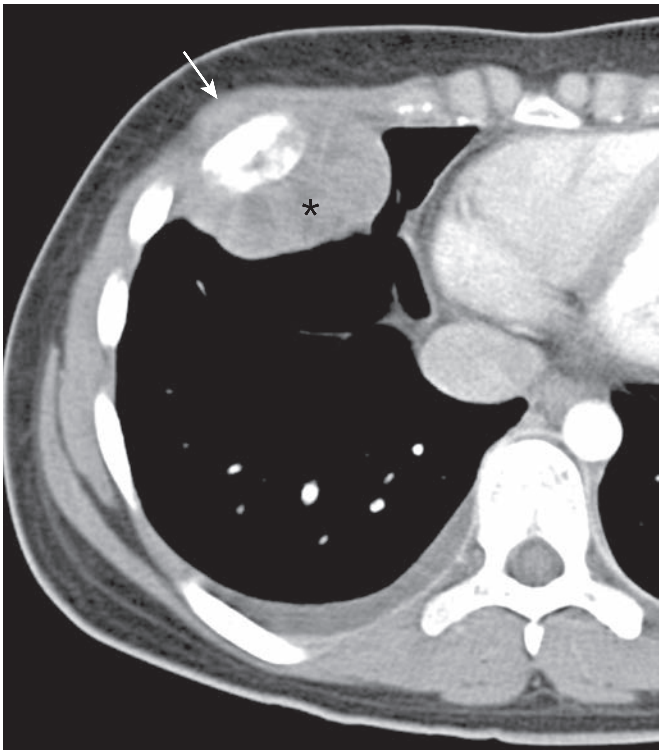

**Figure 59.19. Ewing sarcoma of a rib in an 11-year-old boy who presented with a painful, palpable lump in the anterior chest wall.** Axial contrast-enhanced CT image shows focal thickening of the anterior aspect of a right rib *(arrow)* surrounded by a soft tissue mass *(asterisk).*

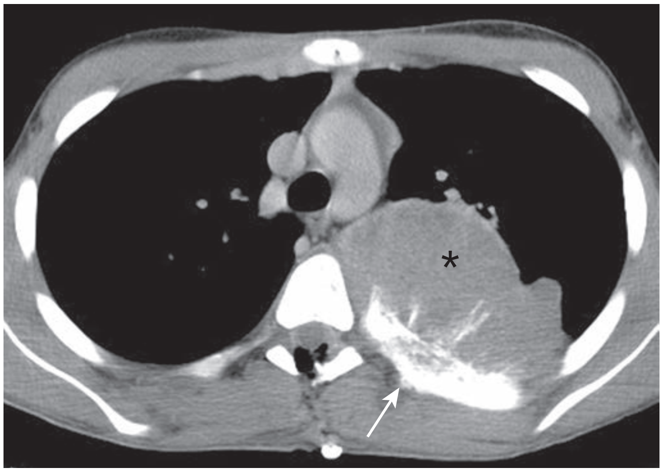
***Imaging.*** On chest radiographs, ESFT usually presents as an extraparenchymal and lytic osseous mass with associated bone destruction and aggressive periosteal reaction. An associated soft tissue component can be suggested on plain radiographs but is best seen on CT or MRI (Fig. 59.19).[91-93] Calcifications within the mass may be present in approximately 10% of cases.[93] On CT and MRI, an ESFT mass typically presents as a lytic and destructive osseous lesion associated with aggressive periosteal reaction and heterogeneous soft tissue components (e-Fig. 59.20). On MRI, the soft tissue component is isointense or slightly hyperintense to muscle and hyperintense on fluid-sensitive sequences. Heterogeneous contrast enhancement is seen frequently, except in areas of necrosis. Pleural effusions that obscure the soft tissue mass can be present. Regional lymphadenopathy in patients with ESFT is unusual.[91-94]

***Treatment and Follow-up.*** Chest wall ESFT is currently treated with chemotherapy to reduce the size of the tumor and achieve optimal local control, as well as to treat distant microscopic metastatic lesions, followed by surgical resection.[80,83,90,91] Currently, CT-PET is used to stage the tumor and monitor patients. CT in the follow-up of these patients plays an important role in detecting pulmonary metastasis, because surgical resection of the pulmonary metastasis and radiotherapy may be curative.[87,95]

### Osteosarcoma

***Etiology.*** Chest wall osteosarcoma is rare. Osteosarcomas that do present in this location occur more frequently in younger children. It can arise from a rib, scapula, or clavicle or can be a focus of metastatic disease.[83] The incidence of osteosarcomas is 4.8 per 1 million children, with about 1% located in the chest wall and spine.[83] The peak incidence of osteosarcoma lesions occurs in the second decade of life.[96] Much like the other malignant chest



**e-Figure 59.20. Primitive neuroectodermal tumor of a rib in a 10-year-old boy with back pain.** Axial contrast-enhanced CT image shows a large, extrapleural, soft tissue mass arising from the medial aspect of a left rib *(asterisk).* The patient has aggressive associated periosteal reaction, sclerosis, and thickening of the rib *(arrow).*

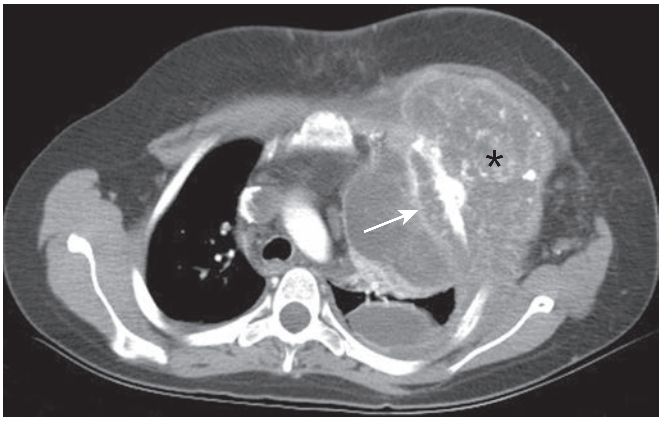


**Figure 59.21. Osteosarcoma in an adolescent boy who presented with a painful asymmetry of the anterior chest wall.** Axial contrast-enhanced CT image shows destruction of a left rib with aggressive periosteal reaction *(arrow)* and a large, partially calcified soft tissue mass *(asterisk)* that is causing deformity of the anterior left chest wall.

wall tumors, osteosarcomas typically present as rapidly growing and usually painful chest wall masses.

***Imaging.*** An osteosarcoma typically demonstrates prominent new bone formation on all imaging modalities. Chest radiographs show a lytic or blastic osseous lesion with a soft tissue mass containing calcifications. On CT, areas of bone formation characteristically are seen at the center, rather than the periphery, of the lesion (Fig. 59.21). On MRI, the areas of bone formation are seen as hypointense relative to muscle on T1-weighted images. A mixed but predominantly hyperintense mass is seen on fluid-sensitive sequences. Heterogeneous contrast enhancement of the soft tissue component of an osteosarcoma indicates necrosis.[86]

***Treatment and Follow-up.*** Chemotherapy and surgical resection constitute the current treatment of choice for chest wall osteosarcoma; this lesion is relative insensitivity to radiotherapy. The possibility of complete surgical resection is the primary factor in determining the ultimate outcome of affected patients.[80]

## TRAUMA OF THE CHEST WALL

### Overview

The chest wall in children is more elastic and flexible than in adults because of its larger cartilaginous component, and thus less force is absorbed by the chest wall with impact and proportionally more force is transmitted to intrathoracic organs. Thus intrathoracic injury may occur without visible damage to the chest wall. Although death from a chest injury is uncommon, after head injury, chest trauma is the second most common cause of death in pediatric patients. In children younger than 12 years, 60% to 80% of chest injuries are the result of blunt trauma, and more than half are accounted for by impact with motor vehicles.[97-99] However, among infants and young children, it is important to recognize that rib fractures occur most commonly as the result of nonaccidental trauma.[100-103]

***Etiology.*** Rib fractures constitute the majority of chest wall injuries in children. In a prospective study of 80 children after thoracic trauma, 28 (35%) had rib fractures, and one (1%) had a sternal fracture.[100] Rib fractures occur as a result of blunt trauma, such as falls or motor vehicle accidents. In pediatric trauma, the location of rib fractures is more a function of the mechanism of injury than the magnitude of the force that is transferred, although the number of fractured ribs is proportional to the severity of the trauma and the likelihood of associated multisystemic injury.[103]

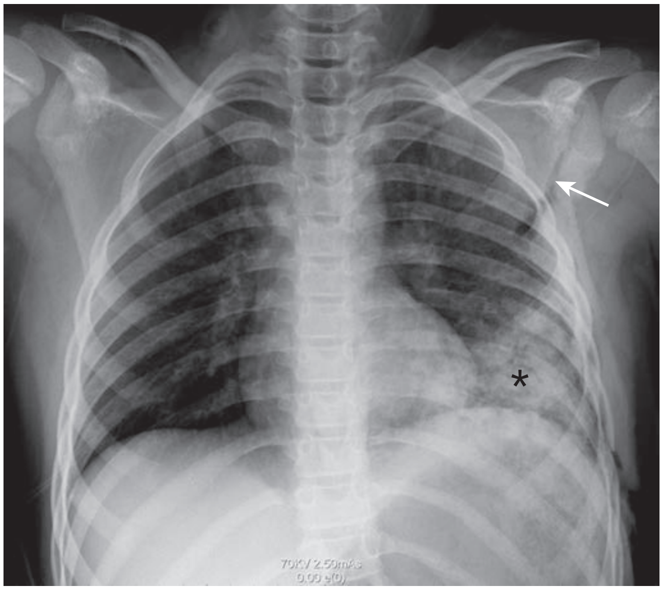

**Figure 59.22. Multiple fractures of the left ribs and a left scapular fracture in a young boy involved in a high-speed jet ski accident.** Frontal chest radiograph shows fractures of the seventh through ninth left ribs posterolaterally and more subtle fractures of the left tenth and eleventh ribs. A minimally diastatic fracture *(arrow)* is seen through the neck and body of the left scapula. Subcutaneous emphysema is seen along the lateral side of the left chest wall, as well as a fluffy consolidation *(asterisk)* in the left lower lobe consistent with a pulmonary contusion.

In infants or young children (<3 years) without underlying metabolic bone disease, rib fractures are very unusual and highly suggest nonaccidental trauma as a result of abuse.[104] Although fractures related to abuse can occur along any part of the ribs, when they are posterior in location they are highly specific for nonaccidental trauma (see also Chapter 143). This specificity occurs because of the substantial posterior levering force that the transverse processes exert over the posterior aspect of the ribs, resulting in fracture during a tight squeeze by the perpetrator.[26,104] In addition to abuse, birth trauma and diseases associated with underlying bone fragility, such as rickets and osteogenesis imperfecta, are other rare causes of rib fractures in infants and young children.[105]

***Imaging.*** In the acute setting, the initial assessment of possible traumatic chest wall injury usually requires chest radiographs. Once the diagnosis of rib fractures is established, careful attention to exclude associated intrathoracic injury must be provided. The most commonly associated nonosseous abnormality with chest wall injury is pulmonary contusion (Fig. 59.22), followed by pneumothorax. In the case of unconscious and hemodynamically unstable pediatric patients, a CT of the chest with contrast using CT angiography technique can be performed to evaluate intrathoracic vascular and nonvascular structures.[99,100] First rib fractures are uncommon but suggest severe trauma and increased risk of intrathoracic vascular injury.[106] Flail chest occurs when a segment of the rib cage fractures and becomes detached from the rest of the chest wall, but is rare in the pediatric population compared with adults.[107] Lower rib fractures can be associated with traumatic injury to the upper abdominal organs, such as the liver, spleen, and kidneys.[108]

In cases of suspected child abuse, a skeletal survey must be obtained. Acute nondisplaced rib fractures can be difficult to detect on radiographs in infants and young children. These fractures become more apparent during healing, when callus is present (Fig. 59.23). Fractures involving the anterior and posterior ends

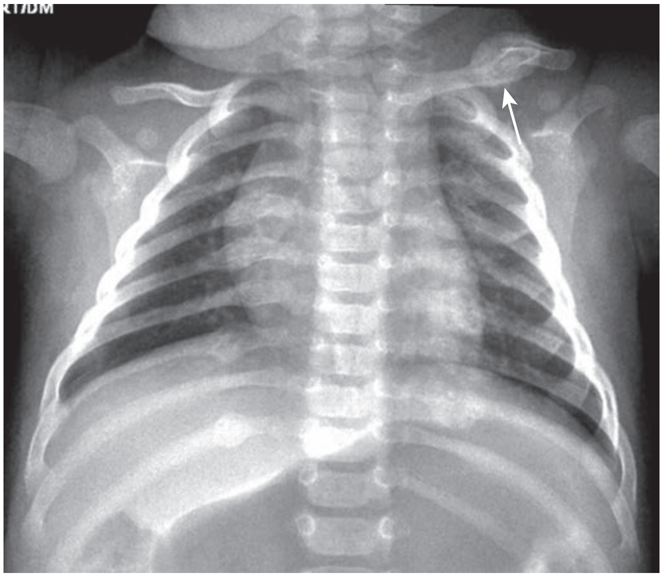

**Figure 59.23. Multiple bilateral rib fractures in a young girl who sustained nonaccidental trauma.** Frontal chest radiograph shows multiple, consecutive, bilateral, posterior rib fractures in the stage of healing. A healing fracture of the left clavicle is also present *(arrow).*

of a rib can be seen better on oblique radiographic views. The presence of acute and healing rib fractures is highly suggestive of abuse.[26,104,105] First rib fractures can be seen in the setting of child abuse.[109] Because not all chest wall fractures are detected on radiographs, a bone scintigraphy or follow-up radiographs may be necessary.[26,104] Assessment of the chest wall musculature and soft tissue injury can be performed with ultrasound or MRI. Ultrasound also allows dynamic evaluation of muscle function.[110]

***Treatment and Follow-up.*** The treatment of rib fractures is supportive, with pain medications and aggressive respiratory therapy to prevent atelectasis and pneumonia. In cases of flail chest, ventilatory support during the healing phase may be necessary.[99,102] Because nondisplaced acute rib fractures can be difficult to identify on plain radiographs, follow-up chest radiographs or bone scintigraphy can be obtained approximately 1 week later to increase the detection of fractures in cases of suspected child abuse.[26,104] Nonoperative, conservative treatment currently is advocated for the low-grade muscular and musculotendinous injury of the chest wall. Early surgical intervention is recommended for patients who have complete tears or avulsion of tendon from the bone.[110]

## KEY POINTS

- Palpable but otherwise asymptomatic chest wall masses in children usually are congenital or developmental osseous or cartilaginous normal anatomic variants.
- Congenital malformations of the chest wall can be isolated or part of a syndrome. These malformations usually cause cosmetic rather than physiologic problems. The two most common chest wall deformities are pectus excavatum and pectus carinatum.
- Chest wall infections in children are rare and usually occur as a result of hematogenous dissemination or local spread. Unusual organisms causing chest wall infections in children include actinomycosis and tuberculosis, and the imaging manifestations may be confused with malignancies.
- Malignant chest wall tumors in children are uncommon and usually present with a rapidly growing, painful mass. Malignant chest wall tumors include rhabdomyosarcomas, which usually involves the soft tissues; the Ewing sarcoma family of tumors; and osteosarcomas, which most commonly involve a rib.
- The chest wall in children is more elastic and flexible than in adults; therefore the chest wall absorbs less impact force, and more force is transmitted to intrathoracic organs. This mechanism allows intrathoracic injury to occur without visible chest wall injury. The presence of rib fractures in pediatric patients indicates a significant traumatic force, and associated internal injuries must be suspected and investigated.

# 60

# The Pleura

Ricardo Restrepo and Edward Y. Lee

The pleura is a serous membrane consisting of two layers, the visceral and the parietal pleura. The parietal pleura covers the inner aspect of the chest wall and the diaphragm. The visceral pleura is strongly adherent to the surface of the lungs and interlobar fissures. In normal conditions, no imaging study can visualize the pleural space because pleural membranes are only 0.2 to 0.4 mm thick, and the physiologic volume of pleural fluid forms a thin 5- to 10-micron layer. However, in children, various pathologic processes can occur within this space that require imaging evaluation. In this chapter, etiologies, imaging characteristics, treatment, and follow-up of pathologic processes involving the pleura are discussed.[1-4]

## PLEURAL EFFUSION

***Etiology.*** The lymphatic system plays an important role in the homeostasis of pleural fluid. Excess production or decreased absorption of lymphatic fluid can result in an increased volume of pleural fluid.[1-5]

Causes of pleural effusion in pediatric patients differ substantially from those in adults. Whereas the most frequent cause of pleural effusions in adults is congestive heart failure, pleural effusions in children are most commonly a result of underlying pleuropulmonary infection (Table 60.1).[3] Although pediatric patients with small pleural effusions are usually asymptomatic, large pleural effusions can result in symptomatic respiratory distress or inspiratory pleuritic chest pain as a result of stretching or irritation of the parietal pleura.[3] When infection is the underlying cause, the predominant symptoms are cough, dyspnea, fever, and elevated white blood cell counts.[1,3]

***Imaging.*** Chest radiography plays an important first-line role in the initial diagnosis of pleural effusions in children. The radiographic appearance depends on the volume and consistency of the pleural fluid, the patient's position, and the presence of septations and/or loculations. On chest radiographs, a free-flowing effusion forms an internally concave meniscus paralleling the chest wall that changes in position on lateral decubitus radiographs. On supine radiographs, mobile fluid may layer over the hemithorax, resulting in diffuse opacity. The presence of a lentiform-shaped effusion with internal convex margins is suggestive of a loculated pleural effusion.[2,6]

The most common indication of chest ultrasound in children is to characterize an opaque hemithorax seen on a chest radiograph (Fig. 60.1).[6,7] Ultrasound is the best imaging modality for diagnosing and characterizing pleural fluid.[7] Ultrasound is more sensitive than radiographs in detecting pleural fluid, particularly when the amount is small (approximately 5 mL).[2,8]

The internal echogenicity of pleural effusions on ultrasound can be categorized into four types (Table 60.2): (1) homogeneously anechoic (see Fig. 60.1B); (2) nonseptated with internal low-level echoes (e-Fig. 60.2); (3) septated (e-Fig. 60.3A); and (4) homogeneously echogenic (Fig. 60.4A).[7,9] Anechoic and free-flowing effusions are called simple pleural effusions, and the remainder are classified as complex pleural effusions.

Computed tomography (CT) also is more sensitive than chest radiographs in detecting small pleural effusions. The advantage of CT is that it provides an unobstructed view of the entire underlying lung parenchyma, mediastinum, and chest wall; however, it is associated with ionizing radiation exposure. Intravenous administration of contrast material is necessary to optimally visualize and assess the pleura and lung parenchyma (Fig. 60.4B). In comparison to ultrasound, CT is limited in characterizing pleural effusions and demonstrating internal septations (see e-Fig. 60.3).[2]

***Treatment and Follow-up.*** Thoracentesis is useful in evaluating the underlying cause of a pleural effusion and also in relieving symptoms. Indications for thoracentesis in children with pleural effusions are persistent fever, respiratory compromise, mediastinal shift, pleuritic pain, and underlying lung disease.[3]

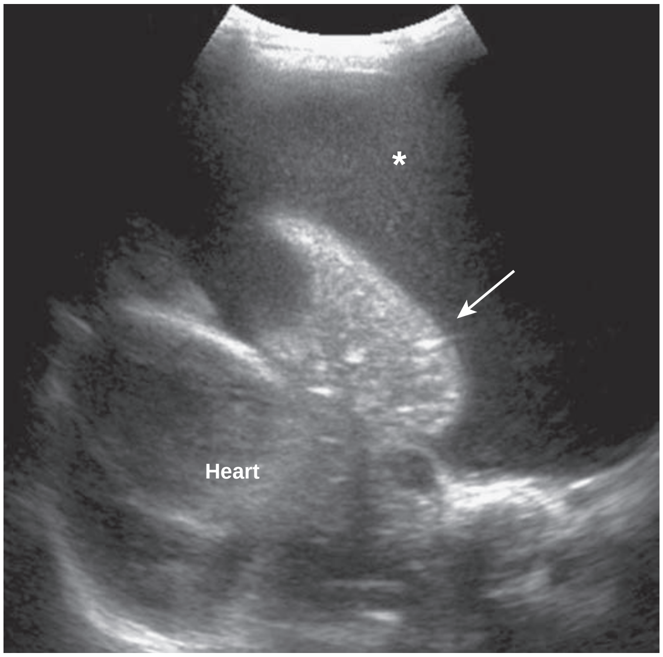
## PARAPNEUMONIC EFFUSION AND EMPYEMA

***Etiology.*** A parapneumonic pleural effusion refers to a pleural fluid collection in association with an underlying pneumonia, whereas empyema is the presence of pus in the pleural space.[1,10] *Streptococcus pneumoniae* is still the main etiologic agent in parapneumonic effusions in children, although the number of cases caused by *Staphylococcus aureus* has increased.[1,10,11] More recently, the *Streptococcus milleri* group, typically found in the oropharynx and upper respiratory and gastrointestinal tracts, has been recognized as an important pathogen causing purulent pleuropulmonary infections, especially in immunocompromised patients.[12]

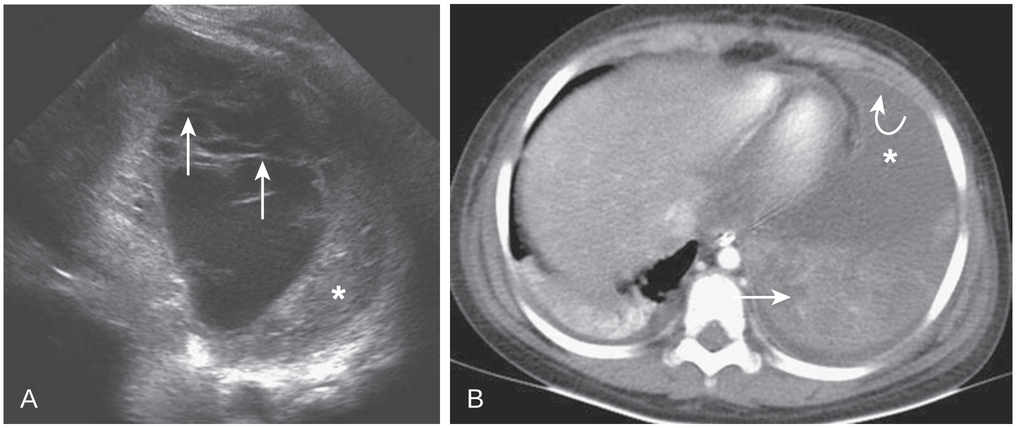
Pleural infection can be classified into three phases based on the progression of infection: exudative, fibrinopurulent, and organizing (Box 60.1). During the exudative phase, the inflammatory process associated with the underlying pneumonia leads to the accumulation of free-flowing clear fluid within the pleural cavity. During the fibrinopurulent phase, deposition of fibrin and white blood cells in the pleural space results in septations and loculations, limiting the flow of pleural fluid. The organizing phase begins when fibroblasts infiltrate the pleural cavity, forming a thick rigid pleural rind. This pleural rind may prevent lung reexpansion, impair lung function, and create a persistent pleural space with ongoing potential for infection.[1,6,13]

***Imaging.*** A chest radiograph is the initial imaging modality for assessing the presence of parapneumonic effusions. Ultrasound subsequently can be obtained for characterization of the parapneumonic effusion. As the underlying infection progresses, parapneumonic effusions may develop low-level internal echoes and floating debris (see e-Fig. 60.2) followed by septations and loculations (see e-Fig. 60.3A), preventing free motion of the fluid. The internal echoes indicate increased underlying cellularity of fluid; these pleural effusions are usually exudates but not necessarily empyemas.[1,6,7,9,14] The parapneumonic effusion eventually may become semisolid in appearance on ultrasound (see Fig. 60.4A). The development of pleural thickening indicates the presence of a fibrous capsule.

The routine use of CT is not necessary to evaluate parapneumonic pleural effusions.[1,6,15] However, CT with intravenous contrast may aid in the evaluation of the lung parenchyma when a complication such as a bronchopleural fistula is suspected (Fig. 60.5) or in the differentiation of a parapneumonic effusion from a lung abscess.[2] An imaging finding suggestive of empyema on CT is a lentiform-shaped fluid collection with pleural thickening and/or enhancement.[16] In contrast, lung abscesses tend to be round and are embedded within the lung parenchyma rather than displacing it.[2] Loculations in parapneumonic effusions, which are best visualized by ultrasound, can be suggested on CT indirectly when the surface of the underlying lung shows smooth indentations due to fibrin



**e-Figure 60.2. Complex effusion with low-level echoes in a 9-year-old girl with bacterial pneumonia.** An ultrasound image of the left hemithorax reveals a large parapneumonic pleural effusion with floating low-level echoes indicating debris *(asterisk)* and the consolidated underlying lung *(arrow).*



**e-Figure 60.3. Complex septated effusion in a 6-year-old patient with bacterial pneumonia.** (A) Ultrasound image of the left hemithorax shows a large parapneumonic effusion with multiple septations *(arrows).* Consolidation of the adjacent lung also is present *(asterisk).* (B) Axial contrast-enhanced CT image shows the pleural effusion *(asterisk)* in the anterior aspect of the left base. The septations seen on the ultrasound are not clearly visualized on CT. Pleural enhancement is present *(curved arrow)* adjacent to consolidated lung *(straight arrow).*

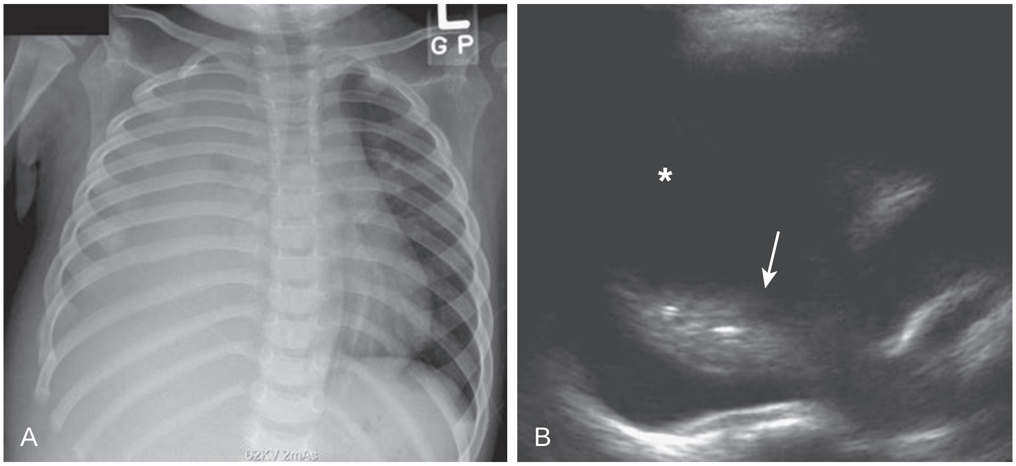


**Figure 60.1. Simple effusion in a 2-year-old boy.** (A) Chest radiograph shows complete opacification of the right hemithorax with obliteration of the right side of the mediastinum and hemidiaphragm. The cardiac and tracheal deviations to the left are imaging findings suggestive of a pleural effusion. (B) Ultrasound of the right hemithorax confirms the presence of a large simple pleural effusion *(asterisk)*. Consolidation *(arrow)* of the underlying lung also is seen.

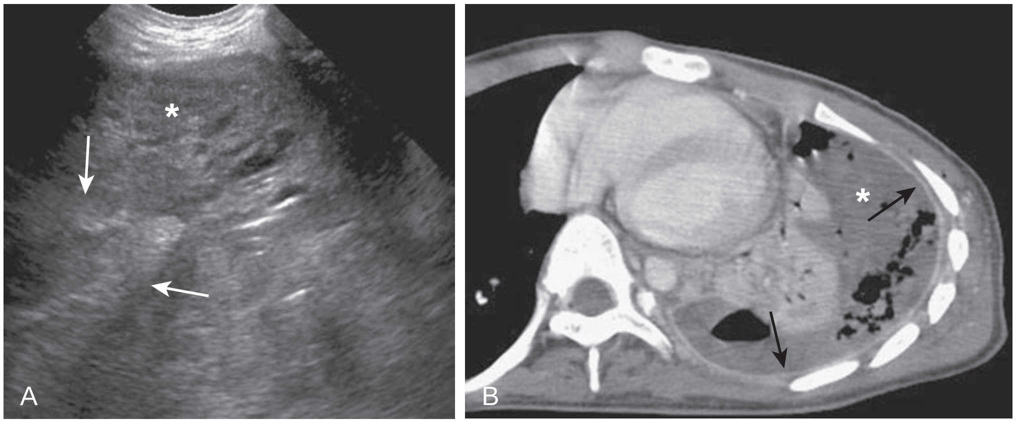

**Figure 60.4. Complex effusion in a 6-year-old patient with bacterial pneumonia.** (A) Ultrasound image shows a mostly solid-appearing parapneumonic effusion *(arrows)*. The consolidated underlying lung *(asterisk)* also is seen. (B) Axial contrast-enhanced CT image shows the large pleural effusion *(asterisk)* with pleural enhancement *(arrows)*.

**TABLE 60.1** Phases of Pleural Infection

| Phase | Description |
|---|---|
| Exudative | Pleural inflammation leads to accumulation of free-flowing clear liquid |
| Fibrinopurulent | Deposition of fibrin in the pleural space results in septation/loculations limiting the flow of fluid; pus accumulates in the pleural cavity |
| Organizing phase | Fibroblasts infiltrate the pleura, forming a rigid pleura and preventing lung expansion |

**BOX 60.1** Common Causes of Pleural Effusions in Children

- Bacterial pneumonia
- Renal disease
- Trauma
- Viral infection
- Malignancy
- Congenital heart disease
- Liver failure
- Sickle cell disease

**TABLE 60.2** Pleural Effusions on Ultrasound Based on Internal Echogenicity

| Type of Effusion | Description |
|---|---|
| Simple | Homogeneously anechoic |
| Complex | Nonseptated with internal low-level echoes<br>Multiseptated<br>Homogenously echogenic |

strands that produce intrapleural adhesions, or in the presence of a lentiform-shaped pleural fluid collection.[2] The presence of air or gas in the dependent portion of the effusion also suggests loculation (see Fig. 60.4B). In the absence of a previous thoracentesis or thoracostomy tube placement, the presence of air/gas or an air-fluid level in the pleural cavity in a patient with pneumonia is diagnostic of a bronchopleural fistula (see Fig. 60.5).[1,2,6,17,18]

***Treatment and Follow-up.*** Anechoic simple pleural effusions can be managed by thoracentesis or percutaneous placement of a chest tube. Because 50% of parapneumonic effusions recur after aspiration in children, the routine placement of a drainage catheter currently is recommended after aspiration.[7] Distinction between parapneumonic pleural effusions and empyema in children is less

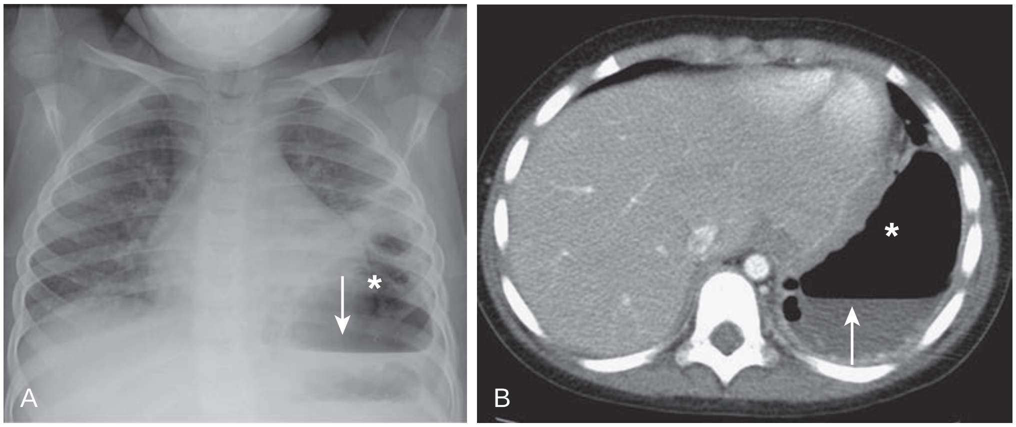

**Figure 60.5. Bronchopleural fistula in a 4-year-old boy with necrotizing pneumonia.** (A) Frontal chest radiograph shows a collection of air in the left pleural space superior to the gastric bubble *(asterisk),* with an air-fluid level *(arrow)* indicating a hydropneumothorax. (B) Axial contrast-enhanced CT image of the same patient confirms the presence of air in the pleural space *(asterisk)* and the air-fluid level *(arrow).*

important than in adults because diagnostic thoracentesis is rarely performed before definitive treatment in children with clinically suspected pleuropulmonary infection.[1,6]

The management choice for complex pleural effusions in children, particularly in the presence of septations, is currently somewhat controversial. Some investigators advocate the use of percutaneous insertion of a chest tube combined with instillation of a fibrinolytic agent, whereas others support the use of video-assisted thoracoscopy (VATS).[1,19-24] The presence of septations or complex effusions is not necessarily a contraindication for percutaneous drainage. However, concomitant fibrinolytic therapy typically is required and should be started promptly to maximize the benefit of the procedure.[25,26] In a retrospective study consisting of 54 pediatric patients with parapneumonic effusions, chest tube insertion with intrapleural instillation of a fibrinolytic agent was successful, safe, and less costly as the first therapeutic option compared with VATS.[27] A recent cost-effective analysis study of the management of empyema in children that was conducted with a Bayesian tree approach showed that chest tube insertion with instillation of a fibrinolytic agent was the most cost-effective strategy for treating pediatric empyema based on the length of hospital stay.[28] The management of bronchopleural fistulas is initially medical, including pleural space decompression with a thoracostomy tube and nutritional support. When conservative management is ineffective, closure of the fistula must be considered through VATS for peripheral fistulas and through an open thoracotomy for central fistulas.[17,29]

In children with parapneumonic effusions or empyema that is successfully treated, most chest radiographs return to the baseline in 3 to 6 months. The British Thoracic Society currently recommends follow-up chest radiographs 4 to 6 weeks after treatment of parapneumonic effusion or empyema.[1] In cases of no improvement on follow-up chest radiographs, a subsequent ultrasound or CT scan may be beneficial to exclude underlying complications.[1,6,30]

## PNEUMOTHORAX

***Etiology.*** Pneumothorax is the presence of air in the potential space between the parietal and visceral pleura. Pneumothorax is classified as spontaneous or traumatic depending on the underlying etiology. Spontaneous pneumothorax can be further subdivided into primary and secondary. Primary spontaneous pneumothorax occurs in an otherwise healthy child and often is attributed to a ruptured preexisting apical bleb or bulla. Secondary spontaneous pneumothorax occurs as a complication of an underlying pulmonary disease, most commonly asthma and cystic fibrosis in children.[31,32] In the United States, the incidence of spontaneous pneumothorax is approximately 1.8 to 7.4 per 100,000 in boys and 1.2 to 6 per 100,000 in girls. The mean age at presentation is 14 to 15.9 years.[31,33] The classic phenotype is a thin, tall male with a low body mass index. Children with primary spontaneous pneumothorax typically present with a sudden onset of unilateral chest pain and dyspnea at rest. Patients with secondary spontaneous pneumothorax often present with cardiopulmonary distress.[31,33] Traumatic pneumothorax occurs as a result of blunt or penetrating mechanisms, with iatrogenic pneumothorax being a subset resulting from medical procedures. The most concerning outcome of traumatic pneumothorax is progression to tension pneumothorax. Tension phenomenon occurs when the lung or airway defect acts as a check-valve mechanism, allowing flow of air into, but not out from, the pleural cavity. The diagnosis of tension pneumothorax is based on both radiologic and clinical findings. Hemodynamic and ventilatory compromise may be present with rapid cardiorespiratory collapse. On physical examination, signs of tension include neck vein distension, tracheal deviation away from the affected side, and cyanosis (Beck triad).[31] Tension pneumothorax in the absence of trauma is rare in pediatric patients, occurring in 1% to 3% of cases.[34]

***Imaging.*** Chest radiography is the initial test in the diagnosis of a pneumothorax by visualizing the visceral pleural with absence of pulmonary markings beyond the pleural margin (Fig. 60.6A). For evaluation of pneumothorax, an upright chest radiograph is the procedure of choice, with a lateral decubitus as an alternative.[31,33] Inspiratory and expiratory views are reported to be equally sensitive in the detection of pneumothorax, and thus the expiratory view does not need to be obtained routinely.[35] On chest radiographs, a tension pneumothorax is characterized by a large pneumothorax, resulting in collapse of the ipsilateral lung and shifting of the mediastinum, including the trachea, to the contralateral side.[31] Widened ipsilateral rib spaces and flattening or eversion of the diaphragm are also often seen in patients with a tension pneumothorax.

Ultrasound is increasingly used for evaluating pneumothorax, particularly in point-of-care applications, and it may be encountered during ultrasound evaluation of the pediatric chest performed for other reasons. Without a pneumothorax, the strong acoustic interface between the pleura and aerated lung produces posterior reverberations (so-called A lines). The normal sliding motion of the lung during respiration also is visualized. When air is introduced into the pleural space, the normal tension between the pleural layers is lost and a gap is created between the parietal and visceral

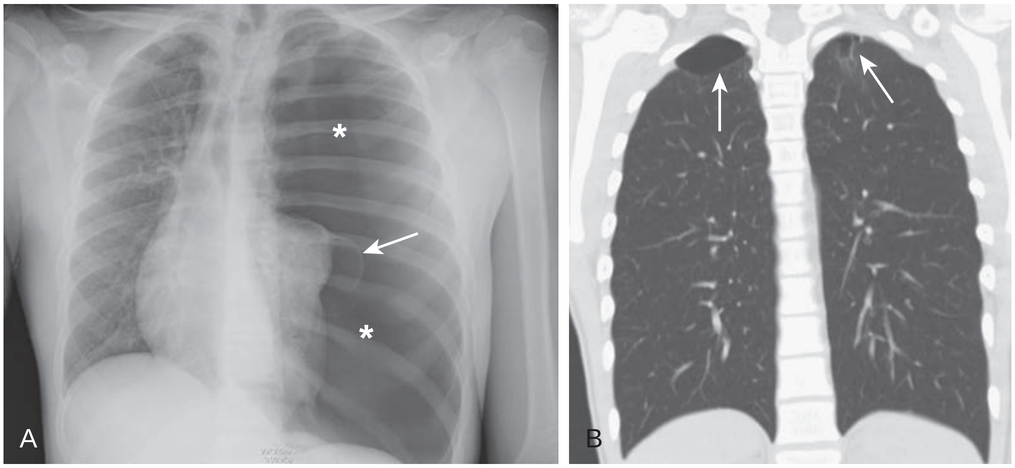

**Figure 60.6. Spontaneous pneumothorax in a tall, thin teenager presenting with tachypnea, tachycardia, and normal blood pressure.** (A) Frontal chest radiograph shows a large pneumothorax occupying the entire left hemithorax *(asterisks),* with a mild cardiomediastinal shift to the right. A bleb is noted along the surface of the collapsed left lung *(arrow).* (B) Coronal CT image obtained 1 month after thoracostomy tube removal shows biapical blebs *(arrows),* which are larger on the right. The right apical bleb was not seen on the chest radiographs.

pleura, disrupting the normal acoustic interface. The sliding of the underlying lung no longer can be seen, and the normal reverberation is replaced by a static homogeneous acoustic shadowing.[7,31] A literature review published in 2010 reported a sensitivity between 86% and 98% and a specificity between 97% and 100% for ultrasound compared with a sensitivity between 28% and 75% for supine chest radiographs in detecting pneumothorax.[36]

In cases of primary spontaneous pneumothorax, a CT scan may play a role in identifying preexisting subpleural blebs and bullae (Fig. 60.6B). The exact relationship between blebs and primary spontaneous pneumothorax is not clear. However, with CT there is an increased recognition of subpleural blebs in patients with primary spontaneous pneumothorax and, in particular, in patients presenting with recurrent pneumothoraces.[37-42]

***Treatment and Follow-up.*** No pediatric-specific management guidelines for primary spontaneous pneumothorax have been developed to date. Pediatric patients have not been addressed separately in the available international guidelines.[32,33] In the setting of primary spontaneous pneumothorax, observation should be the initial management of choice for small closed pneumothoraces separated less than 2 cm from the chest wall in asymptomatic patients. Administration of oxygen should be considered because it may increase the rate of reabsorption of the pneumothorax. Symptomatic pneumothoraces, whether primary or secondary, require active intervention with a simple aspiration or placement of a thoracostomy tube in cases of a large pneumothorax.[31,32] When a tension pneumothorax is present, urgent insertion of a large-bore needle or angiocatheter should be inserted in the affected side at the second intercostal space to decompress the tension pneumothorax.[31]

The risk of recurrence after a single episode of spontaneous pneumothorax with conservative treatment ranges from 16% to 52%.[42] Patients with a primary spontaneous pneumothorax that is treated successfully by a simple aspiration should be observed before discharge. Patients with a spontaneous pneumothorax who are discharged without intervention should have a follow-up chest radiograph after 2 weeks. Patients who have a secondary pneumothorax that is treated with simple aspiration should be admitted for 24 hours for a repeat chest radiograph to ensure no recurrence.[32] A recent study advocates for a CT scan of the chest in children with recurrent primary spontaneous pneumothorax or first episode of a large pneumothorax to evaluate for apical blebs or bullae.[43] It has been advocated that a limited CT scan of the lung apices with coronal reconstruction may suffice in children because most blebs and bullae occur in this location, thus allowing a decrease in radiation exposure.[33,40]

## PLEURAL NEOPLASMS

***Etiology.*** Pleural tumors in children are rare and much less common than in adults. Secondary neoplasms (i.e., metastasis or direct invasion) are more common than are primary tumors.[7] Metastatic neoplasms involving the pleura include lymphoma, neuroblastoma, Wilms tumors, rhabdomyosarcoma, and other sarcomas.[7] A metastatic Wilms tumor may involve the peritoneal, pleural, and pericardial cavities and is one of the most common causes of malignant effusions in children.[44]

Primary malignant tumors of the pleura include desmoplastic small round cell tumors and mesotheliomas. The former more commonly occur in the peritoneal cavity but may arise primarily from the pleura.[45,46] Mesotheliomas are regarded as adult-type neoplasms that rarely occur in children in the second decade. Clinicopathologic features of mesothelioma are similar to those in adults, with a predilection for the pleura, a male predominance, and a poor prognosis.[47] Malignant pleural tumors typically present with chest pain and respiratory distress, especially in the presence of a large pleural effusion.

The most common benign lesions of the pleura include a calcifying fibrous tumor, myofibromatosis, and lipomas.[45] Calcifying fibrous tumors usually are found in subcutaneous and deep soft tissues, but on rare occasions have been reported in the pleura.[45]

***Imaging.*** Malignant pleural neoplasms, whether primary or secondary, usually manifest with pleural effusions that initially are identified on chest radiographs. Ultrasound subsequently can be used for the confirmation and characterization of pleural neoplasms. Pleural metastases tend to produce large effusions with hemorrhage presenting as increased cellularity and low-level echoes on ultrasound. The presence of pleural fluid aids in the detection of nodules or masses adherent to the parietal or visceral pleura on ultrasound (Fig. 60.7).[7] CT and magnetic resonance imaging are helpful imaging modalities for evaluating the tumor, its extent, and its relationship with adjacent organs. Because of the markedly overlapping imaging findings among different types of primary and secondary pleural neoplasms, definitive diagnosis is based on histopathologic analysis. If the neoplasm is visible on ultrasound, biopsy under ultrasound guidance can be performed for the diagnosis.[7]

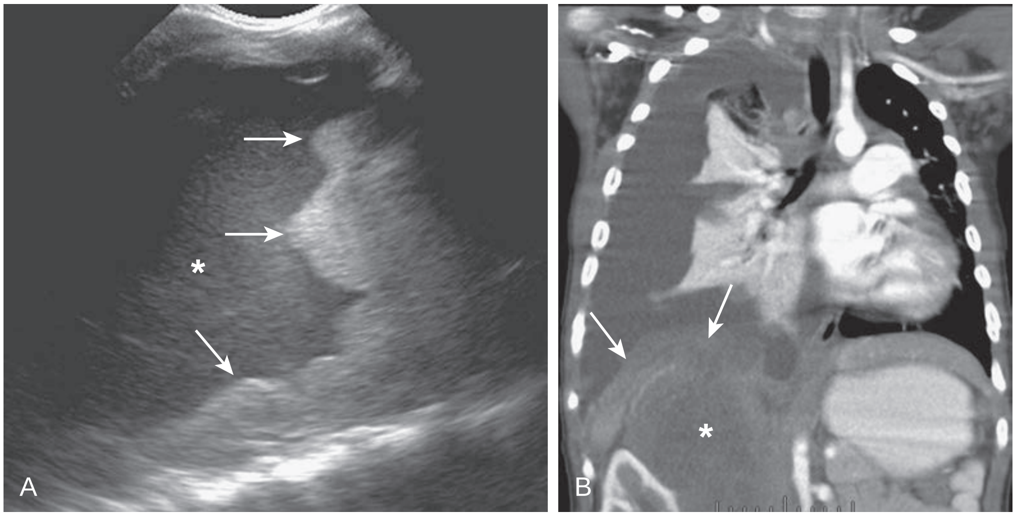

**Figure 60.7. Primary retroperitoneal rhabdomyosarcoma with metastasis to the pleura in a 3-year-old girl.** (A) Ultrasound of the right hemithorax shows a large complex effusion with low-level echoes *(asterisk)* and nodularity of the pleura *(arrows).* (B) A coronal contrast-enhanced CT image shows the large right suprarenal rhabdomyosarcoma *(asterisk).* The soft tissue along the right diaphragm and pleura indicate metastasis *(arrows).* A secondary large right pleural effusion causing collapse of the right lung also is seen.

***Treatment and Follow-up.*** The current treatment of primary malignant pleural neoplasms is surgical resection, often combined with chemotherapy. When pleural metastasis is discovered, it usually indicates advanced disease, and the treatment is aimed at treating the primary tumor. In cases of recurrent intractable pleural effusions, pleurodesis as a palliative treatment can be performed.[48]

## KEY POINTS

- Pleural effusions are best characterized on ultrasound as simple and complex. Simple effusions are anechoic, whereas complex effusions contain floating low-level echoes, septations, and/or semisolid components.
- Parapneumonic effusions and empyema are part of a spectrum of pleural infection.
- The three phases of pleural infection include exudative, fibrinopurulent, and organizing.
- The diagnosis of a tension pneumothorax is both clinical and radiologic, based on cardiorespiratory deterioration in the presence of a large pneumothorax.
- Primary spontaneous pneumothorax occurs in an otherwise healthy child and often is attributed to ruptured preexisting apical blebs or bullae.

# The Diaphragm

*Ricardo Restrepo and Edward Y. Lee*

## OVERVIEW

The diaphragm is a dome-shaped musculofibrous membrane that separates the thoracic and abdominal cavities and performs an important respiratory function. The diaphragm has a fibrous portion centrally (i.e., a central tendon) surrounded by a peripheral muscular portion. Major structures pass through three openings: caval (inferior vena cava and some right phrenic nerve branches), esophageal (esophagus, vagal nerves, and small esophageal arteries), and aortic (aorta, azygous vein, and thoracic duct). The diaphragm is innervated by the phrenic nerve, which is formed from the central nerves of C3, C4, and C5.[1,2] Diaphragmatic lesions can arise from a variety of congenital, traumatic, infectious, and neoplastic conditions.

## CONGENITAL ANOMALIES

### Duplication of the Diaphragm (Accessory Diaphragm)

***Etiology.*** Duplication of the diaphragm, also known as an accessory diaphragm, is a rare congenital anomaly. It is almost always located on the right side and frequently is associated with lobar agenesis-aplasia complex.[3,4] Although the precise pathogenesis of duplication of the diaphragm is currently unknown, it is suggested that this anomaly is the result of a defect of synchronization between the caudal migration of the septum transversum and the development of the bronchial system.[3,5] In gross pathology, the accessory diaphragm is a fine fibromuscular membrane with a serosal lining that is connected to the anterior part of the diaphragm.[3] It follows a posterosuperior direction to join the posterior chest wall, separating the right hemithorax into two parts.[3,4] It is crescentic in form and usually has an opening (i.e., central hiatus) medially, through which vessels and bronchial structures pass. Affected patients may be asymptomatic, but most present with respiratory difficulties of varying degrees.[5]

***Imaging.*** On chest radiographs or computed tomography (CT), the accessory diaphragm may have two different appearances.[3] When the central hiatus is markedly narrowed and the trapped lung is not aerated, it appears like a mass. However, when the trapped lung is aerated, the accessory diaphragm is seen as a fissure-like structure in the right base extending from the anterior aspect of the hemidiaphragm cephalad toward the posterior chest wall. On CT, it is seen as a bandlike structure with crowding of pulmonary structures as the bronchi and vessels traverse the central hiatus (Fig. 61.1).[4,5]

***Treatment and Follow-up.*** Most duplicated diaphragms require no surgical intervention or other treatment. Surgical repair should be performed only when dyspnea or recurrent respiratory infections occur.[3,5]

### Congenital Diaphragmatic Hernia

#### Overview

Traditionally, congenital diaphragmatic hernias (CDHs) have been classified according to their anatomic location. Almost 90% of CDHs are reported to involve the posterolateral aspect of the diaphragm and are referred as to Bochdalek hernias.[6] Nonposterolateral CDHs occur most often in the anterior portion of the diaphragm and are known as Morgagni hernias. However, diaphragmatic defects do not exclusively localize to these two areas, and thus some defects do not follow this classification. In addition, some diaphragmatic hernias have a sac, which is thought to represent focal thinning of the diaphragmatic musculature. Thus the terms *sac hernia* and *eventration* currently are poorly defined. Despite its limitations, an anatomic-based classification system continues to be used (Box 61.1).[6]

#### Congenital Diaphragmatic Hernia: Bochdalek

***Etiology.*** The prevalence of CDH has been reported as ranging from 1.6 to 2.3 per 10,000 births, including isolated cases and those associated with other malformations.[7,8] CDH of the Bochdalek type is associated with significant morbidity and mortality, and accounts for 90% to 95% of CDH.[6,7] Approximately 85% of these hernias occur on the left side, whereas right-sided and bilateral hernias represent only 13% and 2% of cases, respectively.[9]

The diaphragm initially develops as a septum between the heart and the liver, progresses posterolaterally, and closes at the Bochdalek foramen at approximately 8 to 10 weeks of gestation.[9,10] The primary abnormality resulting in a Bochdalek hernia is failure or delay of the pleuroperitoneal fold and transverse septum to properly fuse with the intercostal muscles around the eighth week of gestation.[10] Diaphragmatic hernia and lung hypoplasia can occur concomitantly, possibly a polygenic association.[9,11]

***Imaging.*** Many cases of CDH are initially found prenatally by ultrasound (US) or magnetic resonance imaging (MRI) (see Chapter 50). On a newborn chest radiograph a Bochdalek hernia may appear as an opacified hemithorax with contralateral cardiomediastinal shift. As the infant swallows air, the air-filled bowel located within the hemithorax may become apparent (Fig. 61.2). In the case of intraabdominal solid organ herniation, the hemithorax can remain homogeneously opacified. When the bowel-containing hernia is large, a paucity of abdominal contents causes the so-called "scaphoid abdomen" and can be seen on abdominal radiographs.[10] The position of catheters and tubes is helpful in confirming the presence of a Bochdalek hernia. The nasogastric (NG) tube deviates to the side opposite to the hernia in the chest. If the stomach is herniated within the hemithorax, the tip of the NG tube can project in the chest. The position of umbilical venous catheters is affected by the location of the liver, which is shifted either in the abdomen or chest. In contrast, the position of umbilical arterial catheters is rarely affected because of their retroperitoneal location.[12] Ultrasound with color Doppler may help delineate the venae cavae and the hepatic vasculature, and it may identify the presence of herniated solid organs before surgery. CT and MRI may play an occasional role in excluding a congenital lung anomaly such as congenital pulmonary airway malformation or pulmonary sequestration.[10]

After hernia repair, an ipsilateral pneumothorax is a common finding and should not be rapidly evacuated as this may cause mediastinal rotation and subsequent venae cavae obstruction because of the increased mobility of the neonatal mediastinum.[10] The pleural air typically reabsorbs by itself and sometimes is replaced by fluid.

***Treatment and Follow-up.*** Treatment of all types of CDH includes medical and surgical management. The medical management of CDH focuses on addressing the underlying major causes of neonatal death as a result of CDH, such as pulmonary

## Abstract:

The diaphragm is an organ that in the pediatric population, can be affected primarily by congenital, traumatic and neoplastic diseases; of these, congenital processes being the most common. On this chapter, we discuss the etiology, imaging, treatment and follow up of the different pathology affecting this organ in the pediatric population.

hypoplasia and pulmonary hypertension. It includes the use of extracorporeal membrane oxygenation, high-frequency ventilation, and inhaled nitric oxide.[13-16] Surgical repair of CDH is performed with a transabdominal or transthoracic approach, and more recently, laparoscopic or thoracoscopic techniques have evolved. The herniated abdominal viscera are removed from the chest and repositioned in the abdomen. The posterolateral diaphragmatic defect is usually closed with nonabsorbable sutures if the defect is small or with a prosthetic patch if the defect is larger than 5 cm.[17,18] Currently no specific guideline exists for following up on children with a repaired CDH. However, chest radiographs often are obtained routinely for confirmation of an intact diaphragm and early detection of a possible CDH recurrence. On follow-up chest radiographs, abnormalities including persistent lung hypoplasia, decreased pulmonary vascularity, and mediastinal shift may be observed.

## Congenital Diaphragmatic Hernia: Morgagni

***Etiology.*** The foramen of Morgagni is an anterior opening in the diaphragm that extends between the sternum medially and the eighth rib laterally. In Morgagni hernias, also known as retrosternal hernias, the underlying congenital defect results from developmental failure of the fibrotendinous elements of the sternal part of the diaphragm to fuse with the costal part.[19-21] They account for 9% to 12% of the diaphragmatic defects in infancy. These hernias usually are unilateral and are right sided in 90% of cases.[10] A Morgagni hernia may occur as one of the components of the pentalogy of Cantrell, which is characterized by omphalocele, anterior diaphragmatic hernia, sternal cleft, ectopia cordis, and intracardiac defect such as a ventricular septal defect or a diverticulum of the left ventricle.[10,21] A Morgagni hernia can be seen in association with congenital heart disease, intestinal malrotation, and chromosomal abnormalities, most frequently Down syndrome.[10,21]

***Imaging.*** Most cases of Morgagni hernias are discovered incidentally on chest radiographs that are obtained for evaluation of other conditions in older children and adults. On chest radiographs, the diagnosis is made when anterior herniation of bowel loops is identified on the lateral chest radiograph (Fig. 61.3). When solid organs such as the liver or spleen are involved, the appearance may not be specific and can resemble focal diaphragmatic eventration, lymphadenopathy, or a foregut duplication cyst. Ultrasound, CT, or MRI can be helpful in the diagnosis when solid organs are herniated.[10,20,21]

***Treatment and Follow-up.*** The current treatment of choice for a Morgagni hernia is surgical repair at the initial diagnosis, even in the absence of symptoms, because of the increased risk of developing bowel obstruction and subsequent incarceration. Most Morgagni hernias can be repaired laparoscopically.[1,10,20,22]

## Delayed Presentation of Congenital Diaphragmatic Hernia

***Etiology.*** Approximately 5% to 20% of pediatric patients may present with a delayed CDH.[23] Although currently it is not clear whether the diaphragmatic defect in these patients is congenital

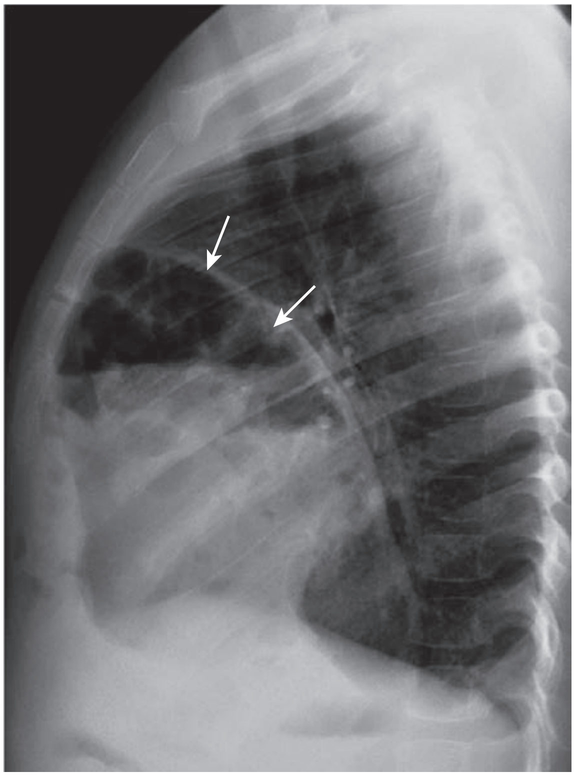

**Figure 61.3. Morgagni hernia in an 8-year-old boy who presented with cough and fever.** Lateral chest radiograph shows multiple bowel loops *(arrows)* projecting in the anterior aspect of the chest.

or acquired, it has been assumed that the defect may have been present prenatally but was either small or temporarily occluded by solid organs such as the liver or spleen.[23,24] In a multicenter retrospective study by the Congenital Diaphragmatic Hernia Study Group,[24] the location, male/female ratio, birth weight, and gestational age all were similar between children with neonatal CDH and infants or children with delayed presentation of CDH. These findings support the assumption that the defect of late-presenting CDH is most likely congenital in nature.[25,26]

Infants with delayed presentation of CDH usually become symptomatic in the first few months of life, often in association with right-sided pneumonia caused by group B streptococcal infection. Initially the hernia may be obscured by consolidative changes. In contrast, the larger group of older children presenting later in life have symptoms of abdominal pain or recurrent vomiting. Approximately two-thirds of this delayed presentation of CDH occurs on the posterolateral right side (i.e., Bochdalek). Asymptomatic cases discovered incidentally also occur.[23-26]

***Imaging.*** Several studies have shown that delayed presentation of a CDH often can be missed on initial chest radiographs.[23,25] The chest radiograph of a neonate with this type of hernia may be normal in the neonatal period. When only solid organs are herniated, a homogeneous opacity may be seen that can be confused with pneumonia or a pleural effusion (Fig. 61.4). In the case of herniated bowel, tubular air-filled, radiolucent structures projecting into the chest may mimic pneumatoceles or a pneumothorax. Such situations may cause mismanagement such as insertion of a chest tube, which is associated with a potential risk of gastrointestinal perforation or bleeding. A gas-filled herniated stomach may mimic a pneumothorax or a lung abscess. A delayed presentation of an anteriorly located Morgagni hernia, if it is not gas filled, may simulate cardiomegaly or a mediastinal mass.[23-26] A chest radiograph

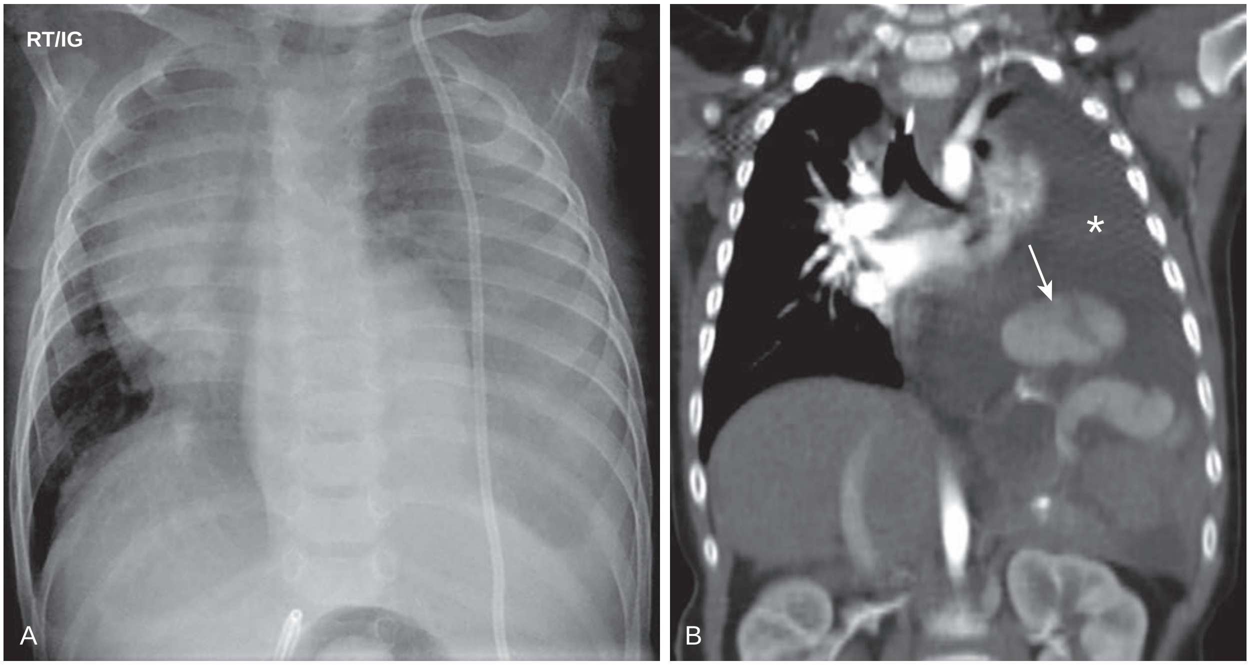

**Figure 61.4. Late-presenting congenital diaphragmatic hernia in a 16-month-old boy with shunted hydrocephalus and vomiting.** (A) Frontal chest radiograph shows an opacity in the left hemithorax without clear visualization of the left hemidiaphragm. Cardiomediastinal shift to the right side is also present. Note a left shunt catheter. (B) Coronal soft tissue window CT image shows a left pleural effusion *(asterisk)* and herniated spleen *(arrow)* into the left hemithorax and poor visualization of the left hemidiaphragm. The left pleural effusion was attributed to a malfunctioning shunt catheter.

after insertion of an NG tube can confirm a late-presenting hernia.[27] An upper gastrointestinal study can be useful if it demonstrates the presence of bowel in the chest; however, it may yield false-negative results in cases of exclusive solid organ herniation. To correctly diagnose a hernia containing only large bowel, it is important to obtain a delayed image during an upper gastrointestinal study. Ultrasound is particularly useful for patients with intrathoracic herniation of only solid organs, or when the hernia mimics a pleural effusion. CT or MRI has the advantage of demonstrating the diaphragmatic defect and herniating mesentery and bowel.[23,26]

***Treatment and Follow-up.*** The treatment of delayed diaphragmatic hernia is surgical, with repositioning of the herniated organs in the abdomen and primary closure of the defect or placement of mesh to patch the defect when it is large. The outcome is generally favorable, but misdiagnosis may result in significant morbidity or death. Gastrointestinal obstruction or volvulus with visceral incarceration is a possible presentation beyond the neonatal period. The role of routine follow-up chest radiographs after surgical repair currently is unclear; however, it may be beneficial for assessing possible recurrence rather than evaluating underlying pulmonary hypoplasia.[25,28,29]

### Eventration

***Etiology.*** *Diaphragmatic eventration* is defined as an abnormal elevation of all or a portion of an attenuated but otherwise intact diaphragmatic leaf. It may be congenital or may develop as a result of paralysis, with the former situation being more common. Congenital diaphragmatic eventration occurs when the fetal diaphragm fails to muscularize, leaving a layer of pleura and peritoneum in that region.[1,30] The focal type of diaphragmatic eventration is more common, most often anteromedially on the right side, whereas the diffuse type tends to be on the left side.[20] Pediatric patients with focal diaphragmatic eventration usually are asymptomatic. With diffuse eventration, an early presentation with respiratory insufficiency due to pulmonary and venous compression by the elevated viscera can be seen.[20,21,31]

***Imaging.*** Focal diaphragmatic eventration, which is a common incidental finding on a chest radiograph, appears as a focal diaphragmatic bulge in the anteromedial side of the right hemithorax (Fig. 61.5).[20,21] Radiographs may show the elevated diaphragm, allowing distinction in some cases from CDH, in which the diaphragm is in a normal position but the intestinal contents have herniated through an opening in the diaphragm.[20,25] After chest radiographs are obtained, ultrasound can be used to exclude a possible underlying mass and also to evaluate the diaphragmatic mobility using M-mode.[21] Total eventration of the diaphragm in older children and adults often is indistinguishable from diaphragmatic paralysis on chest radiographs. A helpful differentiating sign is that an eventration typically will not have adjacent areas of atelectasis, whereas paralysis of the diaphragm will have such areas. During fluoroscopy, an eventrated diaphragm typically displays an inspiratory lag followed by delayed downward motion. However, slight paradoxic movement, little movement, or no movement may occur in cases of an eventrated diaphragm, which sometimes makes the distinction from paralysis challenging.[20,21]

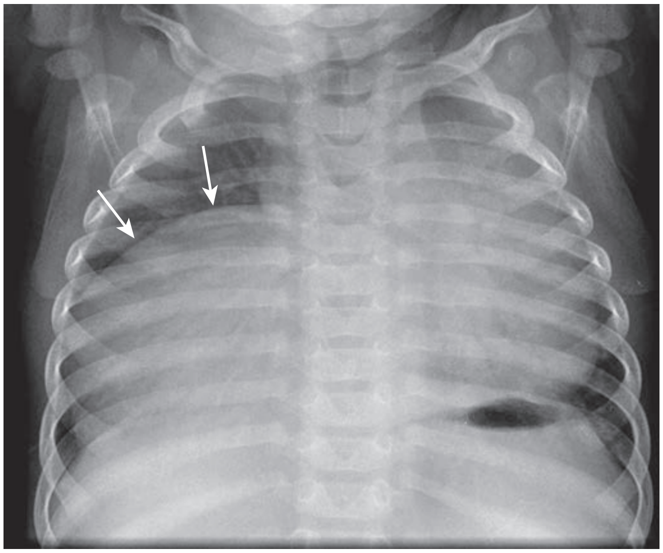

**Figure 61.5. Diaphragmatic eventration in a 2-year-old boy who presented with a cough and fever.** Frontal chest radiograph shows an elevation of the right hemidiaphragm *(arrows).*

***Treatment and Follow-up.*** A focal diaphragmatic eventration generally requires no treatment or follow-up because it is usually of no clinical significance. In pediatric patients with a focal or complete diaphragmatic eventration that causes respiratory distress, the eventration is plicated. Plication involves a folding and subsequent suturing of the eventrated diaphragm to reduce the excess diaphragmatic tissue. The indication for and the timing of surgery are still somewhat controversial.[1,31]

## DIAPHRAGMATIC INJURIES

### Diaphragmatic Paralysis

***Etiology.*** Injury or abnormality of the phrenic nerve leading to diaphragmatic motion abnormalities may occur unilaterally or bilaterally as a result of birth trauma or after surgical interventions, most commonly cardiac surgery.[2] The prevalence of diaphragmatic paralysis is 0.03% to 0.5%.[2] The prevalence after thoracic surgery in children has been reported to range between 0.5% and 10%.[2,32-34] In infants, diaphragmatic paralysis may result in life-threatening respiratory insufficiency and ventilatory failure. Unexplained difficulty in weaning a patient from mechanical ventilation or an increasing oxygen requirement should raise the suspicion of diaphragmatic paralysis.[21,33]

***Imaging.*** Diaphragmatic paralysis usually is suggested on chest radiographs when they show persistent elevation of the affected hemidiaphragm. However, the position of the diaphragm may not be reliable in the newborn period. Fluoroscopic assessment of diaphragmatic motion, which previously was commonly obtained, largely has been replaced by ultrasound. Ultrasound with the use of M-mode is superior to fluoroscopy in the evaluation of the diaphragm because of its portability, lack of ionizing radiation, and ability to visualize the entire diaphragm (Fig. 61.6).[33,35] Diaphragmatic movement is considered normal if the diaphragm moves toward the transducer during inspiration, with excursion of greater than 4 mm and a difference in excursion between the domes of less than 50%.[20,21,32-34]

***Treatment and Follow-up.*** The initial treatment of patients with diaphragmatic paralysis is supportive, which includes positioning the affected patients ipsilateral to the affected side and providing oxygen and mechanical ventilation in cases of respiratory failure.[2,36] After 30 days of unsuccessful noninvasive treatment, plication usually is needed, especially in patients younger than 1 year and those with iatrogenic injuries of the phrenic nerve.[1,2,21,37]

### Diaphragmatic Rupture

***Etiology.*** Diaphragmatic rupture, which is rare in children, typically occurs after a blunt or penetrating trauma. In one large study, the incidence of traumatic diaphragmatic rupture was found to be 0.07%, with a mean age of 7.5 years.[38] It was slightly more frequent in boys and occurred more commonly as a result of blunt, rather than penetrating, trauma.[38] Associated injuries such as a

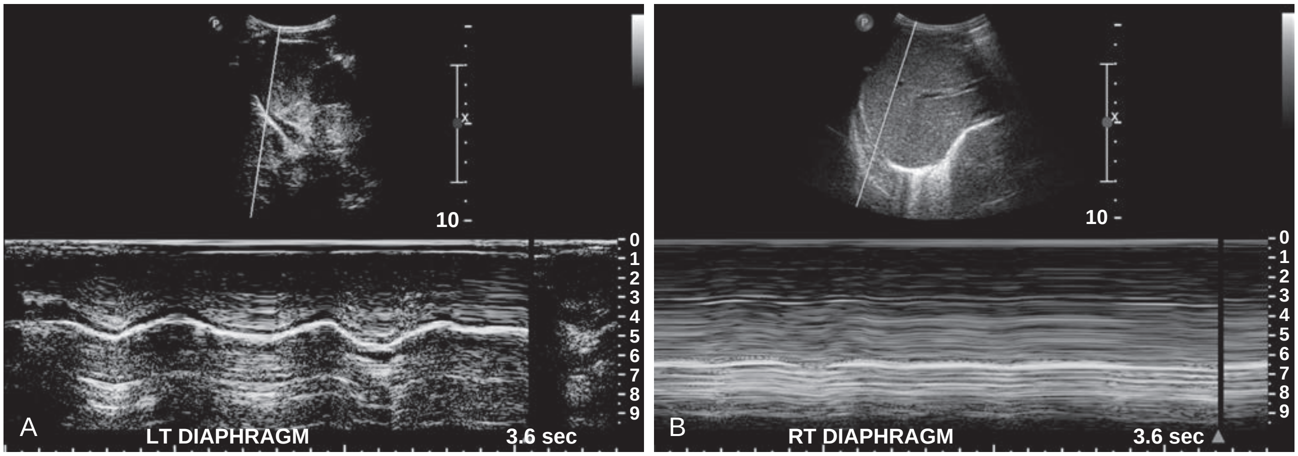

**Figure 61.6. Diaphragmatic paralysis in a 10-month-old boy after tetralogy of Fallot repair who was unable to be weaned from the ventilator.** (A) Longitudinal M-mode sonogram of the left hemidiaphragm reveals a normal diaphragmatic motion. (B) Longitudinal M-mode sonogram of the right hemidiaphragm reveals a flat waveform, indicating no diaphragmatic motion.

head injury, pelvic fractures, and splenic and renal injuries are common. However, isolated diaphragmatic injuries have been reported more often in children than in adults. Diaphragmatic rupture is more common on the left than on the right. The left-sided predominance probably is the result of a protective effect by the liver on the right diaphragm.[39] Because of its rarity, the correct diagnosis of diaphragmatic rupture often is delayed or missed; this may lead to bowel herniation, obstruction, and ischemia.[38]

***Imaging.*** Diaphragmatic rupture in children is difficult to detect clinically and on imaging, and it requires a high index of suspicion.[38-40] Several studies show that chest radiographs have suggestive findings in 64% to 77% of cases; however, they are diagnostic in only 25% to 50% of cases.[40] Nonspecific but suggestive imaging findings of diaphragmatic rupture on chest radiographs include (1) an archlike soft tissue opacity in the lower chest; (2) unusual densities or gas bubbles resulting from bowel herniation; and (3) atelectasis, pleural effusions, and a mediastinal shift to the nonaffected side.[40] Imaging findings considered diagnostic of a diaphragmatic rupture after trauma are the presence of herniated abdominal organs (e.g., bowel loops or solid organs) and an NG tube in the chest (Fig. 61.7).[40] CT, especially coronal reformations, may confirm the diagnosis of diaphragmatic rupture by showing irregularity and thickening of the diaphragmatic leaflet and herniated abdominal organs.[39,40] Fluoroscopy and contrast studies have limited use in the acute setting.[41]

***Treatment and Follow-up.*** The treatment of diaphragmatic rupture is surgical, whether the patient presents in the acute or delayed setting. Repair of the acute traumatic diaphragmatic rupture is directed by the concomitant injuries. Small defects are repaired by direct suturing, whereas larger defects are patched with mesh.[1,39] Although fluoroscopy plays little role in the preoperative diagnosis of diaphragmatic rupture, it can be useful in assessing the diaphragm after repair to evaluate diaphragmatic motion and hernia recurrence.

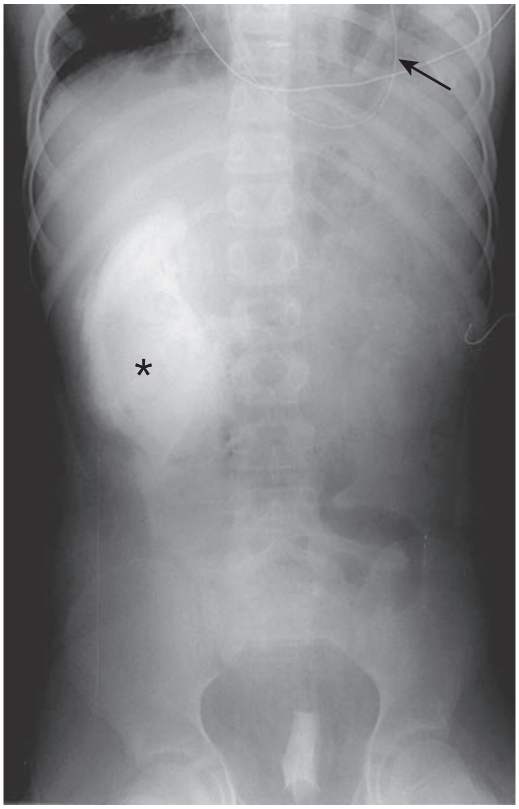

**Figure 61.7. Diaphragmatic rupture in a 5-year-old boy who fell from playground equipment.** Abdominal radiograph shows obliteration of the left hemidiaphragm with soft tissue and lucencies projecting in the left base. The tip *(arrow)* of a nasogastric tube projects in the chest, confirming a left diaphragmatic rupture. The hyperdensity in the right flank is due to perinephric intravenous contrast extravasation as a result of a shattered kidney *(asterisk)*.

## DIAPHRAGMATIC NEOPLASMS

***Etiology.*** Primary diaphragmatic tumors are very rare.[21] In a study by Cada and colleagues,[41] 41 cases were found in patients younger than 18 years with equal gender frequency and a mean age at diagnosis of 10 years. Most diaphragmatic tumors are malignant, with rhabdomyosarcoma being the most common tumor found in the diaphragm.[21,42] Other primary diaphragmatic malignant tumors in children are undifferentiated sarcomas, germ cell tumors, and the Ewing sarcoma family of tumors.[21,42-44] Secondary involvement of the diaphragm by adjacent malignant tumors also can occur.[21,42] Benign tumors include neurofibromas, lipomas, myofibroblastic tumors, and hemangiomas.[21] Cystic lesions (not necessarily neoplasms) involving the diaphragm include mesothelial cysts, bronchogenic cysts, cystic teratomas, and hydatid cysts.[21,45]

Affected patients, especially those with benign lesions, usually are asymptomatic and the diagnosis of diaphragmatic neoplasm is made incidentally as part of unrelated imaging, at surgery, or even at autopsy. Patients with a large or malignant diaphragmatic tumor usually present with symptoms such as chest pain, cough, dyspnea, nausea, vomiting, and dysphagia.[21,42,44] An exophytic, large diaphragmatic tumor also may be palpable on physical examination.

***Imaging.*** The greatest challenge in assessing a diaphragmatic tumor is determining its exact site of origin. Especially with right-sided lesions, the site of origin frequently has been mistakenly assigned to the liver. No single imaging modality has demonstrated superiority in diagnosing diaphragmatic tumors, and frequently a combination of ultrasound, CT, and MRI is necessary for a correct diagnosis.[21,42] The majority of malignant tumors present as large masses with advanced local disease or metastasis to the pleura and lung.[43] The claw sign, the pattern of organ displacement, and the presence of an obtuse angle between the tumor and the diaphragm may help determine diaphragmatic origin (Fig. 61.8).[42] Not infrequently, the diaphragmatic origin of the tumor becomes more evident after size reduction after chemotherapy. In cases of a palpable mass or a mass seen on chest or abdominal radiographs, ultrasound may be the initial study of choice to begin the investigation.

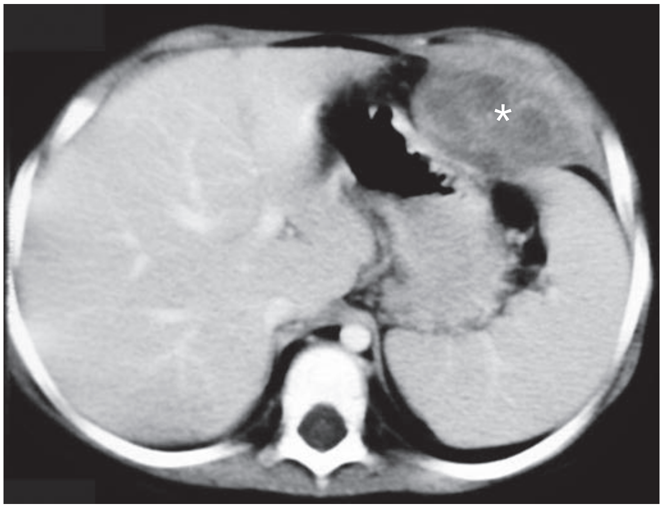

**Figure 61.8. Germ cell tumor of the diaphragm in a 7-year-old boy with a palpable mass.** Axial CT image at the thoracoabdominal junction shows a heterogeneous anteriorly located mass *(asterisk)* with obtuse angles in relation to the diaphragm.

***Treatment and Follow-up.*** After imaging studies, a definitive diagnosis of diaphragmatic tumors can be made on the basis of histopathologic evaluation of a biopsy specimen. Once a histopathologic diagnosis is made, chemotherapy usually is instituted to reduce the size before surgical resection. Adjuvant preoperative radiation therapy may help in cases of infiltrative tumors. Germ cell tumors may go into remission after chemotherapy because of their high chemosensitivity.[21,42,43]

## KEY POINTS

- The Bochdalek hernia, which involves the posterolateral aspect of the diaphragm, is the most common subtype, accounting for approximately 90% to 95% of all CDHs.
- The clinical presentation of late-onset CDH is varied and may require multiple imaging modalities to reach a diagnosis.
- Ultrasound with M-mode is the imaging modality of choice to evaluate diaphragmatic paralysis and motion.
- The diagnosis of diaphragmatic rupture is usually delayed because of its rarity and multiple associated injuries, and it requires a high index of suspicion.
- Primary diaphragmatic tumors are very rare in children. Most diaphragmatic tumors are malignant, with rhabdomyosarcoma being the most common diaphragmatic tumor.

## PART 1 Overview

# 62 Introductory Embryology

James René Herlong

## CARDIAC DEVELOPMENT

The major task in cardiac development is to form a four-chambered heart that functions in a coordinated fashion from a straight tube that functions merely by peristalsis. Cardiac development can be thought of as proceeding along various phases: fusion of myocardium and endocardium in the ventral midline to form a simple tube, onset of function, looping to the right side, specification and formation of chambers, development of specialized conduction tissue, formation of the coronary circulation, innervation of the heart, and formation of mature valves. The approximate times at which these various events occur in human development are shown in Table 62.1.

Three main groups of cells contribute to the morphogenesis of the heart. These main groups are the mesoderm of the primary heart fields (located in the splanchnic layer of lateral plate mesoderm bilaterally), the secondary heart fields (located in the pharyngeal mesenchyme), and the cardiac neural crest (a subdivision of the cranial portion of the neural crest). These tissues and their roles in the developing heart are illustrated in e-Fig. 62.1, along with the two important extracardiac populations of cells described later in this chapter.

The first stage in the development of the heart is the formation of a single midline heart tube from the bilateral cardiogenic fields (e-Fig. 62.2). The heart begins to beat even at this single tubular stage. Cells are then added to each end of the heart tube, and the tube begins to loop to the right. During looping, the tube is further lengthened by the addition of cells from the secondary heart field to the outflow pole. Looping and convergence bring the inflow and outflow poles of the heart into proximity (Fig. 62.3), setting the stage for septation and definitive chamber formation. The traditional names of the various segments of the recently looped heart are illustrated in e-Fig. 62.4. Note that the heart in this configuration is set up to become a double-inlet left ventricle and a double-outlet right ventricle; if septation proceeds properly, these forms of congenital heart disease are avoided. Formation of a four-chamber heart requires the right ventricle to obtain an inlet and the left ventricle to obtain an outlet.

The atrioventricular canal of the heart is divided into right and left sides by endocardial cushions that develop at the atrioventricular junction and ultimately form the septum of the atrioventricular canal and the atrioventricular valves (Fig. 62.5). The right atrioventricular canal and right ventricle expand to the right, and the atria are septated from one another. Septum primum, the primary atrial septum, is led by the spina vestibuli (vestibular spine) and ultimately fuses with the endocardial cushions to close the first interatrial communication or ostium primum. As the septum primum is growing, fenestrations begin to develop within it. These fenestrations coalesce to form the secondary interatrial communication, or ostium secundum (see Fig. 62.5). A second septum, or septum secundum, forms to the right of the septum primum much later, and postnatal fusion of the two septa obliterates any interatrial communication. Note that septum primum is ultimately a left atrial structure and that septum secundum is considered a right atrial structure, even though it expresses left-sided molecular markers. Note further that, in the common parlance of naming atrial septal defects, the defect is named for the embryonic ostium that persists, not for the embryonic tissue in which the defect exists. Thus, for example, a secundum atrial septal defect is persistence of the embryonic ostium secundum, even though the defect itself is most often in the septum primum. This naming practice is one of the more confusing points in the nomenclature of congenital heart disease.

Just as the atria and the atrioventricular canal portions of the heart are septated, so are the ventricles. The muscular ventricular septum arises from the deepest convexity of the cardiac loop and grows toward the atrioventricular septum. The membranous septum ultimately will bridge the gap between these two portions of the septum. The outlet, conal, or infundibular septum (i.e., the portion of the septum that ultimately will lie just below the semilunar valves and between the outflow tracts) forms from the conal cushions. Initially it is mesenchymal and only later muscularizes. Ventricular septal defects tend to occur at the locations where these various primordia of the ventricular septum fuse.

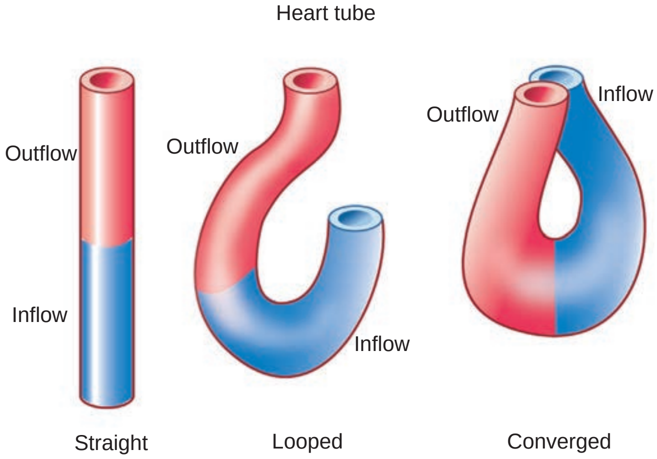

**Figure 62.3.** The heart tube begins as a straight midline tube with blood entering caudally via the inflow tract and exiting cranially via the outflow tract. Under normal circumstances, the tube loops to the right, creating an inflow limb *(blue)* and an outflow limb *(red)*. The distal extremities of the inflow and outflow limbs grow toward each other in a process called *convergence*. Convergence is necessary before septation can create a four-chambered heart. *(From Kirby ML.* Cardiac development. *New York: Oxford University Press; 2006.)*

## Abstract:

This chapter describes the development of the heart from straight tube to fully differentiated heart. Embryonic tissues and mechanisms responsible for heart development are detailed. The chapter then describes development of the vascular system. Remodeling of embryonic vascular networks into definitive vasculature is demonstrated.

## Keywords:

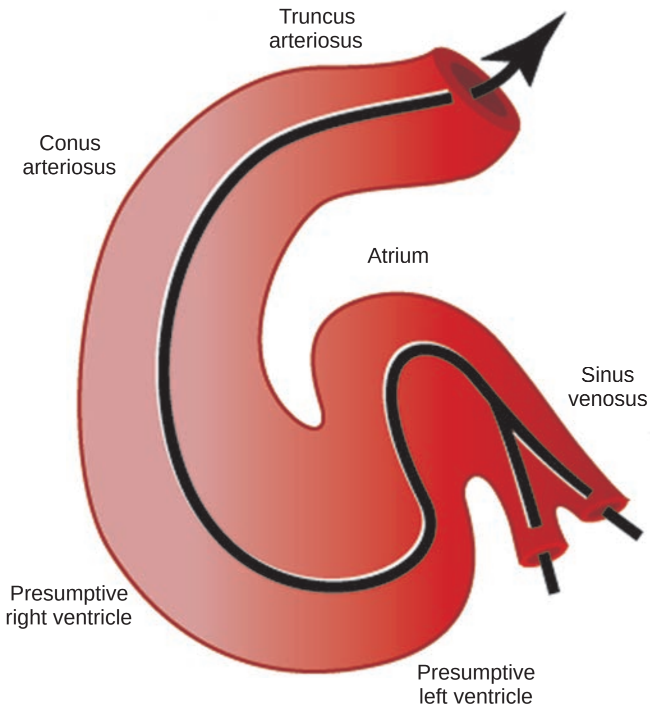
**e-Figure 62.2.** Steps in development of the bilateral cardiogenic fields in the splanchnic mesoderm into a single midline heart tube (A–D). Formation of the midline heart tube depends on formation of the foregut pocket that forms the pharynx. The myocardial trough (C and D) already shows three layers: cellular endocardial and myocardial layers with an acellular layer of cardiac jelly in between. *(From Kirby ML.* Cardiac development*. New York: Oxford University Press; 2006.)*



**e-Figure 62.4.** Traditional names of the various parts of the tubular heart. *(From Kirby ML.* Cardiac development*. New York: Oxford University Press; 2006.)*

The aorticopulmonary septum is derived from the cardiac neural crest and functions to separate the aortic sac into the aorta and pulmonary artery and to separate the truncus into the aortic and pulmonic valve orifices. This septum is contiguous proximally with the conal septum. The aorticopulmonary septation complex segregates the ventricular outflows from one another just as the septation of the atrioventricular canal segregates the ventricular inflows.

**TABLE 62.1** Timing of the Onset of Various Events in Human Cardiovascular Development

| Event | Gestational Age (wk) |
|---|---|
| Formation of a heart tube | 3 |
| Aortic arches form | 3 |
| Onset of function | 4 |
| Looping | 4 |
| Onset of chamber septation | 5 |
| Development of specialized conduction tissue | 5 |
| Formation of the coronary circulation | 5–6 |
| Onset of innervation of the heart | 7–8 |
| Formation of mature valves | 10 |
| Definitive venous system established | 12 |

The cardiac electrical system, which is composed of pacemaking cells and a specialized conduction system, develops from regions of specialized myocardial cells that are set aside from working myocardium for this purpose. One of the most important processes involved in the electrical coordination of cardiac function is the electrical isolation of the atria from the ventricles by the fibrous skeleton of the heart. Only the penetrating bundle of His normally electrically connects (via muscle to muscle) the atria and the ventricles. This atrioventricular discontinuity is established by the incorporation of nonmyocardial tissue into the atrioventricular junction.

The epicardium of the heart is derived from an extracardiac population of cells known as the proepicardium. These cells come from the mesenchyme of the septum transversum or liver and literally jump across the coelomic cavity to reach the heart (see e-Fig. 62.1). The proepicardium not only forms the definitive epicardium of the heart but also the endothelium and smooth muscles of the coronary arteries, as well as the connective tissue of the heart. The formation of the coronary arteries and the connective tissue of the heart is made possible by a process known

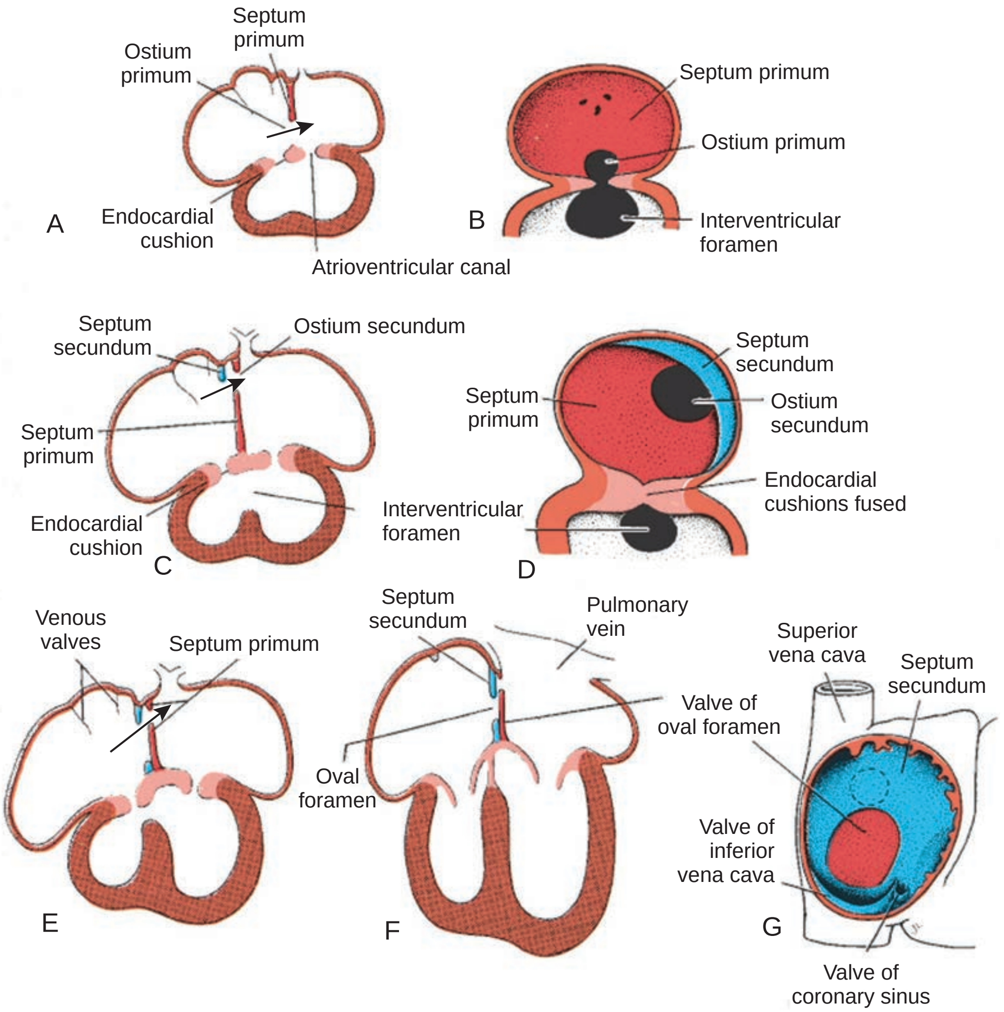


**Figure 62.5. Development of the atrial septum.** (A) Cross-sectional and (B) en face from the right atrium show the atrial septum at 30 days of gestation. (C) Cross-sectional and (D) en face from the right atrium show the atrial septum at 33 days of gestation. (E) The atrial septum at 37 days of gestation. (F) Cross-sectional and (G) en face from the right atrium show the atrial septum immediately after birth. *(From Sadler T.* Langman's medical embryology*. 10th ed. Philadelphia: Lippincott Williams & Wilkins; 2004.)*

as epithelial to mesenchymal transformation. The epicardium of the outflow tract is distinct from that of the remainder of the heart and is derived from the splanchnic mesoderm of the ventral pharynx. Because of the diversity of cells that the proepicardium provides, many investigators consider the proepicardium to be an important potential source of cardiac stem cells.

Before the development of the coronary arteries, the loosely packed myocardium of the embryonic heart is nourished from the cavities by sinusoids. As the myocardium becomes more compact, arteries and veins develop within the epicardial layer, with the intramyocardial circulation developing within the myocardium itself. The arterial channels then grow into the developing aortic valvar sinuses to form true coronary arteries arising from the aorta.

Innervation of the heart is a late development and is not complete until well after birth. Parasympathetic ganglia are intrinsic to the heart and develop from the cardiac neural crest. Sympathetic ganglia are paravertebral and develop from the truncal neural crest. All postganglionic neurons develop from the cardiac neural crest.

The final step in cardiac development is sculpting of the endocardial cushions at the ventricular inflow and outflow to form functional valves. This process occurs at the atrioventricular junction by undermining of the cell layers just underneath the luminal cells to free the leaflets from the myocardium and to create the support apparatus (papillary muscles and chordae tendineae) of the valves. At the ventriculoarterial junction, the sculpting occurs distal to the cushions themselves, and no such support apparatus is formed.

## VASCULAR DEVELOPMENT

The arteries and veins are developed by a combination of vasculogenesis and angiogenesis. Vasculogenesis occurs first to form the major arteries and veins, and vessels sprout from these larger vessels by angiogenesis. The vasculature of the embryo begins as a bilaterally symmetric system of arteries and veins. This symmetry is maintained in the head and limbs as well as in the derivatives of the somites and spinal cord.

The central vessels, however, lose their symmetry and are extensively remodeled. The great arteries begin as bilaterally symmetric, paired arch arteries that connect the ventral aortic sac to the bilateral dorsal aortae. These symmetrical arch arteries undergo involution and remodeling to form the aortic arch, arch vessels, main and branch pulmonary arteries, and the ductus arteriosus (e-Fig. 62.6). This patterning is supported by cells from the cardiac neural crest. Abnormal arterial remodeling leads to aberrant origins of arch arteries and to vascular rings. To understand the embryonic origin of various arch anomalies, it is useful to consider a “totipotential arch” that includes all the relevant arch arteries and imagine how this arch may be “cut” to produce each anomaly. The “totipotential arch” is a theoretic construct. Such an arch never exists in fetal life; because of involution and remodeling, all of the represented components never exist simultaneously. However, the concept (illustrated in Fig. 62.7) is quite useful in understanding how various arch anomalies occur and which of them produce vascular rings.

The embryonic venous system is also extensively remodeled. Originally there are bilaterally symmetric vitelline, umbilical, and cardinal systems. The original systems drain to ipsilateral horns of the sinus venosus portion of the developing heart. Because the left sinus horn regresses and systemic venous return is directed solely to the right atrium, the left system of veins must involute or form anastomotic connections with the right system. The inferior vena cava is composed of elements of four separate systems (e-Fig. 62.8). When the inferior vena cava is interrupted, as in cases of the polysplenic form of heterotaxy, bilateral symmetry of all but the intrahepatic portion is largely maintained. The inferior venous drainage then proceeds to one or both superior venae cavae via azygous or hemiazygous veins.

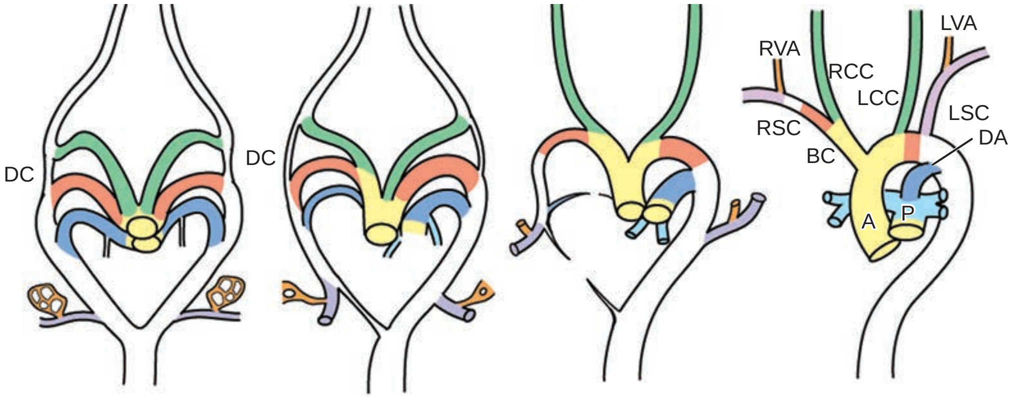
The *small black arrows* point to the ductus arteriosi bilaterally, and the *larger black arrows* indicate the direction of blood flow. *LCC,* Left subclavian artery; *LPA,* left pulmonary artery; *LS,* left subclavian artery; *PT,* pulmonary trunk; *RCC,* right common carotid artery; *RPA,* right pulmonary artery; *RS,* right subclavian artery. *(From Stewart JR, Kincaid OW, Edwards JE.* An atlas of vascular rings and related malformations of the aortic arch system*. Springfield, IL: Charles C. Thomas; 1964.)*

The head and neck veins derive from the anterior cardinal veins. The left anterior cardinal vein involutes, and anastomotic channels drain the left head, neck, and arm to the remnants of the right anterior cardinal system and ultimately to the heart by the right superior vena cava. A persistent left superior vena cava is a common variant of normal. This vein drains into the coronary sinus, which is a remnant of the left horn of the sinus venosus.

The pulmonary veins form from fusion of the veins developing in the mesoderm surrounding the bronchial buds with the common pulmonary vein that develops as an evagination of the developing left atrium. Before this fusion, connections of the developing pulmonary veins to the systemic venous system are formed. These connections persist as “vertical veins” when atresia of the common pulmonary vein occurs, a condition known more commonly as totally anomalous pulmonary venous connection.



**e-Figure 62.6.** Diagram of the bilaterally symmetrical aortic arch arteries that carry the early cardiac output to the dorsal aorta, which then distributes blood to the embryo. The early symmetry is lost when these vessels are remodeled to be the adult great arteries of the thorax. *Green,* Aortic arch artery 3; *red,* aortic arch artery 4; *blue,* aortic arch artery 6; *A,* aorta; *BC,* brachiocephalic; *DA,* ductus arteriosus; *DC,* ductus caroticus; *LCC,* left common carotid artery; *LSC,* left subclavian artery; *LVA,* left vertebral artery; *P,* pulmonary trunk; *RCC,* right common carotid artery; *RSC,* right subclavian artery; *RVA,* right vertebral artery. *(From Kirby ML.* Cardiac development*. **e-Figure 62.8. The primordial veins of the trunk in the human embryo (ventral views).** Initially, three systems of veins are present: the umbilical veins from the chorion, the vitelline veins from the umbilical vesicle (yolk sac), and the cardinal veins from the body of the embryo. Next, the subcardinal veins appear, and finally the supracardinal veins develop. (A) At 6 weeks. (B) At 7 weeks. (C) At 8 weeks. (D) Adult. This drawing illustrates the transformation that produces the adult venous pattern. *(From Moore KL, Persaid TVN.* The developing human: clinically oriented embryology. *8th ed. Philadelphia: Saunders Elsevier; 2008. Fig. 13.4; as modified from Arey LB.* Developmental anatomy. *7th ed revised. Philadelphia: WB Saunders; 1974.)*

To understand common associations in congenital malformations, it is important to realize that the heart develops in close juxtaposition to the forebrain, face, and anterior neck as part of what has been called the cardiocraniofacial field. The simultaneous occurrence of defects in these other organ systems with congenital heart defects therefore is not surprising.

### Acknowledgment

I thank Dr. Margaret L. Kirby for her lucid teaching, her patience with this clinician, her sharing of figures, her review of this manuscript, and her enormous contributions to the field of cardiovascular development.

### KEY POINTS

- Looping and convergence of the primitive heart tube set the stage for cardiac septation and definitive chamber formation.
- Atrial septal defects are named for the embryonic ostium that persists, not for the embryonic tissue in which the defect exists.
- The proepicardium gives rise to a very diverse population of cells and is an important potential source of cardiac stem cells.
- The vasculature of the head, limbs, and derivatives of the somites maintains its embryonic symmetry, whereas the central vessels are remodeled extensively.

# Cardiovascular Anatomy and Segmental Approach to Imaging of Congenital Heart Disease

*Rajesh Krishnamurthy*

Because of the large variety of human hearts in nature, a standardized approach and nomenclature is needed to understand and describe cardiac anatomy and physiology in the setting of congenital heart disease. The most widely used approach is called the segmental approach to heart disease, first proposed by Richard Van Praagh in 1972 and later modified by others. It is strongly rooted in embryologic principles, and follows a logical sequence from evaluation of morphology and physiology of the heart to decision making regarding treatment.

## EMBRYOLOGIC BASIS FOR THE SEGMENTAL APPROACH TO HEART DISEASE

Embryology of the heart is covered in a separate chapter (see Chapter 62). In this section, some embryologic events that are fundamental to understanding the segmental approach to heart disease are reiterated.

The heart develops from two simple epithelial tubes that fuse to form a single tube (Fig. 63.1) with the following components:

**Sinus venosus:** Consists of right and left horns. Each horn receives blood from three important veins: the umbilical vein, the common cardinal vein, and the vitelline vein.

**Paired primitive atria:** Will later fuse together to form a common atrium.

**Atrioventricular sulcus:** Divides the common atrium and the primitive ventricle.

**Primitive ventricle:** Becomes the left ventricle, and the inflow portion of the right ventricle.

**Interventricular sulcus:** Divides the left and right ventricles.

**Bulbus cordis:** This may be divided as follows: the proximal one-third contributes to the body of the right ventricle; the distal one-third is called the truncus arteriosus, which develops into the aortic root and part of the pulmonary artery (PA); and the middle third is called the conus cordis and connects the primitive right ventricle to the truncus arteriosus. The conus cordis partitions to form the outflow tracts of the right and left ventricles.

Although the two ends of the heart tube remain relatively fixed, rapid growth of the middle section results in the development of a large S-shaped curve called the *bulboventricular loop* (see Fig. 63.1). As the heart tube grows and becomes longer, it usually bends to the right, termed by Van Praagh as D-looping. D-looping is responsible for the proximal bulbus cordis (RV) lying anterior and to the right of the primitive ventricle (LV). If the heart tube loops to the left, termed L-looping, the RV will lie anterior and to the left of the LV.

In the heart tube stage, the primitive LV and the proximal bulbus cordis (primitive RV) are separated from the truncus arteriosus (which gives rise to both great arteries) by the conus or infundibulum. The conus consists of the subpulmonary and subaortic conus cushions. Normally, there is expansile growth of the subpulmonary conus, causing it to protrude anteriorly on the left, carrying the pulmonary valve anteriorly, superiorly, and to the left of the aortic valve. There is resorption of the subaortic conus. Hence, the aortic valve lies posterior, inferior, and right-sided, in direct fibrous contiguity with the mitral valve (Fig. 63.2). The anterior PA arises above the anterior ventricle (RV) and leads to the posterior sixth arterial arch, which forms the branch pulmonary arteries. The posterior aorta originates above the posterior LV, and leads to the anterior fourth arterial arch (which forms the aortic arch).

The segmental approach involves the analysis of the three major cardiac segments: atria, ventricles and great arteries, and the two connecting segments: the atrioventricular canal and the conotruncus. These segments of the heart can be distinguished in the very early embryo. There are some important embryologic concepts that underlie the segmental approach to heart disease:

1. The development of the suprahepatic portion of the inferior vena cava (IVC) is closely linked to the growth of the liver, so that the anatomic right atrium and the liver almost invariably develop on the same side of the body. This concept of visceroatrial situs is fundamental to the segmental approach.
2. Another important concept underlying the segmental approach is the recognition that the ventricular looping is independent of the visceroatrial situs. This gives rise to the concept of concordance (RA-RV and LA-LV) and discordance (RA-LV and LA-RV).
3. Similarly, ventricular looping and great arterial relationship are independent entities. The direction of bulboventricular looping, and the development of the conotruncus is responsible for the ultimate relationship of the great arteries to each other, and to the underlying ventricles and atrioventricular valves.

## THE SEGMENTAL APPROACH TO DIAGNOSIS OF CONGENITAL HEART DISEASE

Any imaginable combination of visceral, atrial, ventricular, and great vessel morphology can and does occur in congenital heart disease. A simple, logical, step-by-step approach to diagnosis and decision-making and a standardized nomenclature go a long way in advancing patient care by ensuring that different caregivers have similar understanding of the disease, and are speaking the same language. This approach is known as the segmental approach to heart disease, first described by Richard Van Praagh in 1972.

One can think of the heart as a three-level house (Fig. 63.3). The first level is the visceroatrial situs, the middle level is the ventricular loop, and the third level is the conotruncus. To describe it simply, the three levels are the atria, ventricles, and great arteries. There are two staircases: the atrioventricular junction and the ventriculoarterial junction. The levels represent the major cardiac segments. The staircases represent the connecting segments.

The segmental approach to heart disease comprises the following steps:

1. What is the anatomic type of each of the three major cardiac segments: the atria, the ventricles, and great arteries?
2. How is each segment connected to the adjacent segment?

## Abstract:

Because of the large variety of human hearts in nature, a standardized approach and nomenclature is needed to understand and describe cardiac anatomy and physiology in the setting of congenital heart disease. The most widely used approach is called the segmental approach to heart disease, first proposed by Richard Van Praagh in 1972 and later modified by others. It is strongly rooted in embryological principles, and follows a logical sequence from evaluation of morphology and physiology of the heart to decision making regarding treatment.

Baltimore: Williams & Wilkins; 1983.)*

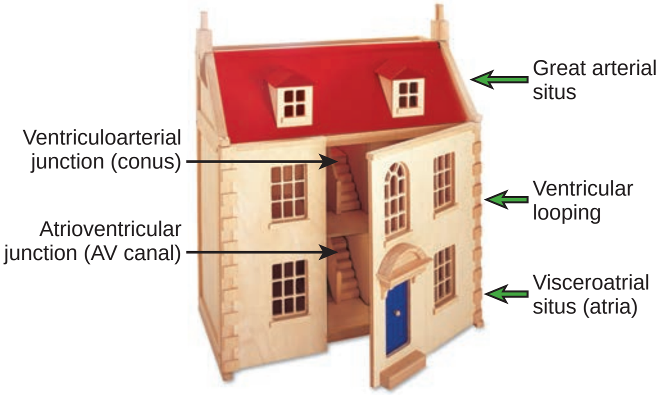
3. What are the associated anomalies involving the valves, atrial and ventricular septum, the great vessels, and the systemic and pulmonary veins?
4. How do the segmental combinations and connections function, with or without the associated malformations?

The first three steps in the segmental approach are concerned with morphology, while the last step determines physiology.

Van Praagh used a segmental set to provide a shorthand description of the floorplan of the heart. The first letter stands for the visceroatrial situs, the second for the ventricular loop, and the third for the great arterial relationship. In a person with situs solitus of the viscera and atria, D-looping of the ventricles, and solitus relationship of the great arteries, the segmental set is {S,D,S}.



Great arterial situs
Ventriculoarterial junction (conus)
Ventricular looping
Atrioventricular junction (AV canal)
Visceroatrial situs (atria)

**Figure 63.3. The "house" model of the heart.** The three levels (major cardiac segments) are the atria, ventricles, and great arteries. The house has two connecting walls with doors (connecting segments): the atrioventricular junction and the ventriculoarterial junction. The house has two entrances: the systemic veins and the pulmonary veins.

## IDENTIFICATION OF THE MAJOR CARDIAC SEGMENTS

Reliable identification of the cardiac chambers based on specific morphologic features is the first step in the segmental approach to heart disease. It is important to remember that right and left do not refer to the side of the body on which the chamber lies but to specific morphologic criteria that identify each component of the heart. For instance, right atrium does not refer to the atrium that is on the right side of the body but to the atrium that receives the insertion of the IVC and the coronary sinus, and has a triangular appendage with a broad base. Hence, the morphologic right atrium will be on the right side of the body in situs solitus and on the left side in situs inversus.

### Atrial Identification

The defining features of the morphologic right atrium (systemic venous atrium) and left atrium (pulmonary venous atrium) are based on their venous connections as well as their appendage and pectinate muscle morphology. Using venoatrial connections for atrial identification is based on the fact that the sinus venosus, which carries the systemic venous return, is an integral part of the morphologic right atrium. Hence, the morphologic right atrium receives the inferior and superior vena cavae, and orifice of coronary sinus. However, the superior vena cava (SVC) and coronary sinus have a high incidence of variation, which can be a source of diagnostic confusion. These variations include left SVC to an unroofed coronary sinus, and bilateral SVCs with the left SVC draining to an unroofed coronary sinus. In these cases, the SVC would appear to drain into the left atrium. In rare instances, even the IVC may drain into the coronary sinus, which may be unroofed, or the coronary sinus septum may be absent. In spite of this rare exception, the most reliable means of identifying the morphologic right atrium by cross-sectional imaging is by recognizing its connection to the IVC (Fig. 63.4). Even in the setting of an interrupted IVC, a suprahepatic segment of the IVC is present entering the right atrium, allowing accurate identification.

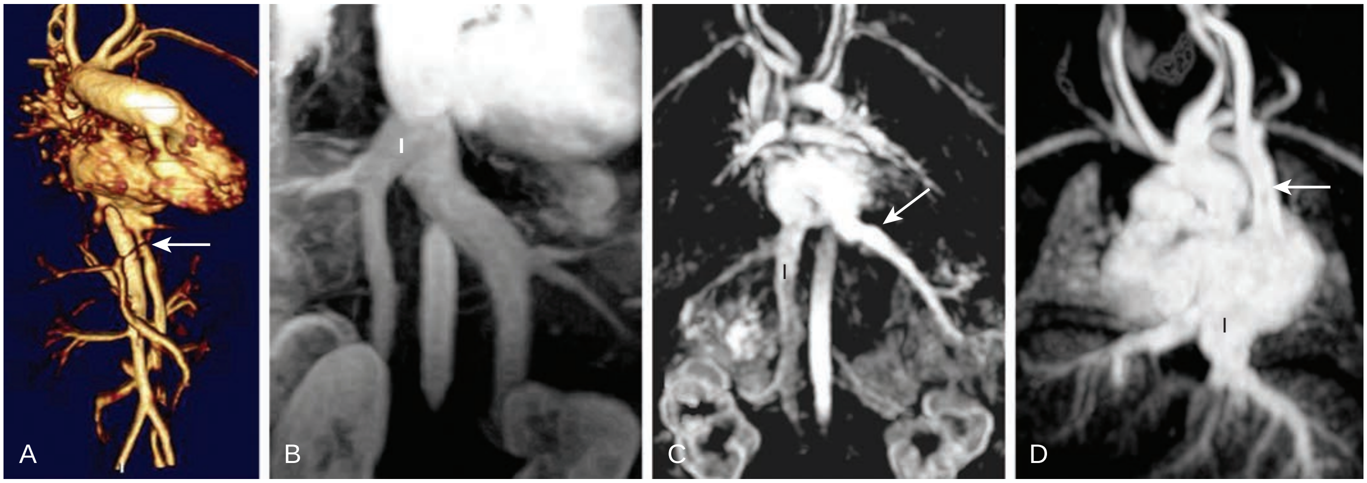


**Figure 63.4. The inferior vena cava (IVC) as a marker of the morphologic right atrium (RA).** (A) The IVC *(arrow)* and aorta are on the left and the IVC enters the left-sided atrium, which represents the morphologic RA. (B) Bilateral IVC that fuse *(I)* prior to entering the right atrium. (C) The right hepatic vein enters the IVC *(I)*, which drains into the RA, while the remaining hepatic veins *(arrow)* drain separately into the left atrium. (D) Left sided-interrupted IVC with azygos continuation. A suprahepatic segment of the IVC *(I)* drains into the left-sided right atrium in this patient with atrial situs inversus. A left superior vena cava also is present *(arrow)*.

The morphologic left atrium is defined as the atrium that receives all or half of the pulmonary veins and none of the systemic veins (except an SVC to an unroofed coronary sinus). The left atrium is also the chamber that may receive no veins at all (in the setting of total anomalous pulmonary venous return). When all systemic veins and part or all of the pulmonary veins drain into one atrium, this atrium represents the morphologic right atrium.

Robert Anderson has described the morphologic right atrium (systemic atrium) as being characterized by the presence of a triangular appendage with a broad junction and by the recognition of pectinate muscles extending to the atrioventricular junction. The morphologic left atrium is characterized by a tubular narrow-based appendage and lack of pectinate muscle extension to the atrioventricular junction. Because determination of pectinate muscle morphology is beyond the resolution of MRI or CT, atrial identification is performed by recognition of venoatrial connections and morphology of the appendages. If this analysis fails to yield a confident identification of the right and left atrium, then a diagnosis of atrial situs ambiguous is made. Even in the setting of visceral situs ambiguous, reliable identification of atrial situs may be made in more than 80% of the cases.

## Ventricular Identification

Ventricles are defined by their morphologic features, not by their spatial relationships. The morphologic right ventricle is defined by the following features:

1. Muscular connection between the free wall and the interventricular septum (moderator band) (Fig. 63.5A).
2. The septal attachment of the AV valve of the RV (tricuspid valve) is more apically placed relative to that of the LV (Fig. 63.5B).
3. Presence of a conus/infundibulum. The infundibulum is identified as a muscular cone of tissue that separates the atrioventricular valve from the semilunar valve on the same side, resulting in lack of fibrous contiguity between the two valves (Fig. 63.5C).

The morphologic LV is identified by the following features:

1. Smooth surface of the interventricular septum without any muscular attachments to the free wall (Fig. 63.6).
2. The septal attachment of the AV valve of the LV (mitral valve) is more cranially located relative to that of the RV (Fig. 63.6B).
3. Absence of a conus/infundibulum, resulting in fibrous contiguity between the atrioventricular valve and the semilunar valve on that side (see Fig. 63.6).

The atrioventricular valves follow the ventricle, rather than the atrium. Thus, the tricuspid valve is related to the morphologic right ventricle, and the mitral valve to the morphologic left ventricle. The tricuspid valve typically has papillary muscle attachments to the right ventricular septal surface (septophilic valve) while the mitral valve is septophobic and only attaches to the free wall of the left ventricle.

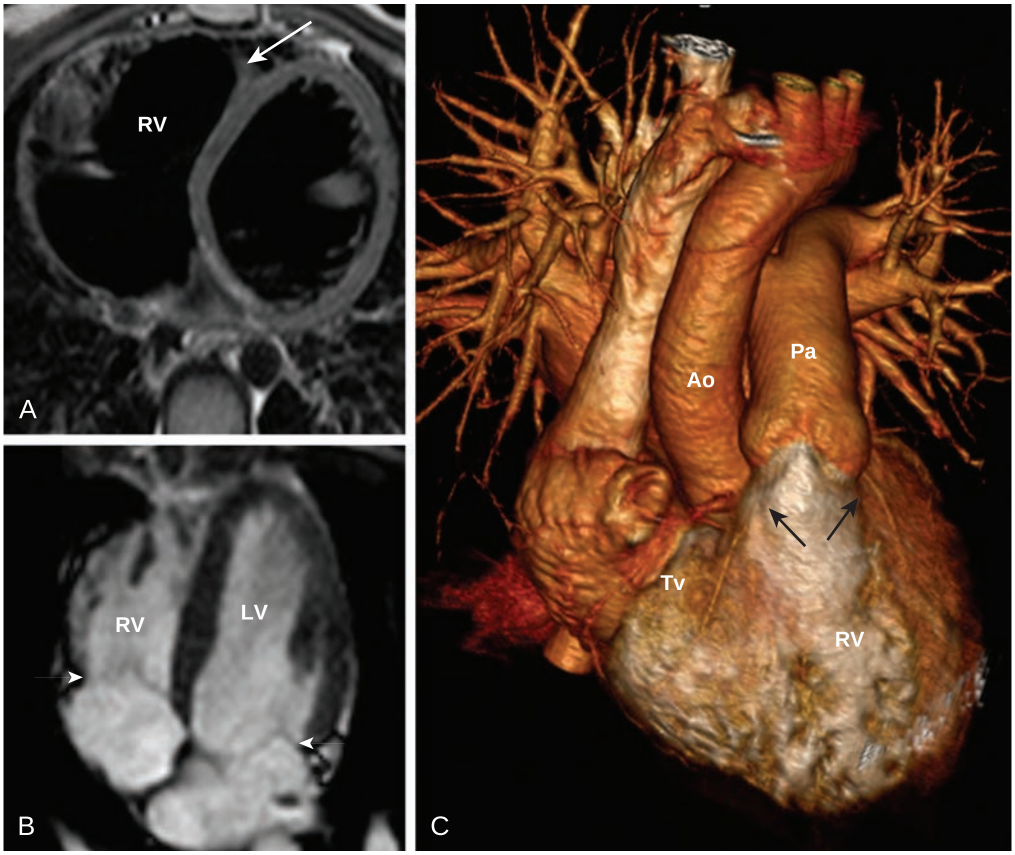

**Figure 63.5. Right ventricular identification.** (A) Moderator band of the right ventricle *(RV) (arrow)*. (B) The atrioventricular (AV) valve of the *RV* (tricuspid valve) is more apically displaced *(long arrow)* than the AV valve of the left ventricle *(LV)* (mitral valve) *(short arrow)*. (C) The conus *(arrows)* is a marker of the *RV*. It is a muscular cone of tissue that separates the AV valve *(Tv)* from the semilunar (pulmonary) valve on the same side. *Ao,* Aorta; *Pa,* pulmonary artery.

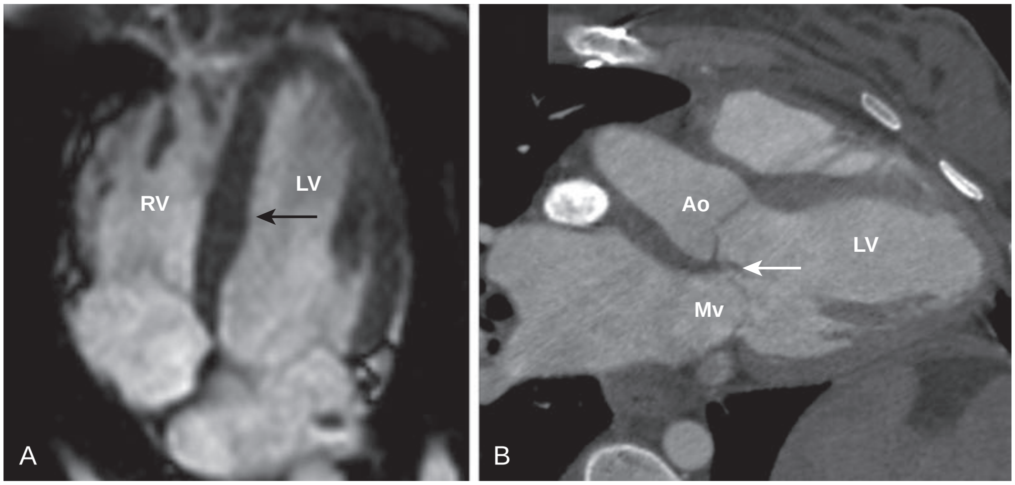

**Figure 63.6. Left ventricular identification.** (A) Smooth septal surface of the left ventricle *(LV) (arrow)*. (B) The *LV* does not have a conus, resulting in mitral *(Mv)* to aortic *(Ao)* fibrous contiguity *(arrow)*. *RV,* Right ventricle.

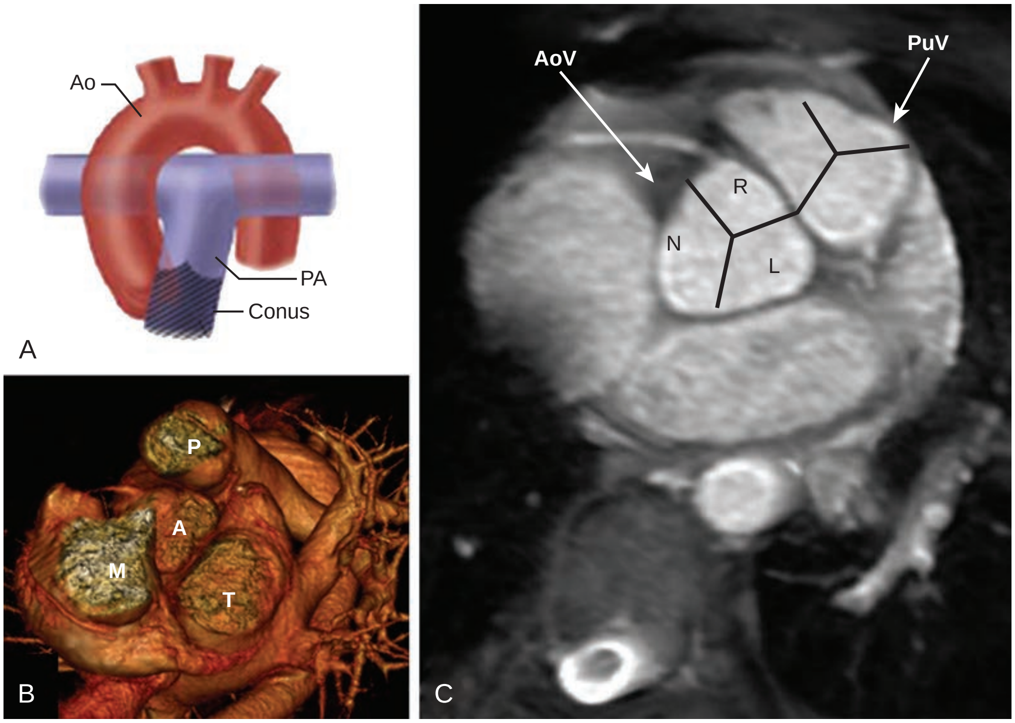

**Figure 63.7.** (A) Solitus (normal) relationship of the great arteries. (B) Three-dimensional view of the heart from above. The aortic valve *(A)* has direct fibrous contiguity with the mitral *(M)* and tricuspid *(T)* valves, whereas the pulmonary valve *(P)* lies ventrally, and is separated from the atrioventricular valves by the conus. (C) The aortic valve annulus *(AoV)* lies posterior and to the right of the pulmonary valve annulus *(PuV)*. The intercoronary commissure of the aortic valve is pointed toward the right-left commissure of the pulmonary valve. *Ao,* Aorta; *L,* left sinus of Valsalva; *N,* noncoronary sinus of Valsalva; *PA,* pulmonary artery; *R,* right sinus of Valsalva.

Neither the shape of the ventricle nor the degree of trabeculation or hypertrophy is considered a reliable marker for ventricular identification, as they are frequently affected by pressure or volume changes in the ventricle.

## Great Arterial Identification

The PA gives rise to branches to the lungs and no branches to the body. The aorta gives rise to branches to the body as well as the coronary arteries. A common vessel arising from the ventricles that gives rise to the coronaries and branches to the body as well the lungs is termed a common arterial trunk or truncus, and a segmental relationship is not assigned (labeled X for undetermined). On transverse cross-sectional imaging at the level of the outflow tract, the coronary artery origin is used to identify the aortic annulus. The intercoronary commissure of the aortic valve is pointed toward the right-left commissure of the pulmonary valve and is an important landmark for determining great arterial relationship (Fig. 63.7). In solitus relationship of the great arteries, the aortic valve annulus lies posterior and to the right of the pulmonary valve annulus.

## ANALYSIS OF THE THREE MAJOR CARDIAC SEGMENTS

### First Major Segment: Visceroatrial Situs

Situs refers to the position of the atria and viscera relative to the midline. There are three types of situs: solitus (S), inversus (I), and ambiguous (A) (Fig. 63.8). Heterotaxy is synonymous with situs ambiguous, and is simply defined as “situs other than solitus or inversus.”

Visceral situs solitus is characterized by the presence of a right-sided liver, a single or dominant left-sided spleen, three-lobed right lung with an eparterial bronchus, and a two-lobed left lung with a hyparterial bronchus. Atrial situs solitus is characterized by the presence of the systemic venous atrium on the right and the pulmonary venous atrium on the left. Situs inversus is defined as the “mirror image” of situs solitus. Hence, visceral situs inversus is characterized by a left-sided liver, a single or dominant right-sided spleen, three-lobed left lung with an eparterial bronchus, and a two-lobed right lung with a hyparterial bronchus. Atrial situs inversus is characterized by the presence of the systemic venous atrium on the left and the pulmonary venous atrium on the right. Although the location of the cardiac apex and the stomach is usually on the left in situs solitus and on the right in situs inversus, they are not considered reliable markers of visceral situs due to the high incidence of variation in the setting of normal situs.

Because heterotaxy is defined as “situs other than solitus or inversus,” it is not a specific disease but a constellation of cardiac, vascular, and visceral abnormalities, including situs ambiguous of the viscera, lung symmetry, atrial appendage symmetry, anomalous

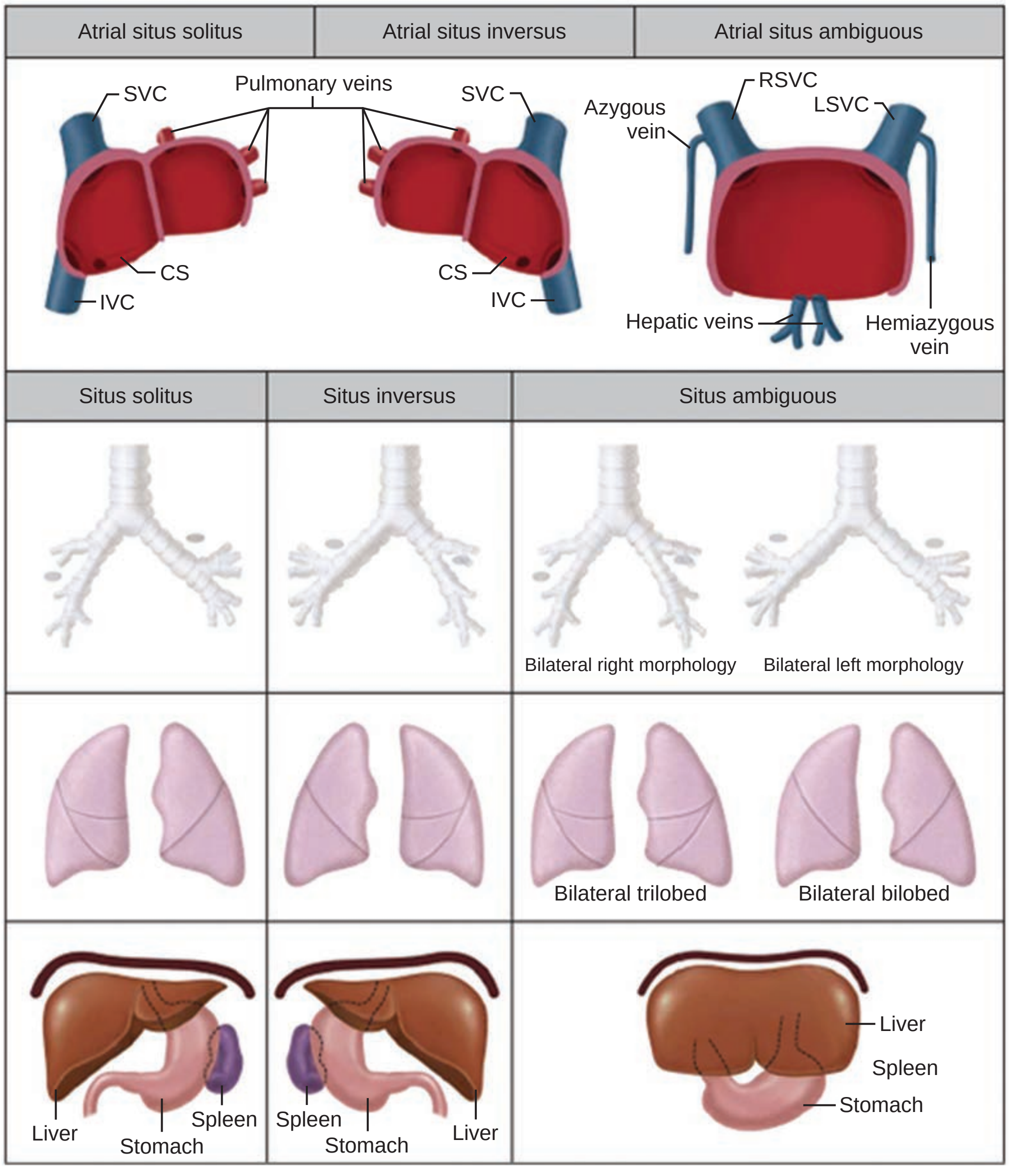

**Figure 63.8. First major cardiac segment: visceroatrial situs.** The three types of visceroatrial situs: situs solitus, situs inversus, and situs ambiguous. *CS,* Coronary sinus; *IVC,* inferior vena cava; *LSVC,* left-sided vena cava; *RSCV,* right-sided vena cava; *SVC,* superior vena cava. *(Modified from Van Praagh R, Weinberg PM, Matsuoka R, et al. Malposition of the heart and the segmental approach to diagnosis. In: Adams FH, Emmanouilides GC, eds.* Moss’ Heart Diseases in Infants, Children and Adolescents. *3rd ed. Baltimore: Williams & Wilkins; 1983.)*

systemic venous return, anomalous pulmonary venous return, and associated intracardiac defects. No single finding is pathognomonic. There is a tendency toward clustering of defects into two syndromes based on the predominance of right-sided or left-sided structures:

1. Asplenia complex—Manifestations include bilateral three-lobed lungs with eparterial bronchi, a transverse or symmetric liver, bilateral SVCs, and bilateral triangular broad-based atrial appendages. The spleen is absent.
2. Polysplenia complex—Manifestations include bilateral two-lobed lungs with hyparterial bronchi, a transverse liver, multiple splenic fragments, and bilateral tubular atrial appendages. The renal to hepatic segment of the IVC is frequently absent, with associated azygos continuation.
3. Van Praagh has added a third syndrome of heterotaxy manifested by levocardia with a single right-sided spleen. Features of this syndrome are similar to that of right isomerism.

The use of the terms *atrial isomerism*, *bilateral right-sidedness*, or *bilateral left-sidedness* as substitutes for the syndromes of situs ambiguous is discouraged because they are semantically inaccurate representations of the anatomy found in these patients.

### Second Major Segment: Ventricular Loop

Depending on the direction of ventricular looping during development, the right ventricle may be located spatially on the right or left side of the heart (Fig. 63.9). If the bulboventricular loop occurs to the right, it is termed a D-loop, and the morphologic RV lies anterior and to the right of the morphologic LV. If the bulboventricular loop occurs to the left, it is termed an L-loop, and the morphologic RV lies anterior and to the left of the morphologic LV.

### Third Major Segment: Great Arterial Relationship

Normally, the aortic annulus lies posterior, inferior, and to the right of the pulmonary valve annulus. This position is called solitus (S) (Fig. 63.10A). In situs inversus, the aorta lies posterior and to the left of the pulmonary valve, termed inversus (I) (Fig. 63.10B). Any other position of the aorta and PA other than solitus or inversus is termed malposition. If the aorta lies to the right of the PA, it is called D-malposition (Fig. 63.10C). If the aorta lies to the left of the PA, it is termed L-malposition (Fig. 63.10D).

## DIFFERENT TYPES OF HUMAN HEARTS

The segmental possibilities at each level are as follows:

Atria: Solitus (S), inversus (I), and ambiguous (A)
Ventricles: D and L
Great arteries: Solitus (S), inversus (I), D-malposition, and L-malposition

Based on the various permutations and combinations of atrial, ventricular, and great arterial relationships, as well as on the anatomy of the conus, Van Praagh provided an overview of the diversity that exists in human hearts (Fig. 63.11). It becomes immediately apparent that a pattern-based approach or an approach based on connections or the direction of flow of blood will not do justice to the complexity of the disease processes. The segmental approach not only takes into account the morphologic variations at each level but also provides structural landmarks to distinguish the variations from each other, determine their impact on physiology, and thereby allows informed decision making regarding management.

## ANALYSIS OF THE CONNECTING SEGMENTS

### First Connecting Segment: Atrioventricular Junction

The anatomic possibilities at the atrioventricular junction level may be classified based on the number of ventricles as follows:

1. Biventricular AV connections
2. Univentricular AV connections

The types of biventricular AV connections (Fig. 63.12) include

1. Concordant AV connections (RA-RV and LA-LV)
2. Discordant AV connections (RA-LV and LA-RV)
3. Straddling AV valve, in which there is abnormal attachment of the tensor apparatus of the valve to the opposite ventricle
4. Overriding AV valve, in which the AV valve annulus crosses the interventricular septum and partly overlies the opposite ventricle
5. Overriding and straddling AV valve
6. Balanced common AV canal with two symmetric sized ventricles

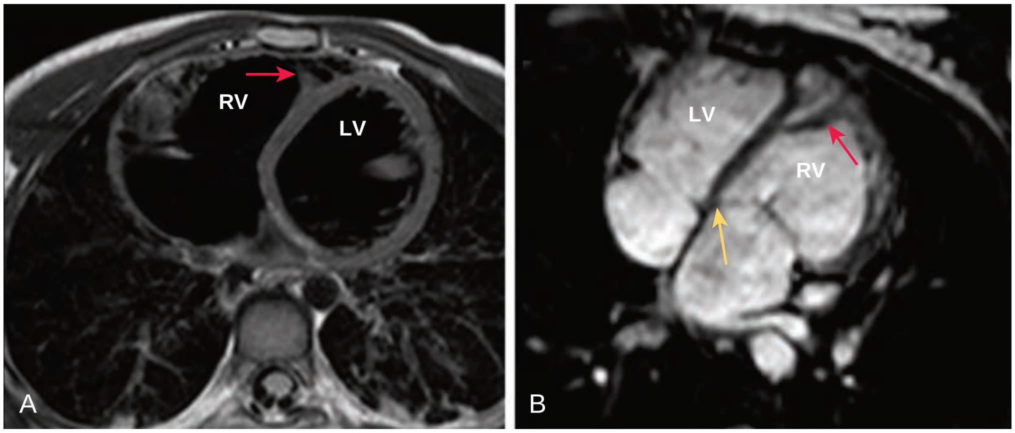

**Figure 63.9. The second major cardiac segment: ventricular looping.** (A) D-looping with the right ventricle *(RV)* lying anterior and to the right of the left ventricle *(LV)*. (B) L-looping, with the RV lying anterior and to the left of the LV. The RV is identified by the moderator band *(red arrow)*, apical displacement of the AV valve *(yellow arrow)*, and the conus *(not shown)*.

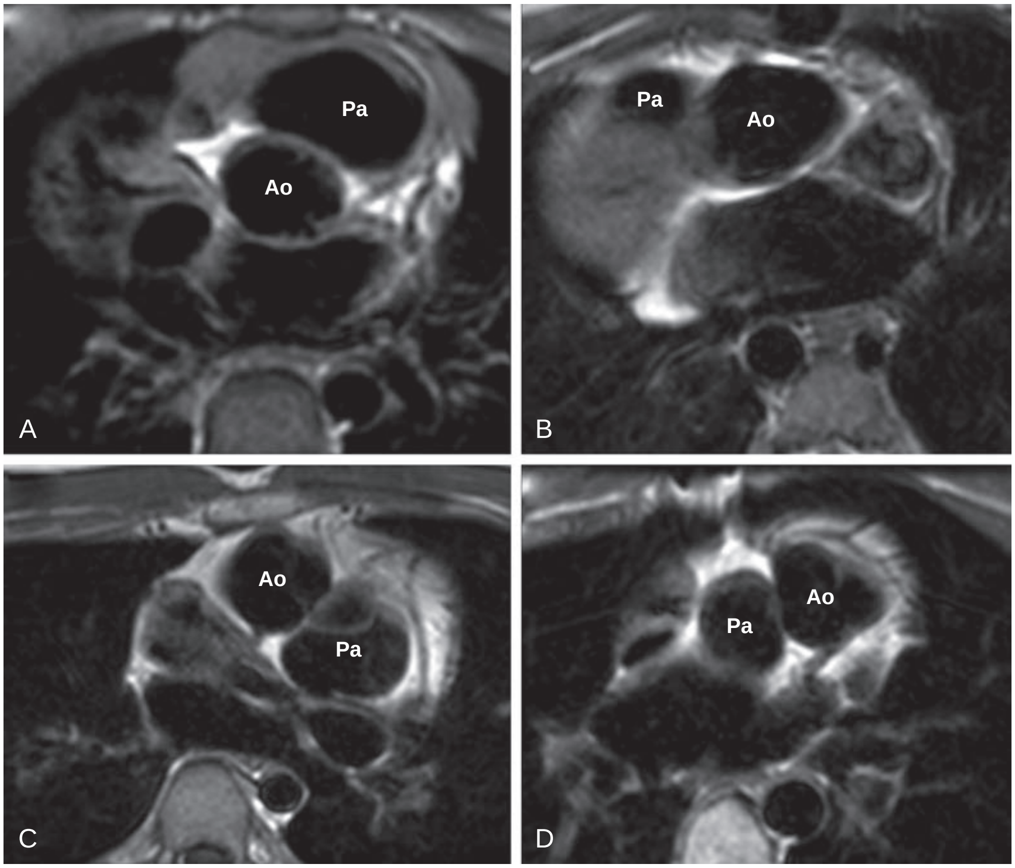

**Figure 63.10. The third major cardiac segment: arterial relationship.** (A) Solitus: the aortic annulus *(Ao)* lies posterior, inferior, and to the right of the pulmonary valve annulus *(Pa)*. (B) Inversus: the aorta lies posterior and to the left of the pulmonary valve. (C) D-malposition: the aorta lies anterior and to the right of the pulmonary artery. (D) L-malposition: the aorta lies anterior and to the left of the pulmonary artery.

The types of univentricular AV connections (Fig. 63.13) include:

1. Unilateral left AV valve atresia (mitral atresia)
2. Unilateral right AV valve atresia (tricuspid atresia)
3. Double inlet LV
4. Double inlet RV
5. Left dominant unbalanced common AV canal
6. Right dominant unbalanced common AV canal

In the setting of univentricular AV connections, one of the AV valves is atretic or both AV valves open partly or wholly into the same ventricle. The second ventricular chamber is subsequently very small or just an outflow chamber and is of little functional use, apart from serving as a conduit for one of the great arteries. Single ventricles may be of a left ventricular, right ventricular, or indeterminate morphology. The functional single LV is characterized by the presence of a bulboventricular foramen, which connects the LV chamber to the small anteriorly located infundibular outlet chamber of the RV. The RV sinus (inflow portion) is typically absent. A functional single RV is characterized by the presence of a septal band, and in most cases, by a rudimentary posterolaterally located LV chamber.

## Second Connecting Segment: Conotruncus or Ventriculoarterial Junction

The development of the conotruncus is the most important variable in the genesis of outflow tract anomalies. The differential growth of the subpulmonary and subaortic conus cushions largely determines the relationship between the semilunar valves, between the semilunar valves and the ventricles, and between the semilunar valves and the atrioventricular valves. It also determines the presence of distal infundibular stenosis and the location of the ventricular septal defect (VSD) in outflow tract anomalies. Based on conal development, the following anatomic types of conus (Fig. 63.14) may be recognized:

1. Development of subpulmonary conus and resorption of the subaortic conus results in ventriculoarterial concordance and normal relationship of great arteries. The aorta lies posterior and to the right in a D-loop heart (solitus) and posterior and to the left in an L-looped heart (inversus).
2. Development of the subaortic conus and resorption of the subpulmonary conus results in ventriculoarterial discordance and transposition of the great arteries. Transposition means that the left ventricle is connected to the main PA and the right ventricle to the aorta. The aorta lies anterior and to the right in a D-looped heart (D-malposition) (Fig. 63.15) and anterior and to the left in an L-looped heart (L-malposition).
3. Persistence and development of both the subaortic and subpulmonary conus leads to double outlet RV. Double outlet right ventricle means that both great vessels arise predominantly from the RV (Fig. 63.16). There may be variable development of the pulmonary and aortic conus resulting in variable location of the VSD in relation to the great arteries.

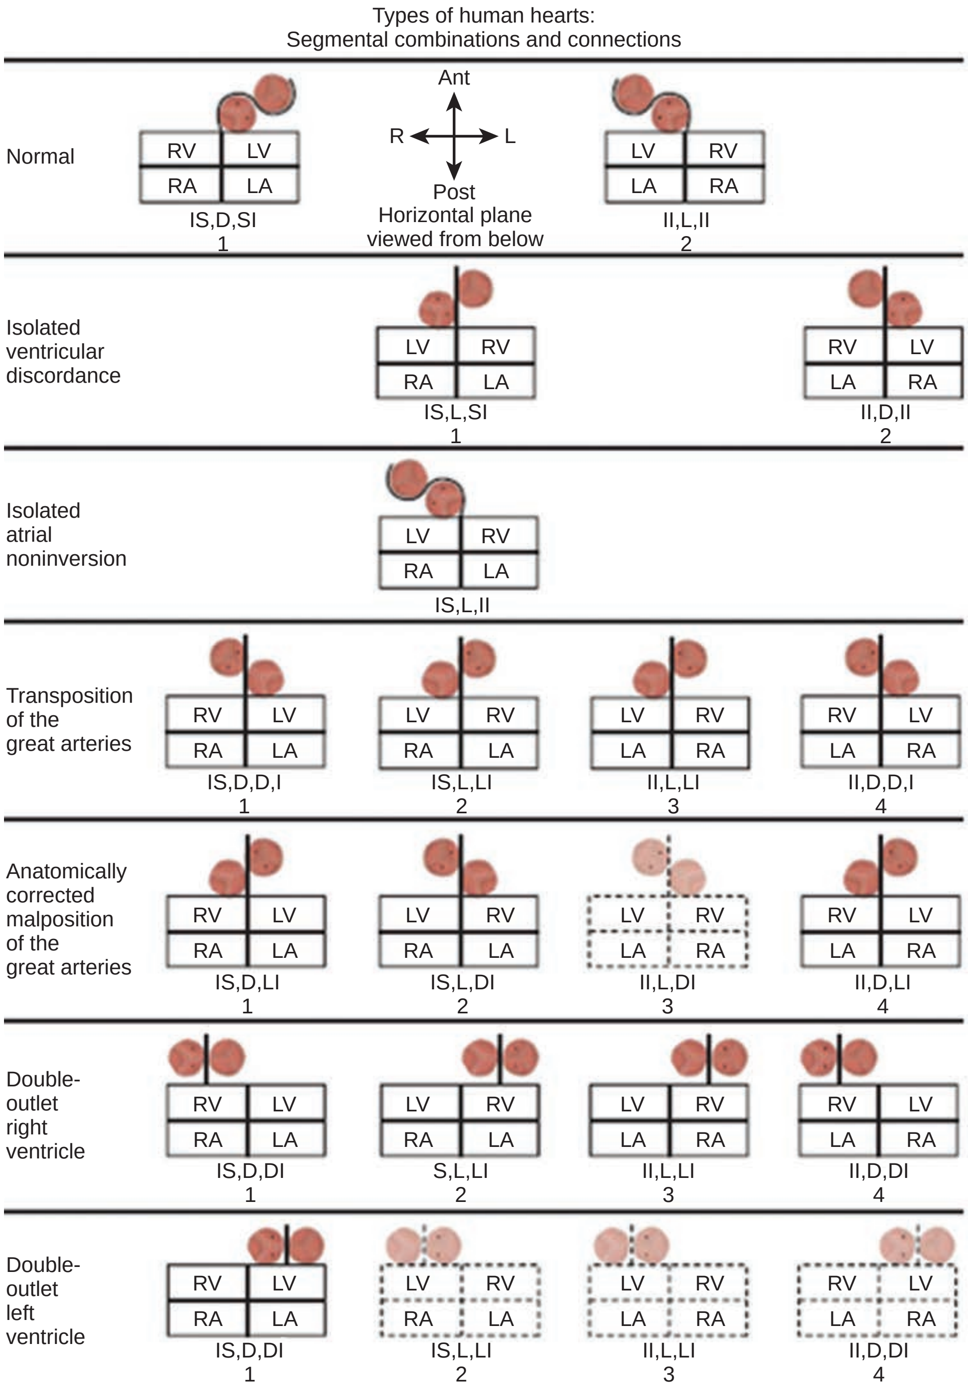

**Figure 63.11. Van Praagh's types of human hearts, based on segmental combinations of visceroatrial situs, ventricular looping, and great arterial situs.** The segmental combination is expressed as a set, within braces. For instance, a normal heart would be expressed as {S,D,S} for visceroatrial situs solitus, D-looping of the ventricles, and solitus relationship of the great arteries. The segmental connections and associated anomalies are expressed outside the braces. For instance, physiologically corrected transposition would be expressed as {S,L,L} transposition of the great arteries for solitus atria, L-looped ventricles, and L-malposition of the great arteries. If this patient also had straddling atrioventricular valve and an inlet ventricular septal defect (VSD), it would be expressed as {S,L,L} transposition of great arteries, straddling tricuspid valve, and inlet VSD. *Ant,* Anterior; *LA,* left atrium; *LV,* left ventricle; *Post,* posterior; *R,* right; *RA,* right atrium; *RV,* right ventricle. *(Modified from Van Praagh R, Weinberg PM, Matsuoka R, et al. Malposition of the heart and the segmental approach to diagnosis. In: Adams FH, Emmanouilides GC, eds.* Moss' Heart Diseases in Infants, Children and Adolescents. *3rd ed. Baltimore: Williams & Wilkins; 1983.)*

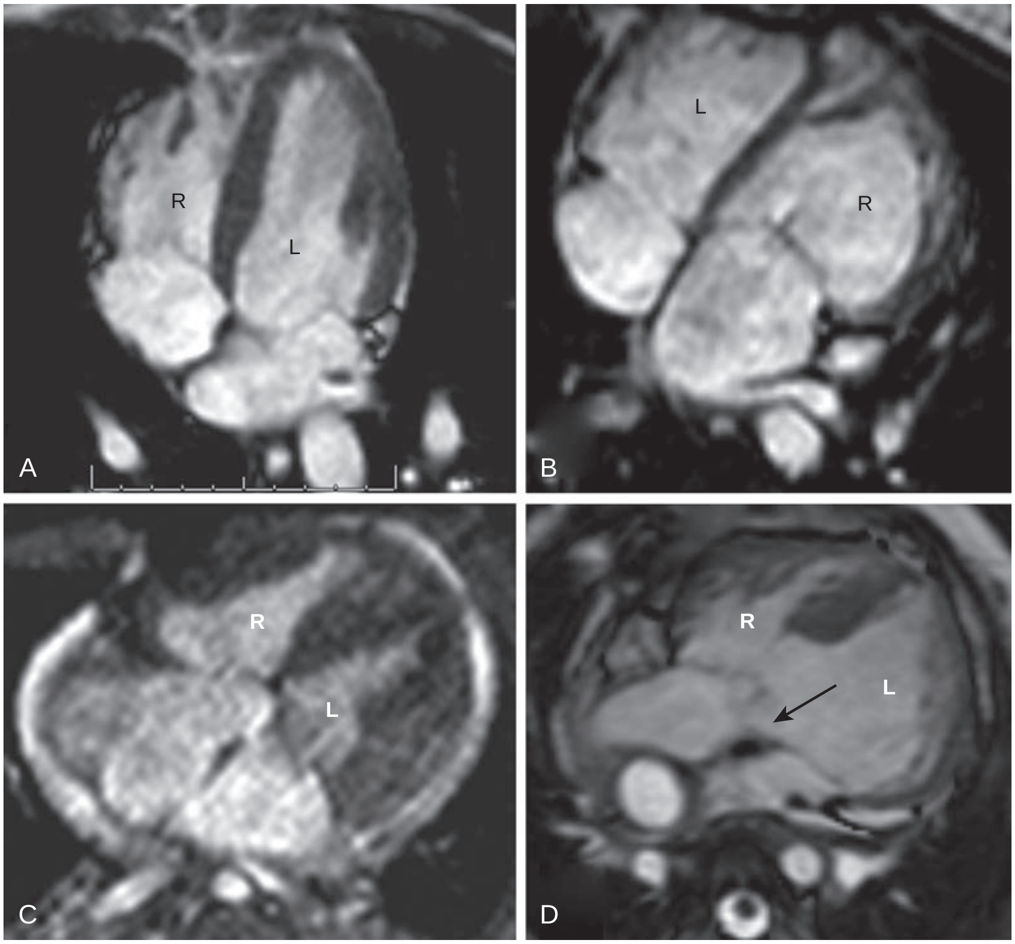

**Figure 63.12. Types of biventricular atrioventricular (AV) connections.** (A) Concordant AV connections (right atrium-right ventricle [RA-RV] and left atrium-left ventricle [LA-LV]) (B) Discordant AV connections (RA-LV and LA-RV). (C) Balanced common AV canal with two symmetric sized ventricles. (D) Straddling and overriding tricuspid valve *(arrow)* in a patient with D-looped ventricles. *L,* Left ventricle; *R,* right ventricle.

4. Resorption of both the subpulmonary and subaortic conus results in double outlet LV. Double outlet LV means that both vessels arise predominantly from the LV.

A rare form of conal maldevelopment is anatomically corrected malposition of the great arteries in which there is origin of the malposed aorta above the LV and origin of the malposed PA above the RV. Malalignment of the conal septum is the cause of infundibular obstruction in tetralogy of Fallot (anterior malalignment) and subaortic stenosis with interrupted aortic arch (posterior malalignment).

## EVALUATION OF ASSOCIATED ANOMALIES

The presence of associated anomalies involving the atrial and ventricular septum, the atrioventricular and semilunar valves, aorta, pulmonary arteries, pulmonary veins, and systemic veins plays an important part in the functional outcome of the patient, and screening for these conditions is an integral part of the segmental approach to heart disease.

## EVALUATION OF FUNCTION

The final step in the segmental approach to heart disease is to determine how the segmental combinations and connections function. Broadly, abnormal function of the congenitally malformed heart may be classified into the following subgroups:

1. Pressure overload related to phenomena such as valvular stenosis, coarctation, and branch PA stenosis
2. Volume overload related to phenomena such as valvular regurgitation and left to right shunts
3. Intermixing, in which there is mixing of oxygenated blood with deoxygenated blood before entering the systemic circulation; this phenomenon typically occurs in the setting of a common chamber, vessel, valve, or in a right-left shunt
4. Poor contractility of the myocardium related to conditions such as cardiomyopathy or ischemia

When all relevant information regarding morphology and function has been collected, decisions regarding management may be made, which may be in the form of medical therapy, surgical therapy, or both.

## ILLUSTRATED CASE DISCUSSION

A case study of a segmental approach to imaging of congenital heart disease is illustrated in Fig. 63.17.

- Situs solitus of the atria (S): The coronary sinus and IVC enter the right-sided atrium, which therefore represents the morphologic RA. The pulmonary veins enter the

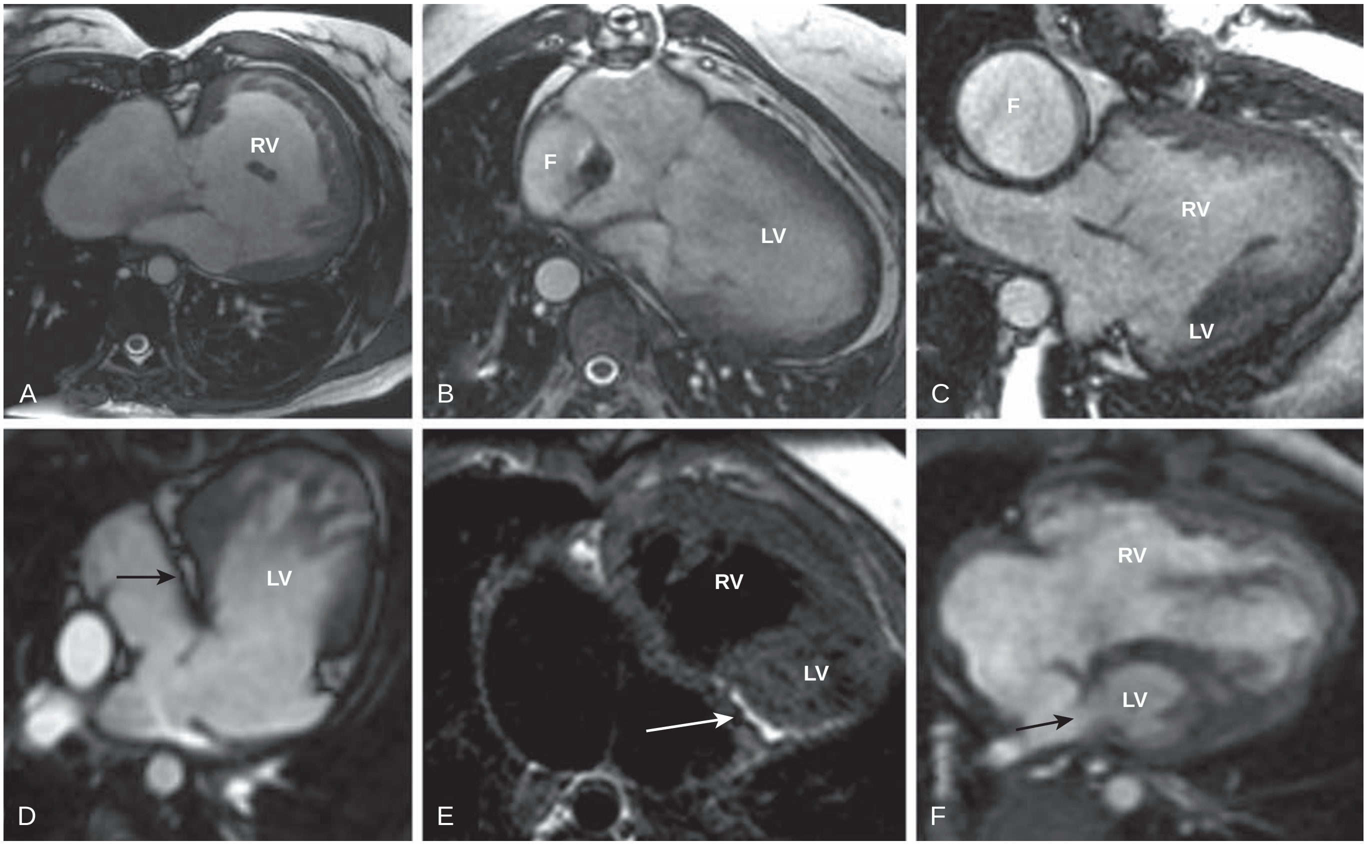

**Figure 63.13. Types of univentricular atrioventricular (AV) connections.** (A) Double inlet right ventricle *(RV)*. (B) Double inlet left ventricle *(LV)*. (C) Right dominant unbalanced common AV canal. (D) Tricuspid atresia (*arrow* shows atretic tricuspid valve plane). (E) Mitral atresia (*arrow* shows atretic fatty mitral valve plane). (F) Severe mitral stenosis *(arrow)* in hypoplastic left heart syndrome. *F,* Fontan.

morphologic LA. The RA connects to the right PA via an atriopulmonary anastomosis. The SVC also connects to the right PA.

- AV connection: The right AV valve (tricuspid valve) is atretic and fatty replaced. The left AV valve (mitral valve) is normal.
- D-looping of the ventricles: The large left-sided ventricle has a smooth septal surface consistent with a morphologic LV. The small blind-ending chamber to the right is the infundibular outlet chamber of the RV, which fills via a bulboventricular foramen.
- Ventriculoarterial connection: RV-PA outflow is atretic. Aortic outflow from the LV is normal.
- Solitus relationship of the great arteries (S): The aortic valve lies posterior and to the right of the atretic pulmonary valve.

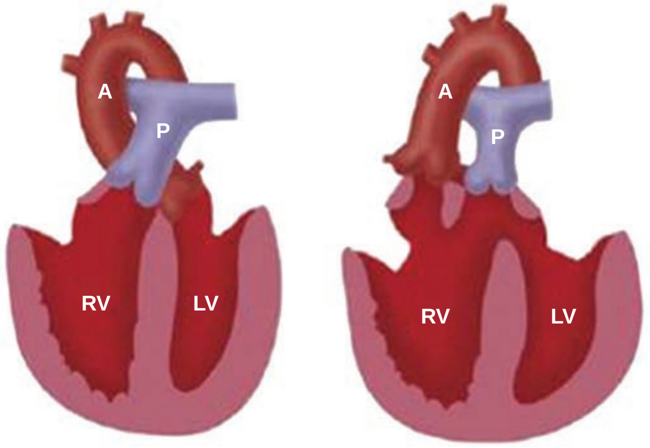
The final diagnosis is {S,D,S} tricuspid atresia, pulmonary atresia, status postoperative Fontan completion.

## CONCLUSION

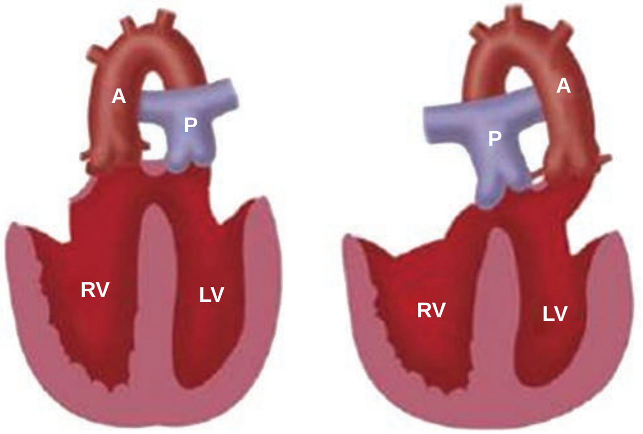
The segmental approach to heart disease provides an elegantly simple method to break down the complexity of congenital heart disease on cross-sectional imaging. It creates a template for standardizing nomenclature, thereby ensuring that caregivers from different specialties understand each other. It is firmly rooted in embryologic principles and is, therefore, intuitive to the beginner in the field. MRI and CT almost rival pathologic evaluation of specimens in the detail that they provide on cardiovascular morphology. Additionally, MRI provides unique information regarding function, flow and tissue characterization that decreases the need for more invasive means of diagnosis. Thus they are ideal vehicles for the segmental approach to heart disease.

### KEY POINTS

- The segmental approach is a simple, logical, step-by-step approach to diagnosis and decision making in congenital heart disease and is rooted in sound embryologic concepts.
- The segmental approach involves the analysis of the three major cardiac segments (atria, ventricles, and great arteries), the two connecting segments (the AV canal and the conotruncus), and associated anomalies involving the atrial and ventricular septum, great arteries, and systemic and pulmonary veins. The final step is evaluation of physiology and function, which paves the way for decision making regarding management.
- Reliable identification of the cardiac chambers based on specific morphologic features is the first step in the segmental approach to heart disease. These features may be appreciated easily on cross-sectional imaging.
- Characterizing the specific type of visceroatrial situs, ventricular looping, and great arterial situs is the next step. Based on the various permutations and combinations of atrial, ventricular, and great arterial relationships, Van Praagh created a chart that outlines the diversity that exists in human hearts.



A Concordant connection B Double-outlet right ventricle



C Discordant connection D Double-outlet left ventricle

**Figure 63.14. Types of ventriculoarterial connections based on conal development.** (A) Concordant ventriculoarterial connection: solitus great arteries with subpulmonary conus. (B) Double-outlet right ventricle *(RV)* with bilateral conus. (C) Discordant ventriculoarterial connection: dextra-posed transposition of the great arteries with subaortic conus. # 64

# Pediatric Echocardiography

*James René Herlong*

Echocardiography is the primary imaging modality used to assess the heart and extracardiac thoracic vasculature in children. Echocardiography is sufficiently robust to be used as the sole imaging modality in assessing cardiac anatomy before surgical repair in most pediatric patients with congenital heart disease, so familiarity with echocardiography is important for anyone involved in diagnostic imaging in these patients.

## TECHNIQUE

Transthoracic echocardiography is an ultrasound technique that is optimized for imaging the moving heart. Standard imaging windows that are free of interference from the lungs are illustrated in Fig. 64.1. These windows allow imaging of the heart in multiple planes. These planes are based on the axes of the heart and not on the axes of the body (Fig. 64.2).

In each acoustic window, the heart is imaged in orthogonal planes. Because the heart is a three-dimensional structure and because ultrasonography is a tomographic imaging technique, slow sweeps in each view are necessary to understand the complex relationships between various segments of the heart. Three- and four-dimensional echocardiography are becoming ever more robust, but they are not yet capable of high-resolution imaging of the entire heart. Currently, the utility of these techniques is largely in the assessment of the cardiac valves, particularly the atrioventricular valves.

Assessment of ventricular systolic function is performed in every echocardiographic examination. Among the various techniques of quantifying left ventricular systolic function, the left ventricular shortening fraction is the most easily accomplished and universally used. Standards for left ventricular dimensions and shortening fraction according to body surface area are available in standard references. Assessment of left ventricular diastolic function is less exact, and techniques continue to be developed to evaluate this rather elusive entity. The method with the most promise is tissue Doppler imaging, which uses the Doppler principle to measure the high amplitude but low velocity signals derived from myocardial motion.

Doppler echocardiography uses color and spectral Doppler in the same manner as in vascular ultrasound imaging. One important difference is that when using color Doppler, the color map is always set so that flow toward the transducer is red, whereas flow away from the transducer is blue. Color Doppler imaging is useful for screening for valvar stenosis or regurgitation, septal defects, and arterial and venous stenoses. Color Doppler should be used to complement two-dimensional imaging, not to replace it, because color Doppler obscures anatomy.

In a typical echocardiographic examination, all cardiac valves are assessed by spectral Doppler, as are the aortic arch at the isthmus and any identified septal defects. As with all Doppler applications, the most accurate assessment is obtained by aligning the angle of interrogation exactly along the direction of flow. The simplified Bernoulli equation states that the pressure gradient across an area is approximately equal to four times the measured Doppler velocity squared ($4v^2$). By using this equation, gradients are estimated in each of the locations that are assessed by spectral Doppler. In general, peak instantaneous pressure gradients across semilunar valves and in the arterial system should be less than 15 mm Hg, and mean gradients in veins and across atrioventricular valves should be less than 3 mm Hg.

Other differences from noncardiac ultrasound involve sedation and image archiving. Because accurate assessment of anatomy and

## Abstract:

This chapter discusses the technique, interpretation and reporting of the normal pediatric echocardiographic examination. It compares and contrasts echocardiography with other ultrasound imaging techniques and points out differences between the pediatric echocardiogram and the adult echocardiogram. Schema for formulating a diagnosis and for formatting a report are presented, as well.

function requires images free of patient movement and because accurate assessment of pressure gradients requires the patient to be in a resting state, sedation may be necessary in patients younger than 3 years. Because assessment of function and complex anatomy requires viewing moving images, echocardiograms are archived as video clips rather than as still-frame images.

Transesophageal echocardiography in the pediatric population is used primarily in the operating room during surgery for congenital heart disease and in the interventional cardiac catheterization laboratory. Techniques are similar to those previously described.

## FORMULATING A DIAGNOSIS

Once the images have been obtained, a comprehensive diagnosis must be constructed; this is accomplished by using the segmental approach to cardiac anatomy (see Chapter 63). A common template for reporting the findings of an echocardiogram is presented in Box 64.1. Note that the scheme is logical and largely follows the blood flow through the various segments of the heart.

### KEY POINTS

- Most pediatric patients with congenital heart disease are taken to the operating room on the basis of an echocardiographic diagnosis alone.
- Standard imaging planes for echocardiography relate to the axes of the heart, not to the axes of the body.
- The heart is best understood by considering its anatomy segmentally.

# Chest Radiography in Pediatric Cardiovascular Disease

*J. A. Gordon Culham and John B. Mawson*

The role of chest radiography in the diagnosis and evaluation of congenital cardiovascular disease continues to evolve. At one time a major tool in the assessment of heart disease, radiography now occupies an ancillary role, with echocardiography serving as the major primary investigation after physical examination, especially in the neonatal period. However, the chest radiograph still may provide the first indication of unsuspected cardiovascular disease, and in infants and children with known cardiac disease radiography offers an important overview of the heart and pulmonary circulation. Moreover, chest radiography is a vital tool in the early postoperative period and is useful in the follow-up of heart disease. These latter topics are beyond the scope of this chapter.

The major chest radiographic findings in patients with cardiac disease are cardiomegaly, pulmonary vascular changes (predominantly overcirculation or undercirculation), and signs of pulmonary venous hypertension and edema. However, several caveats need to be emphasized. First, children with relatively mild structural defects and even some children with severe or complex disease may have normal chest radiographs. This situation is particularly true in newborns. In addition, the chest radiograph usually does not provide useful information about specific chamber size, hypertrophy, or intracardiac connections or malformations. Echocardiography, magnetic resonance imaging, computed tomography, or angiography is needed for precise evaluation of intracardiac structure and function. Furthermore, findings such as a boot-shaped or egg-shaped heart are nonspecific for tetralogy of Fallot or transposition of the great arteries, respectively. On the other hand, plain radiographic findings may be specific for some extracardiac lesions, such as supracardiac total anomalous pulmonary venous return, pulmonary stenosis, aortic arch anomalies, and coarctation of the aorta.

A systematic approach to evaluation of the chest radiograph consists of an assessment of heart size, shape, and position; pulmonary vasculature; the airway and mediastinum; visceral situs; and skeletal abnormalities. Applying such an approach often results in the recognition of a cardiovascular disease category, which in turn leads to a differential diagnosis and the identification of the likely etiology of nonspecific clinical findings, such as congestive heart failure or cyanosis.

## TECHNIQUE

Proper exposure, centering, collimation, patient positioning, and inspiration are necessary to optimize the examination and its interpretation (e-Fig. 65.1). Many infant radiographs are obtained using the anteroposterior projection and supine position. Because of the small size of the chest, this technique results in little magnification of the heart, as can be seen in larger children. Beam angulation also may affect the appearance of the heart and great vessels. With lordotic positioning or low centering for a combined chest and abdomen radiograph, the heart may appear more globular, with an uplifted apex and accentuation of the pulmonary outflow tract; with reverse lordosis, much of the heart may be obscured by the hemidiaphragms. Oblique views are not useful for cardiac evaluation. Chest fluoroscopy is rarely used except to evaluate prosthetic valve function, the diaphragm, or airway dynamics.

## SYSTEMATIC INTERPRETATION

### Normal Anatomy and Physiology

One of the challenges in evaluating the chest radiographs of younger children is their variable anatomy and physiology. For example, the thymus is variable in size and position and may mimic cardiomegaly, abnormally positioned vessels, pericardial fluid, or a mediastinal mass (e-Fig. 65.2). It is rare for the thymus to extend posteriorly. The thymus usually causes few problems in the interpretation of chest radiographs in children older than 6 years.

Newborn infants have physiologic pulmonary hypertension, and as a result, large shunt lesions do not become apparent until the pulmonary vascular resistance falls, which usually manifests by 4 to 6 weeks (Fig. 65.3). Similarly, newborn infants may not show the expected changes of severe pulmonary stenosis or atresia if the ductus arteriosus is patent.

The physiology of small airways in infants and children up to approximately 2 years of age results in unique manifestations of pulmonary edema. Specifically, infants show hyperinflation as a response to interstitial edema, as happens in airway inflammation with bronchiolitis (see Figs. 65.3 and 65.4). The hyperinflation occurs as an adaptive response to the interstitial edema to prevent small airway closure. In the absence of clinical signs of a respiratory infection or aspiration, hyperinflation is an important sign of early pulmonary edema.

### Heart Size

The size of the heart can be difficult to assess in the frontal projection of infants and young children because of the presence of the relatively large thymus and poor inspiration (see e-Figs. 65.1 and 65.2). Measurement of the cardiothoracic ratio is of little use. The lateral view provides a more reliable indication of true heart size by permitting an assessment of the anteroposterior dimension without interference from the thymus. However, the thymus does fill in the retrosternal space, obscuring the right ventricular outflow tract. Posterior displacement of the trachea can be indicative of cardiac enlargement. In older children, the frontal radiograph is more useful; however, the radiologist should evaluate both views to assess the three-dimensional volume of the heart. In a child with pectus excavatum, the heart may appear large in the frontal view but compressed on the lateral view. Marked cardiomegaly is seen in children with severe valve regurgitation, especially tricuspid valve disease (Ebstein anomaly), pericardial effusion, and cardiomyopathy, and it is rarely seen in children with cardiac tumors. Mediastinal masses may mimic cardiomegaly (Box 65.1, e-Fig. 65.5).

### Pulmonary Vasculature

Chest radiography provides a window into the pulmonary circulation, which is the main area in which chest radiography supplements the information gained from echocardiography. The pulmonary vasculature may show evidence of increased flow, decreased flow, normal flow, or pulmonary venous hypertension. The assessment

## Abstract:

In this chapter we review the role and limitations of conventional chest radiography in the detection and evaluation of congenital cardiovascular disease in children. An approach to the interpretation is suggested. Cases illustrate the common findings as well as the unique anatomy, physiology and cardiovascular pathology of infants and young children.

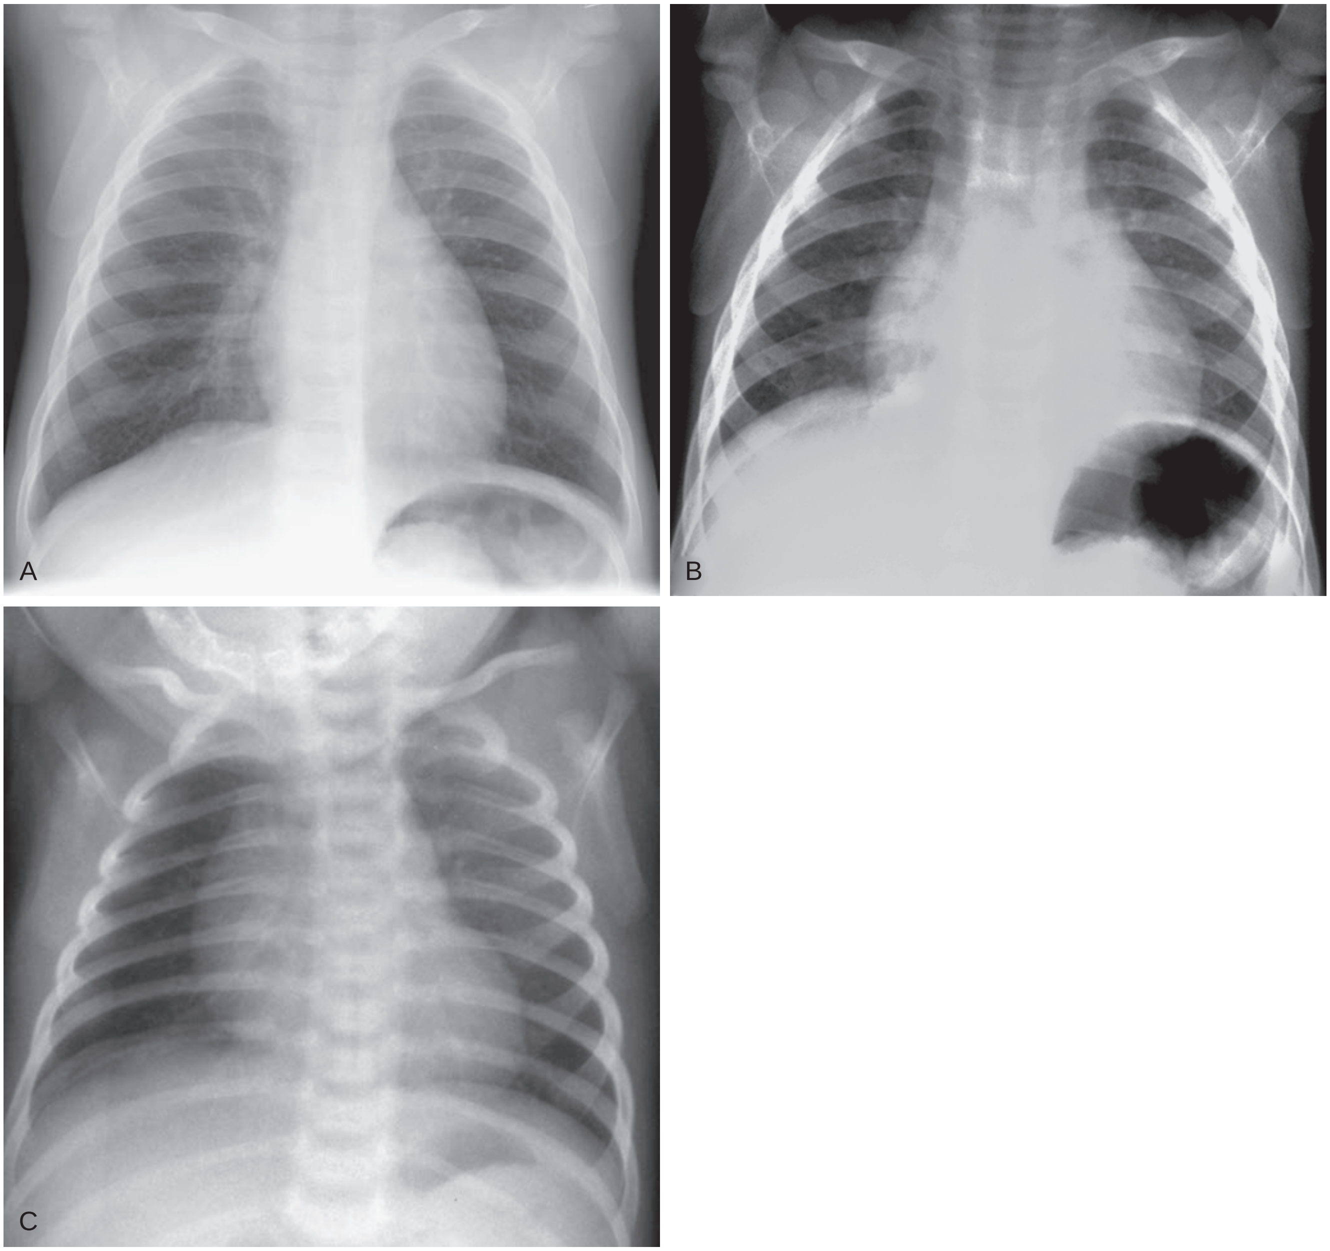
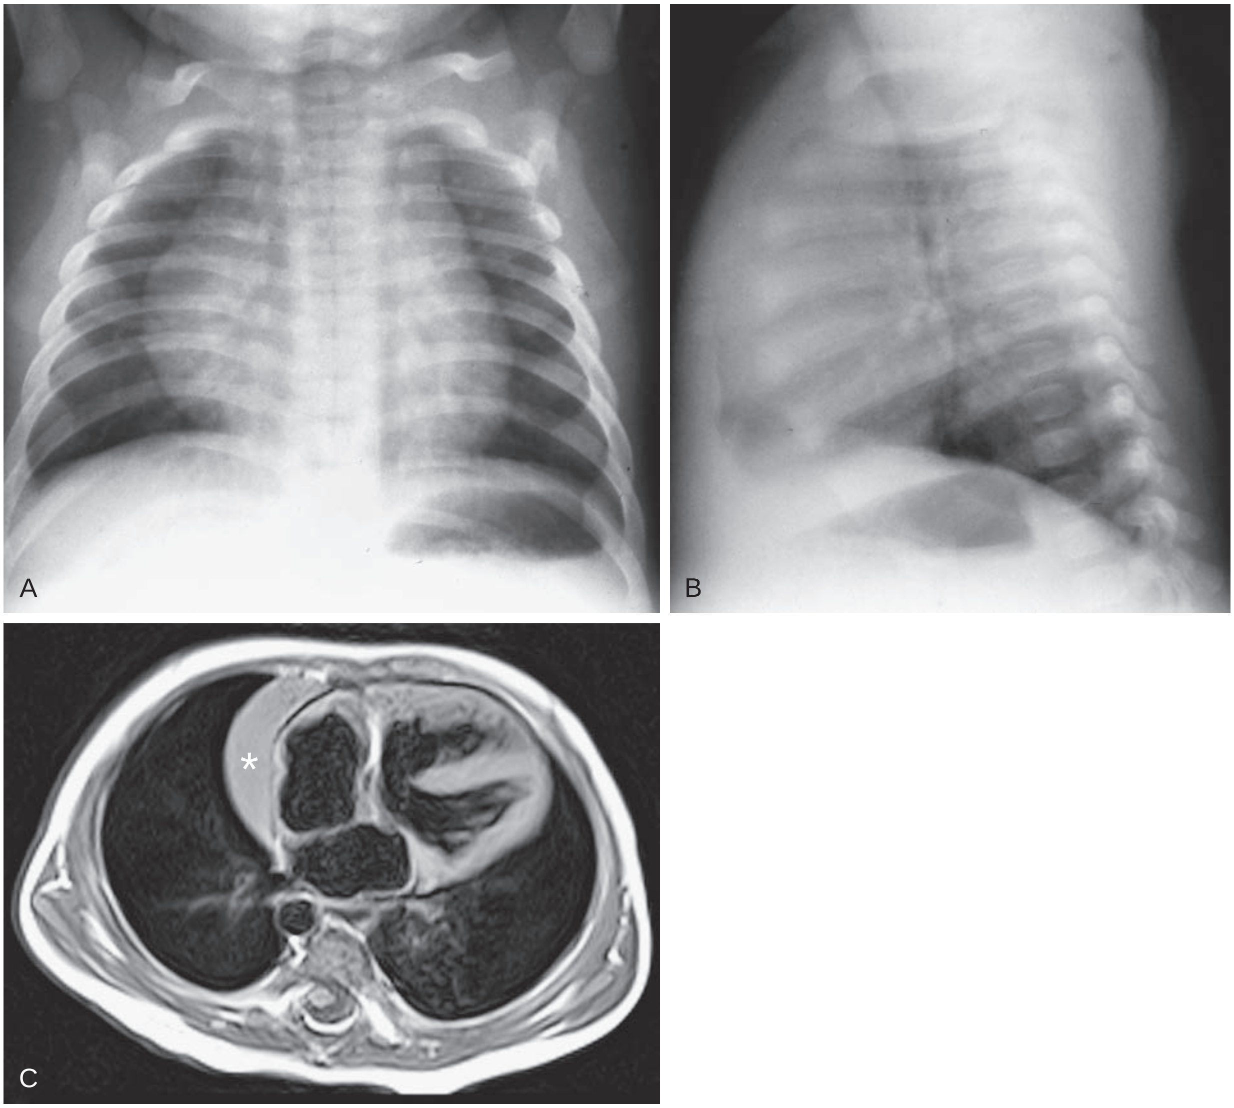
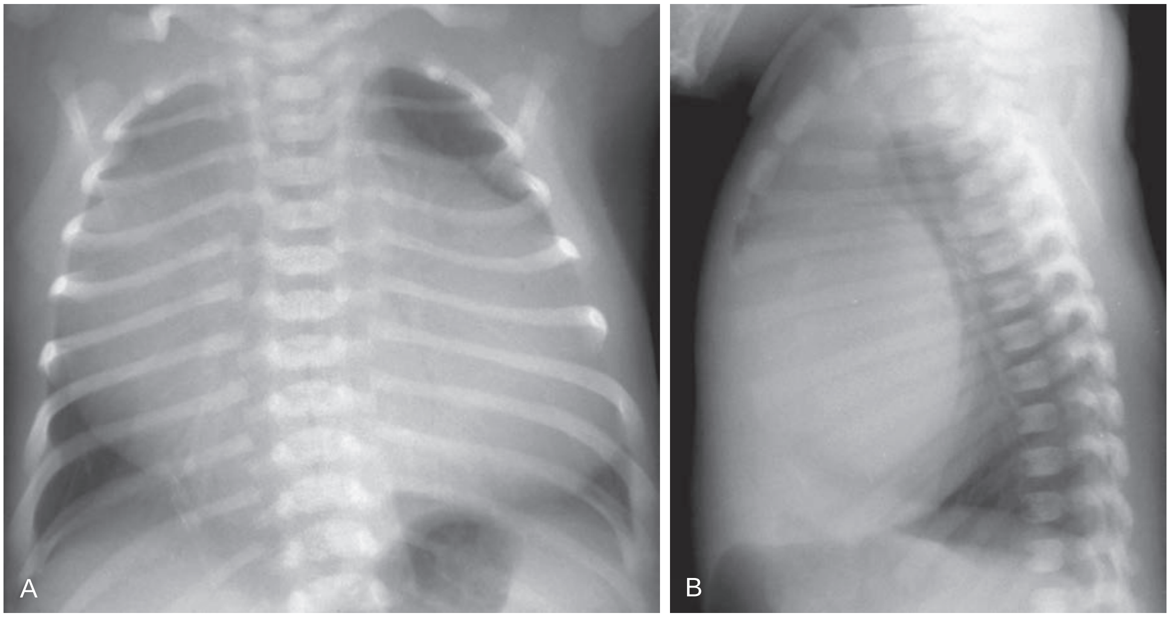
Congenital Cardiovascular Disease



**e-Figure 65.1. Normal chest examination in an infant.** Frontal radiographs in inspiration (A) and expiration (B) show the profound impact of an expiratory radiograph on the appearance of the heart and lungs. In another example (C), a lucent right lung reflects patient rotation to the right rather than asymmetric pulmonary blood flow.



**e-Figure 65.2. Normal chest examination in an infant.** A frontal chest radiograph (A) shows a large cardiomediastinal silhouette, which on the lateral view (B) reflects a normal heart and a large retrosternal thymus. In another child, T1-weighted axial MRI of the chest (C) shows the right lobe of the thymus *(star)* beside the right atrium. Note also the ventricular septal defect, right ventricular hypertrophy, and right-sided descending aorta in this child with tetralogy of Fallot.



**e-Figure 65.5. Ebstein anomaly in an infant.** Frontal (A) and lateral (B) chest radiographs show severe cardiac enlargement. Volume loading of the right atrium and the atrialized portion of the right ventricle account for the cardiac enlargement.

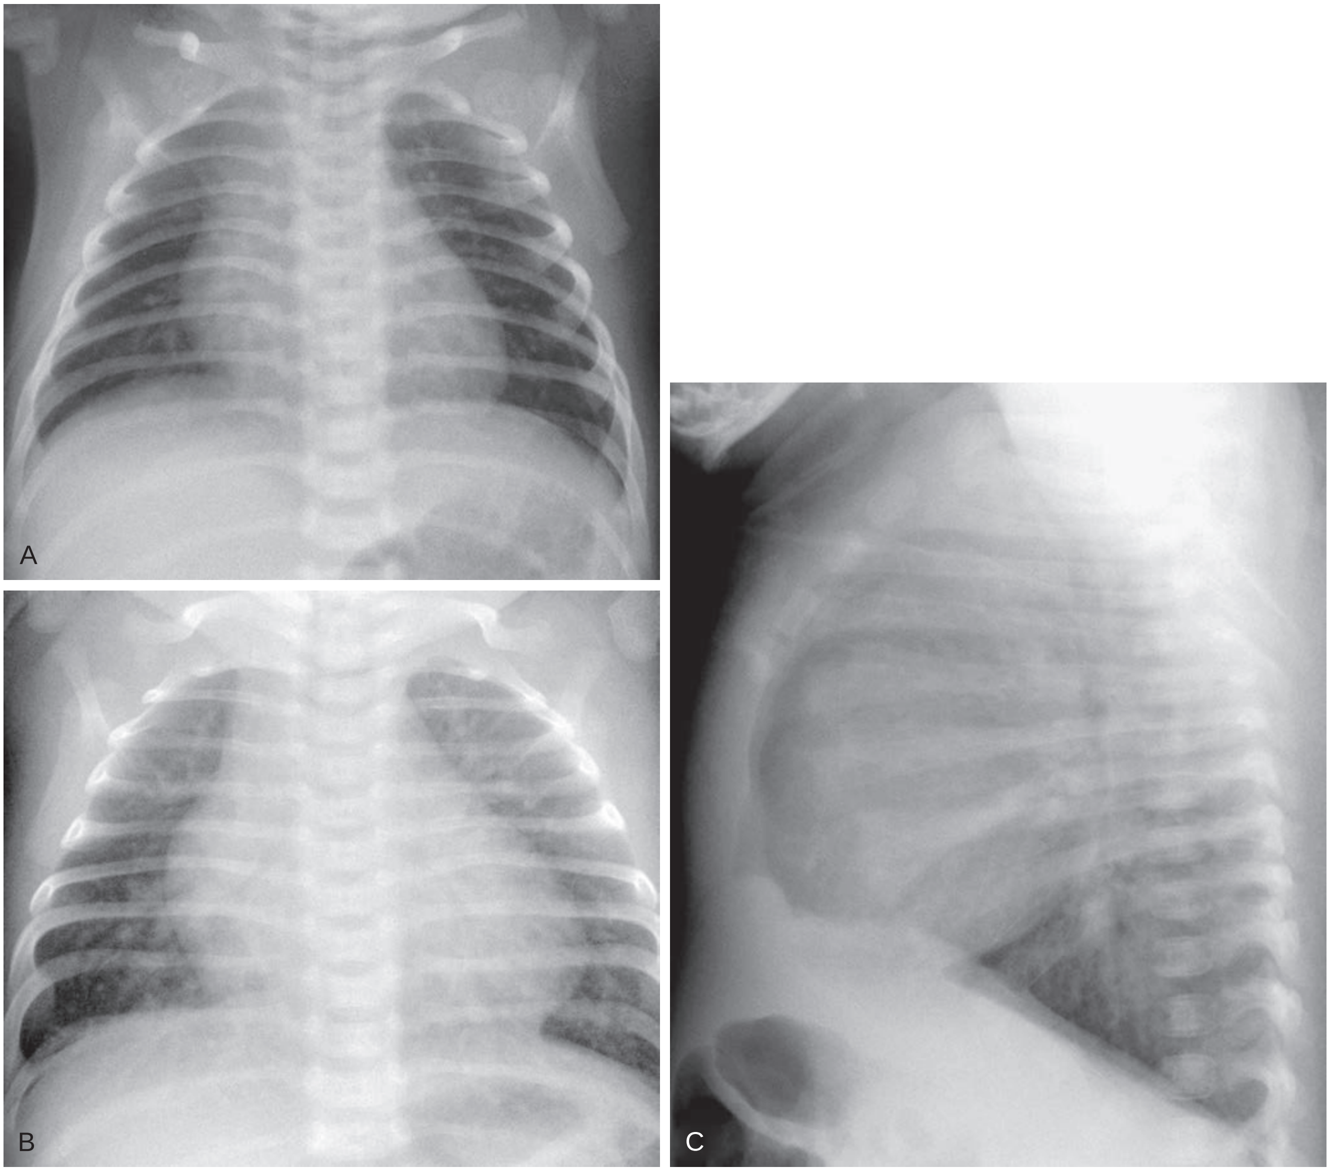


**Figure 65.3. Complete transposition of the great arteries in a neonate.** A frontal radiograph (A) on day 1 of life shows a heart that is within normal limits in size and shows normal pulmonary vascularity. Frontal and lateral radiographs of the same child at 7 weeks of age (B and C) show an enlarged heart and increased pulmonary vascularity. Volume loading of the heart and pulmonary circulation has occurred as pulmonary vascular resistance has dropped.

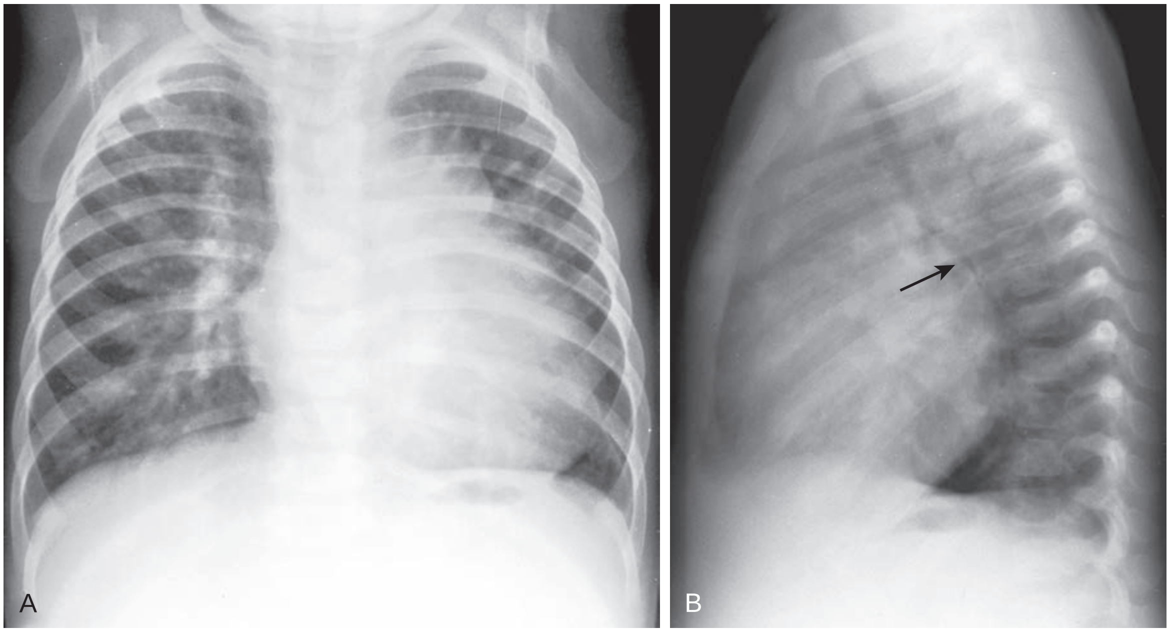
of the pulmonary vasculature is both important and difficult. Poor-quality images that are rotated or obtained during expiration are difficult to interpret (see e-Fig. 65.1). Many radiographs in younger children are obtained in the supine position, and therefore flow is symmetric from base to apex.

**BOX 65.1** Differential Diagnosis of Severe Cardiomegaly

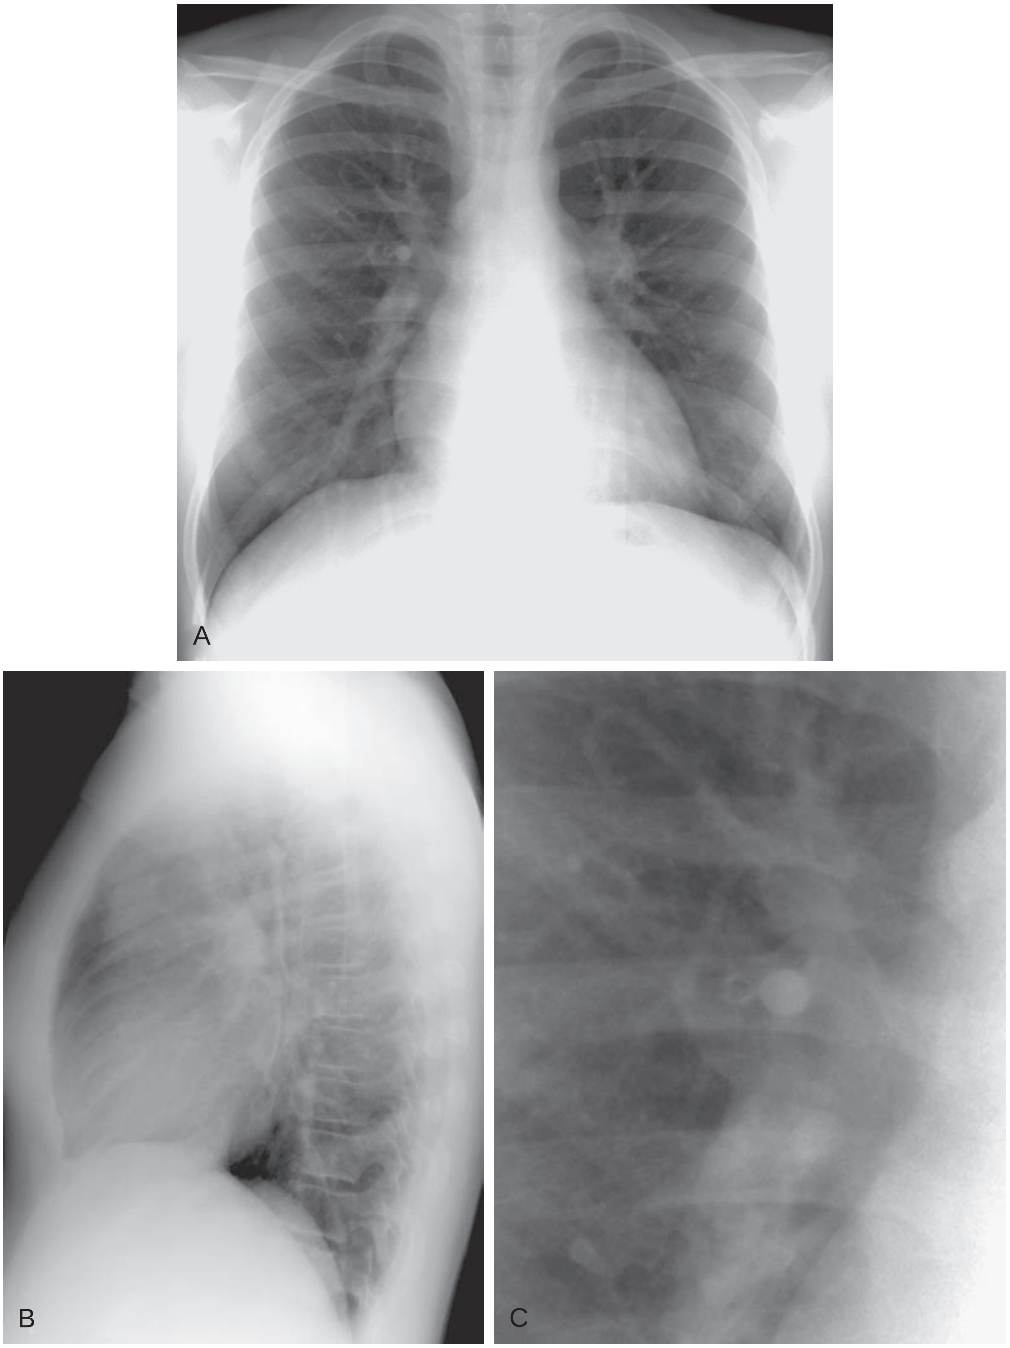
- Volume loading, as seen with severe valve regurgitation (e.g., Ebstein anomaly or pulmonary atresia with intact ventricular septum), large shunts, or both
- Pump failure, as seen with cardiomyopathy (including anomalous origin of the left coronary artery from the pulmonary artery)
- Pericardial disease
- Cardiac or mediastinal mass

## Increased Pulmonary Vascularity

The size of the pulmonary vessels is noticeably larger only when the amount of flow doubles (thus when the pulmonary to systemic flow ratio is 2 : 1 or greater) (e-Figs. 65.6 and 65.7). Smaller shunts are not detectable. Increased vascularity occurs in large left-to-right shunts, admixture lesions without obstruction to pulmonary blood flow, and in high-output states such as severe anemia. To evaluate pulmonary vascularity, the size of the end-on pulmonary artery



**e-Figure 65.6. Ventricular septal defect in an infant.** Frontal (A) and lateral (B) chest radiographs show cardiomegaly with increased pulmonary vascularity. The pulmonary vessels are prominent in the hilar regions and taper in a normal fashion, extending into the periphery of the lung. On the lateral radiograph (B), the left bronchus is displaced posteriorly by the enlarged left atrium *(arrow).* The lungs are hyperinflated and mild interstitial thickening is present, representing congestive heart failure.



**e-Figure 65.7. Ventricular septal defect in an older child.** Frontal (A) and lateral (B) chest radiographs show mild cardiac enlargement and increased vascularity. A magnified view of the right hilum (C) shows that the pulmonary artery is larger than its accompanying bronchus.

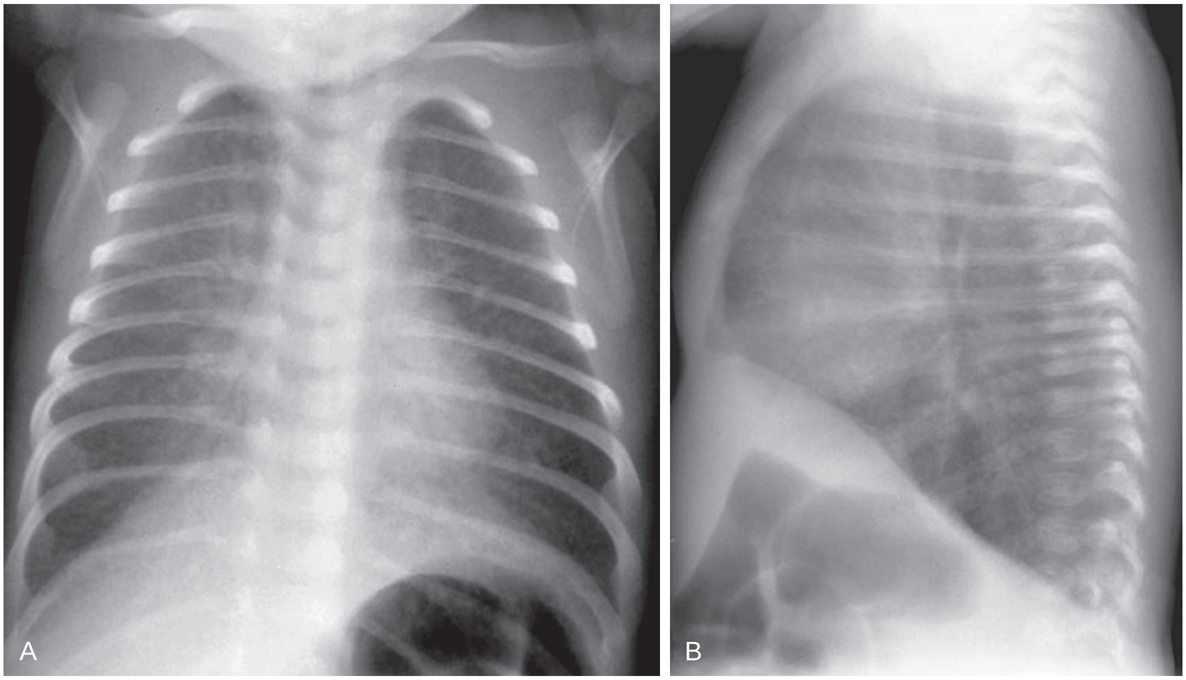


**Figure 65.4. Total anomalous pulmonary venous return with obstruction in an infant.** Frontal (A) and lateral (B) radiographs show a normal heart size, marked hyperinflation, and interstitial thickening consistent with pulmonary edema.

### BOX 65.2 Differential Diagnosis for the Radiographic Appearance of Decreased Pulmonary Vascularity With Cyanosis

Tetralogy of Fallot
Tricuspid atresia
Ebstein anomaly
Critical pulmonary stenosis or pulmonary atresia with an intact ventricular septum
Complex cardiac anomalies associated with significant pulmonary stenosis or atresia

### BOX 65.3 Differential Diagnosis for the Radiographic Appearance of Pulmonary Venous Congestion

Total anomalous pulmonary venous connection with obstruction
Pulmonary vein atresia
Severe pulmonary vein hypoplasia or stenosis
Cor triatriatum
Mitral atresia
Hypoplastic left heart syndrome
Cardiomyopathy
Critical aortic stenosis
Severe aortic coarctation
Large shunts with congestive heart failure
Combined shunts with left-sided obstruction

to the adjacent bronchus can be compared. An arterial dimension greater than that of the bronchus is suggestive of increased flow. However, a slightly larger dimension can be seen normally. The larger vessels extend more peripherally into the lung. Increases in pulmonary blood flow should be accompanied by a proportional increase in heart size because of volume loading.

## Decreased Pulmonary Vascularity

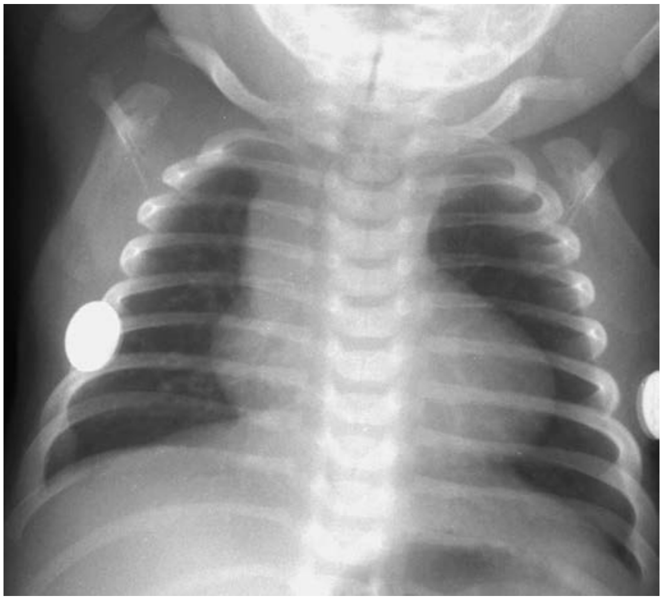
Identifying decreased vascularity is more difficult than identifying increased flow (e-Fig. 65.8). A cyanotic child beyond the newborn period whose flow appears to be within normal limits very likely has a right-to-left shunt Box 65.2.

## Normal Pulmonary Vascularity

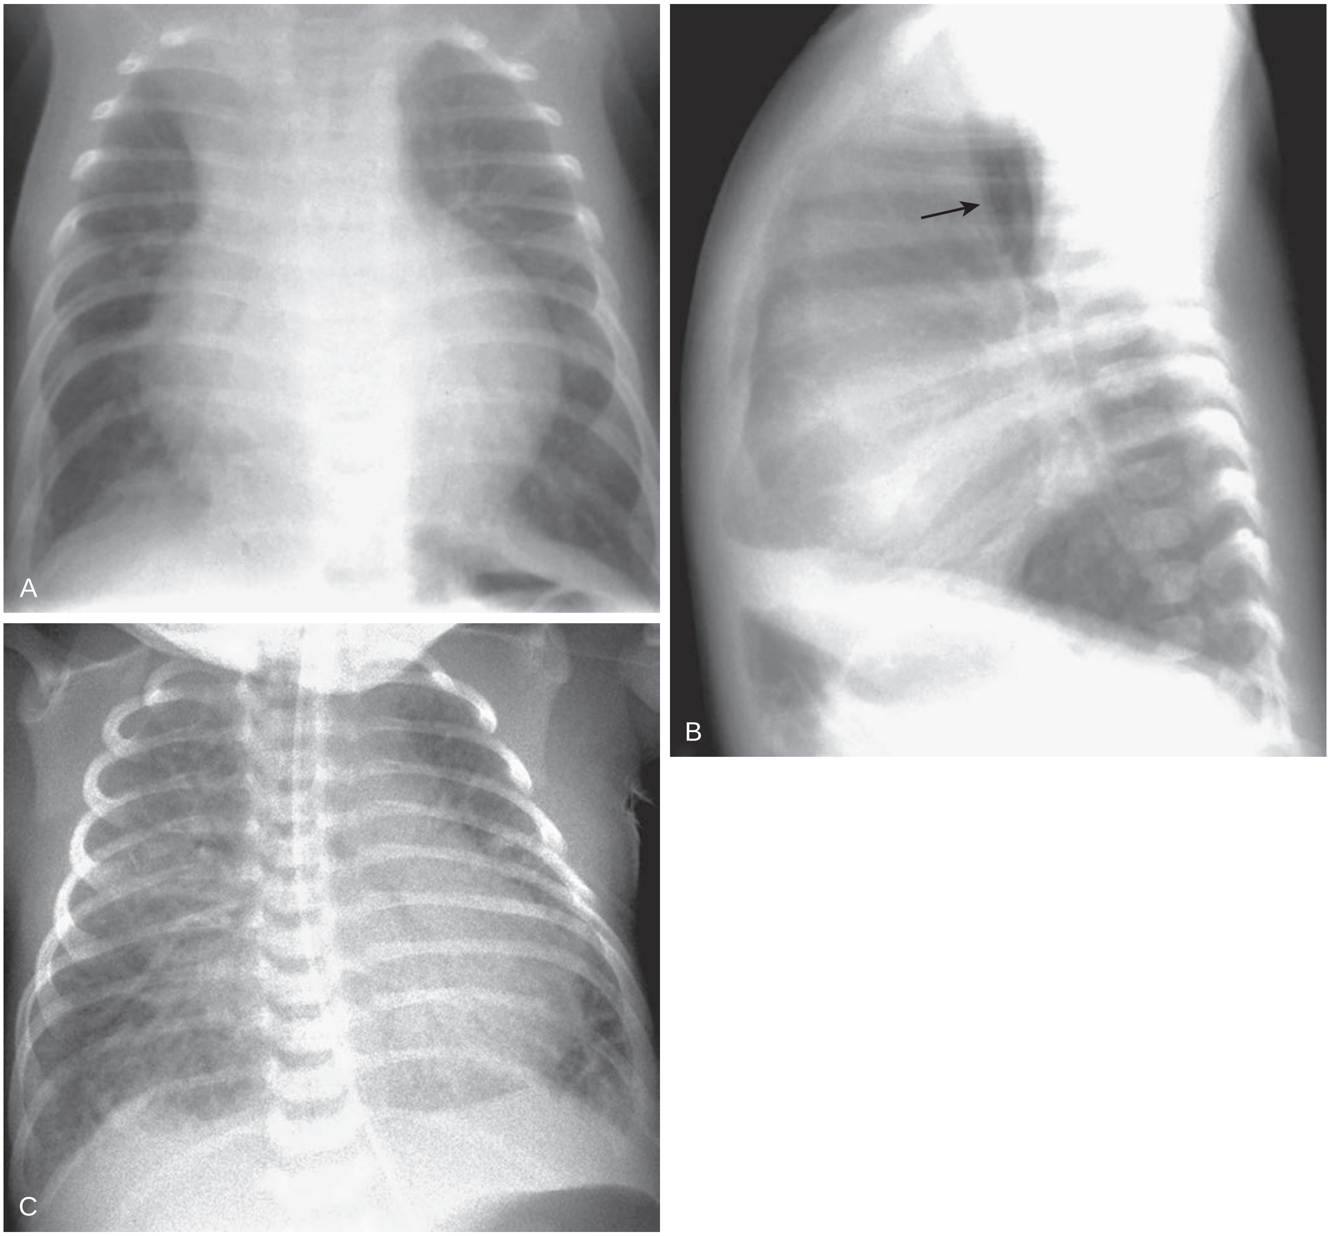
The pulmonary vascularity is normal in the presence of valve lesions without shunting or congestive heart failure, in small to moderate shunts, and even in certain cases of balanced complex congenital heart disease. For example, in a patient with a functionally single ventricle and moderate pulmonary stenosis, the flow to the lungs is neither increased nor decreased.

## Pulmonary Venous Hypertension and Pulmonary Edema

Early pulmonary venous hypertension often manifests as hyperinflation in infants and children younger than 2 years (see Fig. 65.4 and e-Fig. 65.6). As interstitial fluid accumulates, the perihilar bronchi and vessels become poorly defined. Septal (i.e., Kerley) lines are uncommon in children. Eventually, frank alveolar pulmonary edema is seen. In a supine patient, pleural fluid will layer posteriorly creating hazy opacity over the entire thorax. In the presence of severe heart failure, it can be difficult to determine whether the cause is pulmonary venous hypertension alone or is associated with an underlying large left-to-right shunt (e-Fig. 65.9) (Box 65.3). Pulmonary edema can obscure vessel detail, and left-sided heart failure can distend the vessels. The detection of heart disease can be difficult in the child who presents with an acute viral respiratory illness because the inflammation can produce ill-defined vascular markings and hyperinflation similar to the findings in congestive heart failure. Unlike in children with large shunts in whom the heart size is proportional to the increased



**e-Figure 65.8. Tetralogy of Fallot in an infant.** A frontal radiograph of the chest shows a mildly enlarged heart and decreased pulmonary vascularity. The aortic arch is left sided.



**e-Figure 65.9. Coarctation of the aorta.** Frontal (A) and lateral (B) chest radiographs in a 2-month-old show cardiomegaly, normal pulmonary blood flow, and evidence of congestive heart failure as shown by mild interstitial thickening and obvious hyperinflation. Note the posterior displacement of the trachea *(arrow)* by the enlarged heart on the lateral projection. In another child (C) who presented in the first week of life with severe congestive heart failure due to coarctation of the aorta, it is difficult to determine from the chest radiograph whether there is increased vascularity caused by a shunt, severe pulmonary venous hypertension, or a combination of the two. This child had no associated left-to-right shunt.

vascularity, children with left-sided obstruction or pump failure have a disproportionately large heart relative to the degree of increased vascularity (see e-Fig. 65.9A and B).

### Centralized Pulmonary Vascularity

Prominence of the perihilar vessels with rapid tapering as a sign of pulmonary arterial hypertension is rarely seen in children. In a rare variation of tetralogy of Fallot with absent pulmonary valve, large hilar vessels may be seen even during the newborn period due to severe pulmonary regurgitation and are not caused by pulmonary arterial hypertension (e-Fig. 65.10).

### Asymmetric Pulmonary Flow

The chest radiograph must be carefully evaluated for asymmetric flow, which can occur as a result of pulmonary arterial stenosis, hypoplasia or proximal absence, pulmonary venous obstruction, or disturbances in ventilation with secondary vasoconstriction, as well as postoperatively. Care must be taken to avoid misinterpretation of the rotated radiograph (see e-Fig. 65.1). In children with decreased pulmonary blood flow as a result of tetralogy of Fallot or pulmonary atresia, stenosis of the pulmonary artery (at the site of ductal insertion) is a common problem (e-Fig. 65.11).

## Airway and Mediastinum

The chest radiograph is evaluated for the presence of the thymus, a mediastinal mass, the side of the aortic arch, and the presence of a vascular ring. The size and position of the trachea is an important indicator of arch abnormalities. A careful search should be made on both frontal and lateral radiographs for displacement or narrowing of the trachea (e-Fig. 65.12).

Mechanical displacement or obstruction of large airways occurs in anomalies of the aortic arch, pulmonary arteries, and more severe forms of cardiomegaly (e-Fig. 65.13; also see e-Figs. 65.5–65.7, 65.9, 65.10, and 65.12). The position and contour of the descending aorta should be carefully examined. In coarctation of the aorta, the only sign in younger children may be a leftward convexity to the descending aorta (e-Fig. 65.14). Such a contour is seen often in older adults as a result of age-related tortuosity or ectasia, but it is abnormal in children.

## Situs

The chest radiographic assessment is incomplete unless abnormalities of abdominal and thoracic situs (the anatomic location of organs that are asymmetrically positioned in the body) are sought and the cardiac position relative to visceral situs is determined. Abnormal situs can be subtle, with a normal-appearing liver and stomach. Airway anatomy and lung morphology are valuable indicators of visceral situs. Dextrocardia in situs solitus is strongly associated with complex cardiac abnormalities (e-Fig. 65.15). Situs inversus has a small but increased risk of associated congenital heart disease. Symmetric bronchi are seen in most patients with right isomerism (asplenia) (e-Fig. 65.16) and in 68% of patients with left isomerism (polysplenia). Splenic dysfunction and intestinal malrotation occur in children with both right and left isomerism and should be investigated.

## Bony Abnormalities

A complete evaluation of the chest radiograph must include the bony thorax. Few skeletal abnormalities are strongly associated with congenital heart disease, but abnormalities of the spine (e.g., scoliosis, segmentation anomalies, and rib anomalies) and sternum (e.g., an abnormal number of ossification centers and caudal deficiency) occur. Rib notching is rarely seen in younger children with aortic coarctation, but may be present in adolescents and teenagers in whom intercostal artery collaterals have developed (e-Fig. 65.17). Bony changes are common after a thoracotomy, particularly when the surgery was performed in a neonate.

## CONCLUSION

The role of chest radiography has changed with the development of echocardiography. Previous texts and articles have either overstated or understated the utility of the chest radiograph. The carefully performed and thoughtfully interpreted chest radiograph continues to play a useful role in the care of children with congenital cardiovascular disease.

### KEY POINTS

- Changes in pulmonary vascular resistance influence the manifestations of cardiovascular disease in the newborn.
- Hyperinflation is a sign of congestive heart failure in infants.
- Chest radiographs may appear normal in children with serious heart disease.

# Pediatric Cardiothoracic Computed Tomographic Angiography

Elizabeth F. Sheybani and Donald P. Frush

Remarkable advances have occurred in noninvasive imaging evaluation of pediatric cardiothoracic vascular disorders. One such technologic advancement is multidetector array computed tomography angiography (CTA). CTA has become a primary imaging consideration for structural cardiovascular evaluation beginning as early as the newborn period.[1-7] Attention to technique is fundamental for pediatric CTA.[8-10] Without optimal or at least sufficient technical performance, diagnostic capabilities may be limited. This technical aspect (in addition to the diagnostic interpretation and communication of results) is the responsibility of the imaging expert. This chapter provides technical guidelines for performing pediatric thoracic CTA. The clinical examples provided illustrate these technical considerations.

## COSTS AND BENEFITS

Although echocardiography is generally the first-line imaging modality in evaluation of structural congenital cardiovascular disease, pediatric CTA offers several advantages over echocardiography and other imaging modalities.

The primary advantage of CTA is speed. With newer technology, such as wide detector multidetector computed tomography (MDCT) (e.g., 320 detector array single rotation acquisition)[2] or dual-source MDCT (Fig. 66.1),[11,12] an examination of the entire chest of an infant can be completed in less than 1 second. With echocardiography, magnetic resonance (MR) vascular imaging, or angiography, imaging times typically exceed 20 minutes and may last 1 to 2 hours. Its rapid examination time means that CTA is frequently performed without sedation, an important consideration given the potential risks posed by anesthesia to the developing brains of very young children,[13] as well as the frequently tenuous conditions of critical care patients undergoing imaging evaluation.

CTA is particularly useful in evaluation of extracardiac vascular structures and may be used for preoperative evaluation of pulmonary arteries, pulmonary veins, and/or aortic arch and other systemic arteries (such as aortopulmonary collaterals) in children with known congenital heart disease or for investigation of postoperative complications.[14,15] Computed tomography (CT) provides the best global assessment of the lungs and airways (e-Fig. 66.2 and Fig. 66.3).[5] Congenital cardiovascular disorders may cause tracheal compression or deviation (e.g., from vascular rings or pulmonary slings) with resulting obstructive effects or air trapping at the parenchymal level. In addition, CT can suggest or demonstrate associated primary abnormalities of the respiratory system, such as pulmonary hypoplasia or tracheomalacia.

The excellent spatial and temporal resolutions of CTA allow for high-quality off-line multiplanar and three-dimensional (3D) volumetric reconstructions and printed models, a major benefit over both echocardiography and direct angiography. The technical quality is also more consistent with CT compared with echocardiography, a more operator-dependent examination, and compared with magnetic resonance imaging (MRI), where parameter and sequence selection may result in variable study quality. In addition, many of the contraindications of MRI (e.g., pacemakers, internal support apparatus, and some surgical devices) are not contraindications to CTA and produce less image artifact than with MR angiography. The cost of CT is comparable with that of Doppler echocardiography, in general is less than that of MR, and is much less than that of conventional angiography.

CTA has some disadvantages. Similar to catheter angiography, CTA involves the use of ionizing radiation, which is not an issue with MRI or echocardiography. CT radiation doses can vary greatly depending on examination parameters and can be managed with utilization of dose optimization techniques. In general, CTA should be performed with a radiation dose similar to or lower than that of a routine chest CT. CTA dose estimates in young children can be less than 1.0 mSv.[1,11,16] When using electrocardiographic (ECG) synchronization, prospective triggering and smaller volume scanning substantially lower radiation dose when compared with retrospective gating.[17,18] With rare exceptions, properly performed pediatric CTA results in a lower radiation dose than conventional diagnostic angiographic evaluation. ECG-synchronized CTA may involve a greater radiation dosage than limited diagnostic conventional angiography or a nongated CTA. Intravenous (IV) contrast material is required for CTA but also is required for conventional angiography and for MR angiography. The risk of major adverse effects (e.g., airway spasm and cardiovascular collapse) from iodinated IV contrast material is extremely low in children.[19,20] In addition, there is no long-term deposition of components of iodinated contrast media as with gadolinium-based contrast agents. Unlike with echocardiography, MRI, and conventional angiography, pediatric thoracic CTA typically is used for morphologic assessment. Although cardiac function and other hemodynamic information can be obtained from CTA, this requires retrospective cardiac gating with a potential radiation dose penalty and thus is reserved for select circumstances.[18]

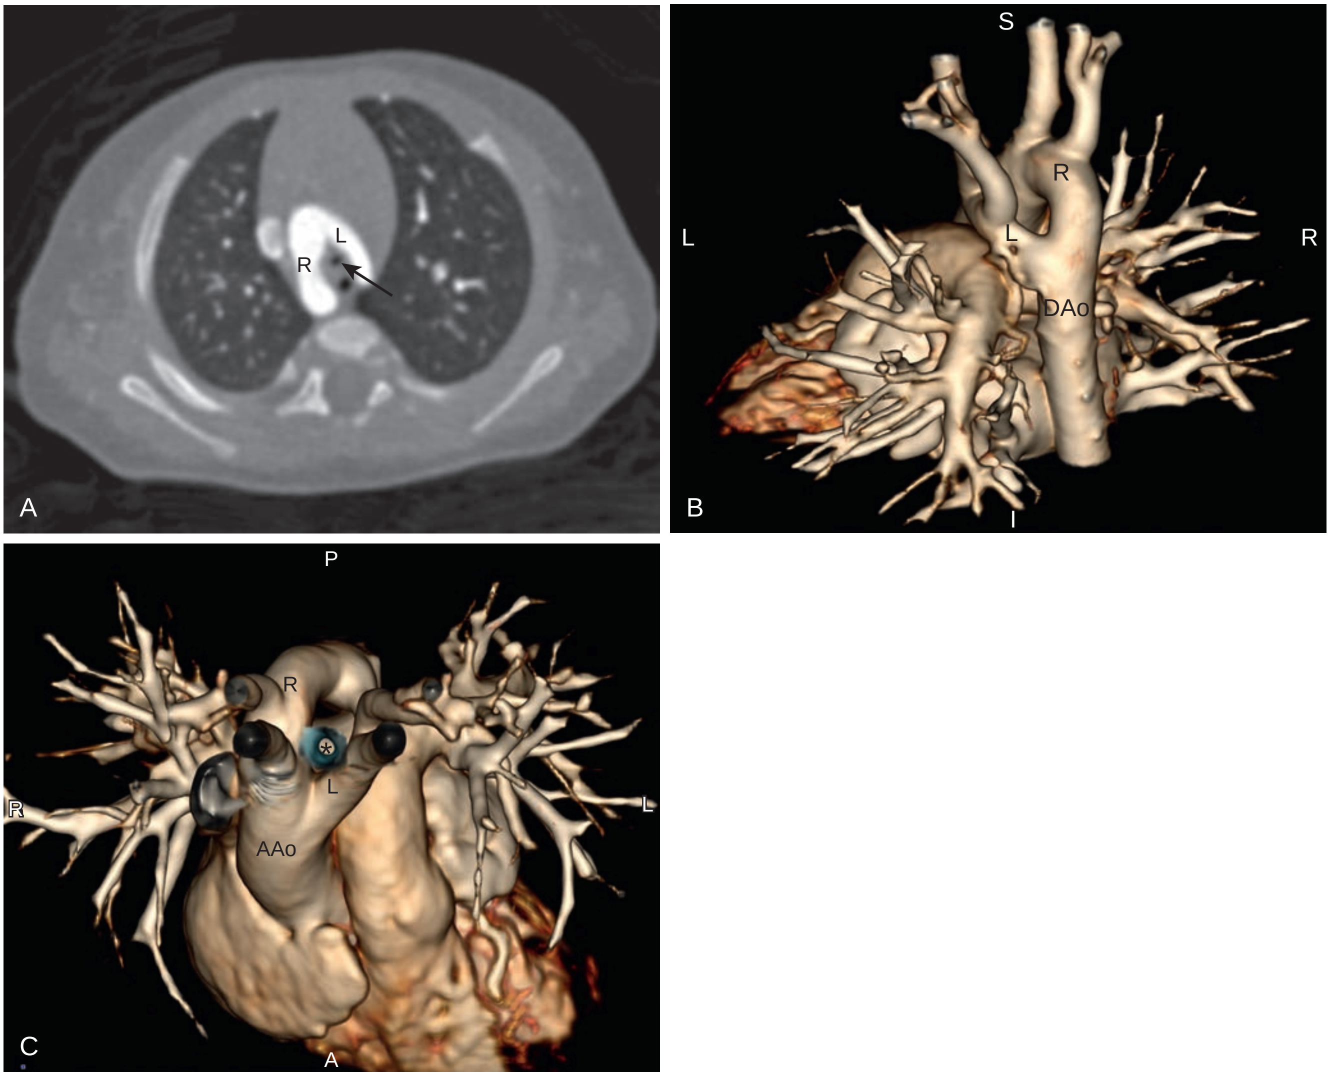
Various factors must be taken into consideration in choosing an appropriate imaging algorithm. Individual expertise is a strong consideration, as is the availability of the desired modality. Personnel must be able to perform these examinations, and imaging experts, such as radiologists, may have preferences. In general, echocardiography should be the first examination considered, followed by MRI or CT. Performing CTA on an MDCT system that is less than 64 slice is problematic, and image quality (both contrast enhancement and multiplanar reformations) is more limited. A CT study that can be performed relatively quickly may be preferred over waiting several days for an MR evaluation.

## TECHNIQUE

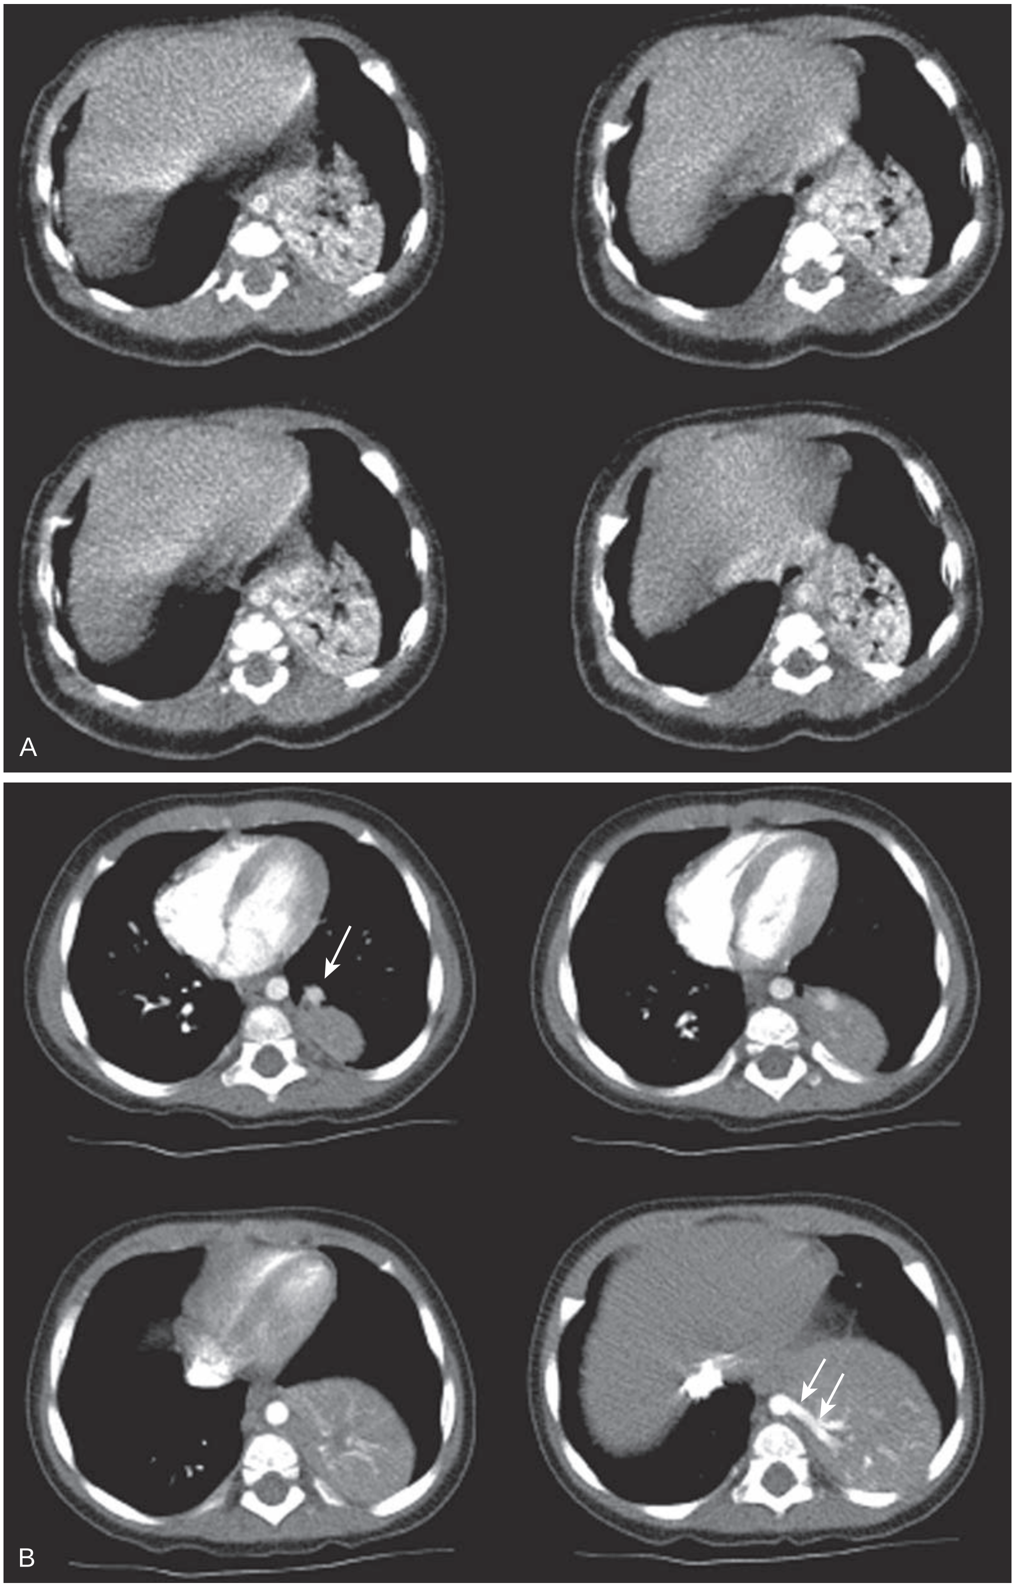
Box 66.1 shows the steps taken to perform a pediatric CTA study (see e-Fig. 66.2).[21,22]

Pediatric cardiovascular CT evaluation is less protocol driven than is cardiovascular CT evaluation in adults. The examination should be constructed to obtain the appropriate diagnostic information while minimizing radiation dosage. The imager should understand the clinical indications for the examination and the anatomy in question. Familiarity of abnormal congenital anatomy and understanding palliative and corrective cardiovascular anatomy is critical to optimal vascular opacification and minimization of streak artifacts.

Patient motion needs to be controlled (e-Fig. 66.4), which may require swaddling of infants or sedation of younger children. Breath holding is preferred during CTA but is not required, especially



**e-Figure 66.2. Vascular ring in a 4-month-old boy with stridor.** (A) Axial contrast-enhanced image from a CTA study in the upper chest shows the right *(R)* and left *(L)* arches. There is associated tracheal narrowing *(arrow)* at the level of the vascular ring. The mildly dilated esophagus is seen posterior to the trachea. (B) Three-dimensional reformation from the posterolateral projection shows the double arch with the larger and higher right-sided arch *(R)* and the smaller and lower left-sided arch *(L)*. *DAo,* Descending aorta. (C) Three-dimensional reformation from the superior projection including the trachea shows significant tracheal narrowing *(*)* at the level of the ring. *AAo,* Ascending aorta; *L,* left arch; *R,* right arch.



**e-Figure 66.4. Effect of motion on image quality in an infant with pulmonary sequestration.** (A) Four basilar axial images from the initial CTA performed without sedation were inadequate because of movement and poor arterial bolus. (B) A subsequent examination performed after adequate sedation and improved contrast administration shows pulmonary venous drainage (*arrow* in upper left image) and systemic arterial supply (*arrows* in lower right image).

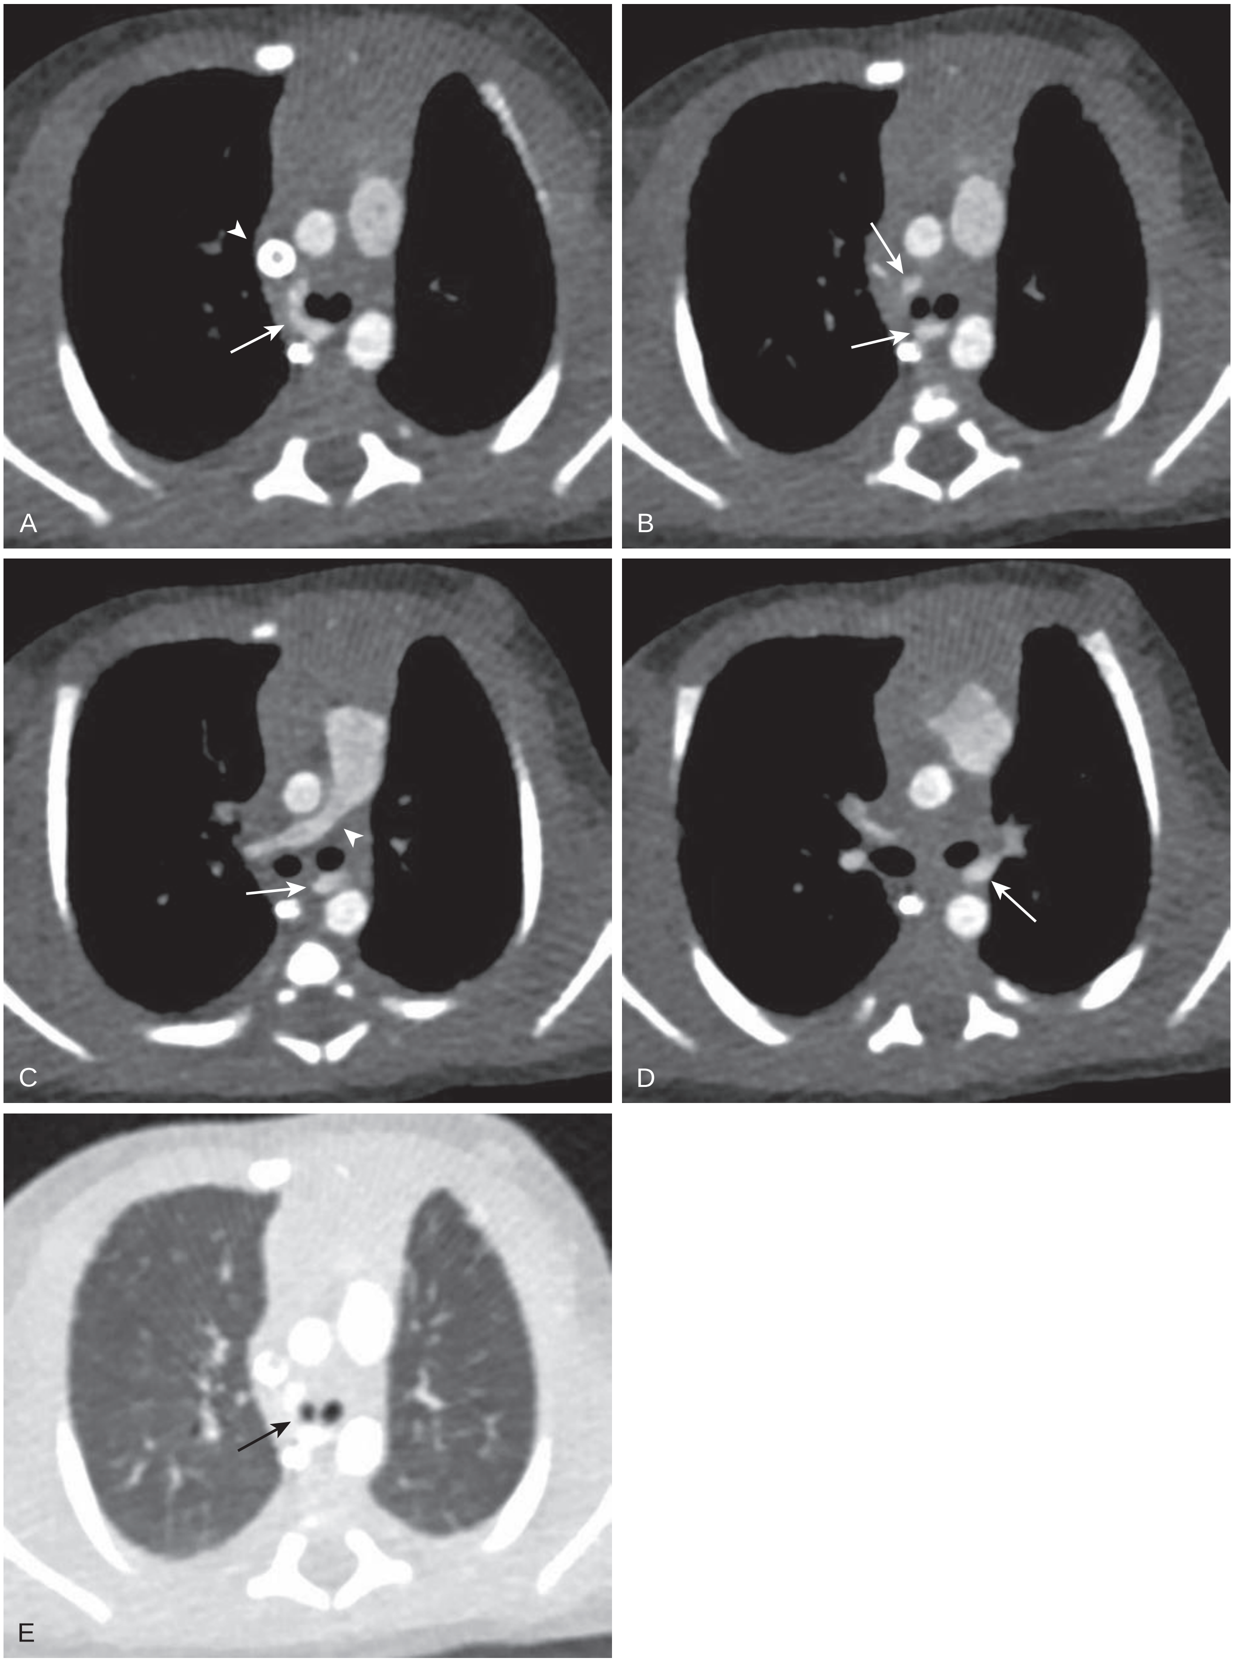


**Figure 66.1. Two-day-old boy on extracorporeal membrane oxygenation (ECMO) for pulmonary hypertension with structural cardiac disease, including a pulmonary artery sling.** Non–ECG-synchronized CTA examination was performed using a total of 3.0 mL of 370 mg/dL nonionic iodinated contrast media through an angiocatheter at 3.0 mL/sec while the ECMO circuit was briefly discontinued. (A–D) The course of the small, aberrant left pulmonary artery originating from the right pulmonary is denoted by the *white arrows* in these axial images. Note the venous ECMO cannula (*arrowhead* in A) and the small right pulmonary artery (*arrowhead* in C). E, The proximal right bronchus is mildly narrowed by the left pulmonary artery (*black arrow* in E).

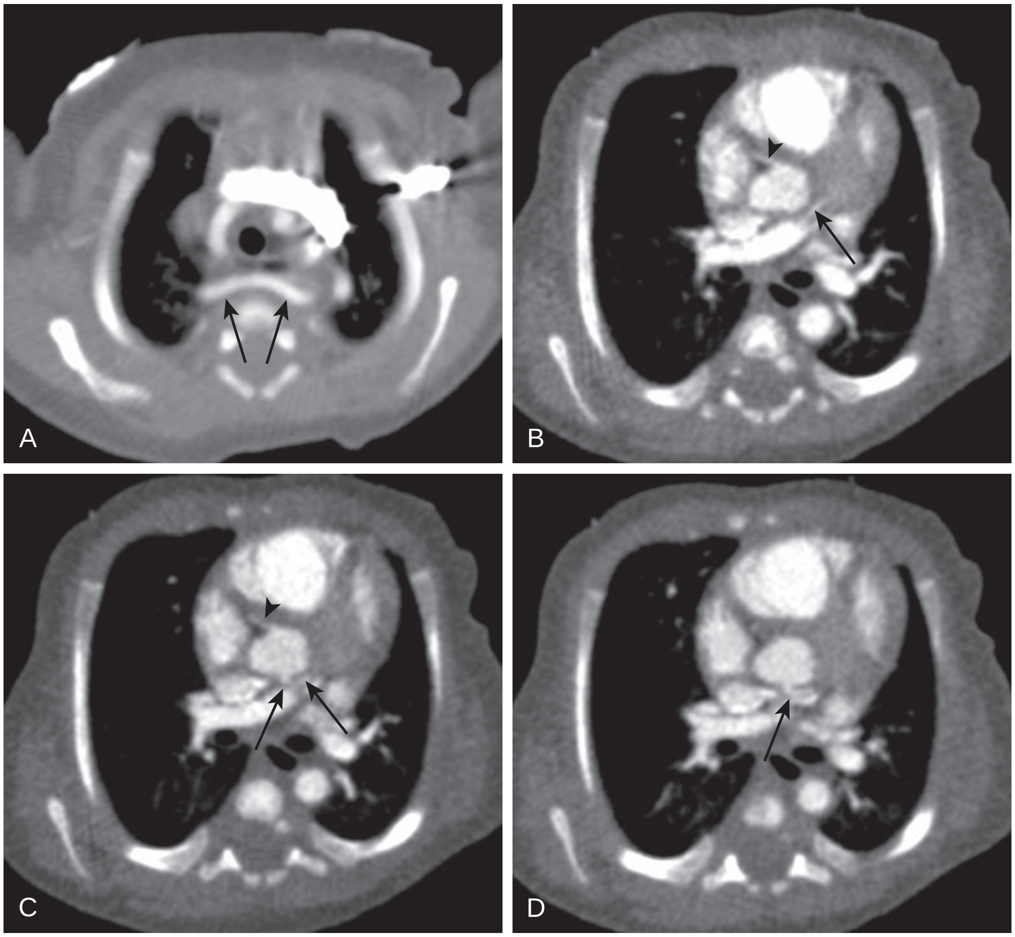

**Figure 66.3. Newborn boy with labored stridor.** Aortic arch anatomy was incompletely assessed on echocardiography. Nongated dual-source cardiac computed tomography angiography was performed using high-pitch (3.2), 80 kVp, 60 effective mA, and 6.0 mL of 300 mg/mL iodine. The scan was performed in about 0.6 seconds. (A) An aberrant right subclavian artery *(arrows)* is seen to pass behind a normal-caliber trachea. No cause for respiratory difficulty was identified. (B–D) Note excellent depiction of small structures as a result of high-pitch scanning, demonstrating the normal origin of the right coronary artery (B and C) *(arrowheads)* and the relatively posterior origin and course of the left main coronary artery, probably from the left coronary cusp in B–D *(arrows).*

with wide detector scanning and other fast scanning technology (e.g., dual-source, high-pitch). If the child is intubated, an inspiratory hold during the CTA evaluation is recommended. Metal (e.g., pacemakers, intracardiac leads, sternal wires, stents, clips, and valves) and arms may cause streak artifacts (Fig. 66.5). Monitors and associated leads should be positioned outside the scan field if possible to minimize streak artifact across the chest. The location and caliber of angiocatheters will determine the rate of intravenous contrast administration and the time it takes contrast material to reach the heart and extracardiac vasculature.[23] Finally, because patients undergoing cardiac CTA may have left-to-right shunts or admixture lesions, extreme care must be taken to avoid injection of air or a thrombus when contrast is administered.

Technical considerations regarding the IV contrast material include type and concentration, dosage, rate of administration, and timing of scan onset after administration.[24] In general, low-osmolar, nonionic contrast media are recommended for contrast-enhanced CT scanning in children. The iodine concentration varies but usually is around 300 mg/mL. For newborns and small children, higher concentrations such as 370 mg/mL may afford better enhancement of smaller vessels with less contrast. A dosage of 1.0 to 1.5 mL/kg is generally adequate, with a maximum total volume of 125 mL. If another CT study must be performed while the patient remains on the scanner, 1.5 to 2.0 mL/kg of additional contrast can be administered. In such cases the maximal dosage would be 3.0 mL/kg, which is still reasonable for a single examination.

The rate of contrast administration depends on whether a manual injection or a power injector is used and also on the size of the angiocatheter. Suggested maximal rates of administration are 1.5 to 2.0 mL/sec for a 24-gauge angiocatheter, 2.5 to 3.0 mL/sec for a 22-gauge angiocatheter, and 4.0 mL/sec for a 20-gauge angiocatheter at a maximum pressure of 300 psi. When possible, contrast should be administered by a power injector, which gives a more predictable and consistent enhancement curve. However, performing manual administration as quickly as possible can provide adequate enhancement when power injection is not appropriate. Use of central venous catheters for power administration varies based on individual practice and catheter suitability.

The timing of contrast administration with respect to scanning initiation is a critical factor in CTA. In general, scanning is started either during or immediately after completion of administration of the contrast. Timing depends on the structures that need to be evaluated. Later scan initiation is used for opacification of the thoracic aorta and major branches or systemic venous structures,

### BOX 66.1 Steps in Performing Pediatric Computed Tomography Angiography

The subject is an otherwise healthy, 4-week-old, 4.0-kg male infant with congenital stridor. Findings of an echocardiogram suggest the presence of a vascular ring.

**PLANNING THE COMPUTED TOMOGRAPHY ANGIOGRAM (CTA)**

1. **Determine that CTA is the appropriate examination.** Echocardiography was inconclusive. Magnetic resonance imaging would require sedation and a 1- to 2-week wait for a sedation slot. CTA has a 1-day turnaround and requires no sedation.
2. **Define the question to be answered.** Aortic arch and airway. A high-detail examination (e.g., for small vessels) is not necessary. It is not necessary to image below the mid to lower thoracic aorta (thus the radiation dose can be lower).
3. **Understand the anatomy.** Vascular rings, including innominate compression; a pulmonary sling is not exhibited with true stridor.
4. **Patient limitations.** Essentially none. The patient will be fed immediately before the CTA but after the intravenous line is in place.

**PERFORMING THE CTA**

1. **Intravenous contrast material**
   **Type:** Low-osmolar, nonionic iodinated contrast, 300 mg/mL
   **Dose:** Total volume of 6.0 mL (4.0 kg at 1.5 mL/kg)
   **Rate and route:** 24-gauge angiocatheter in hand vein; administration via power injector at 2.0 mL/sec or manual injection as quickly as possible
   **Onset of scanning:** Determined with a test bolus of 1.0 mL contrast followed by a flush adequate to clear contrast from the line. Start monitoring images at 2-second intervals and begin push of the test bolus when the first monitoring image appears. Contrast reaches the right ventricle in 5 seconds and the left ventricle in 6 to 7 seconds. Add 3 seconds, so the scan onset for the diagnostic study will be 9 to 10 seconds after starting administration of contrast.
2. **Select scan parameters:**
   **Tube current:** Adjusted for image quality using automatic exposure control
   **Peak kilovoltage:** 80 kVp (or 70 kVp if available)
   **Gantry cycle time:** Fastest available
   **Pitch:** Highest pitch available
   **ECG synchronization:** Not necessary for vascular ring evaluation
   **Data reconstruction:** 2.0 mm at 2.0-mm interval axial, coronal, and sagittal; 0.6 at 0.4-mm interval for three-dimensional reformations
   **Iterative reconstruction:** On

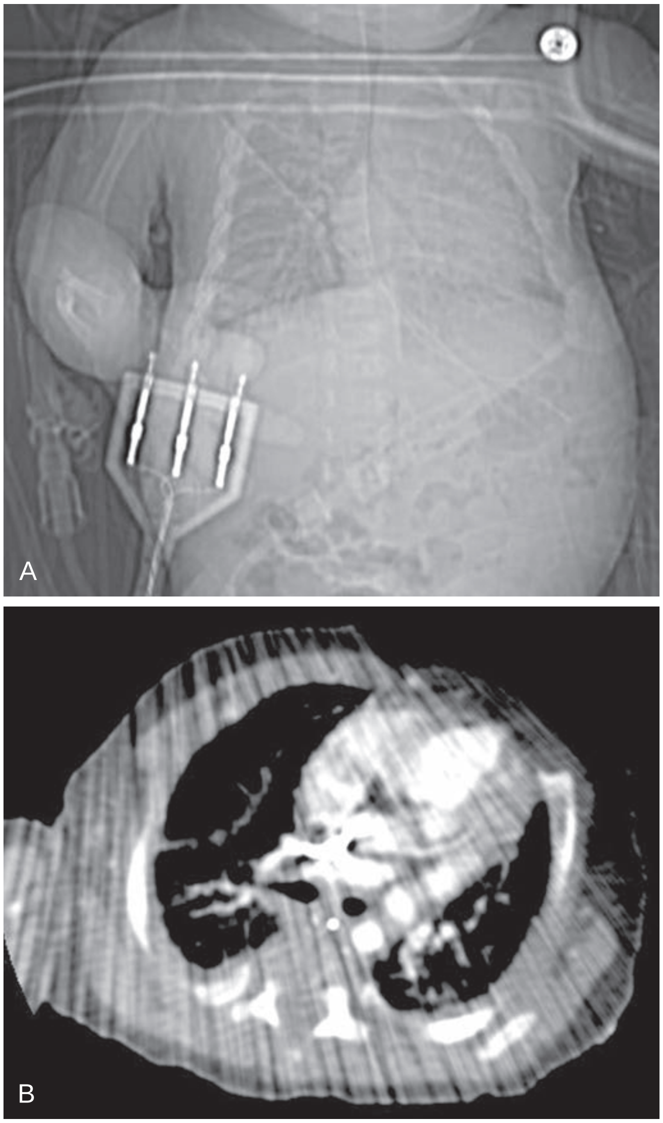

**Figure 66.5. Artifact from leads.** (A) Topogram demonstrates the leads that were in the scan range. (B) Note substantial streak artifact. *(From Frush DP. Thoracic cardiovascular CT: technique and applications.* Pediatr Radiol*. 2009;39(3):464–470. Reprinted with permission.)*

whereas earlier scan initiation is appropriate for right-sided structures, especially pulmonary arteries. An empiric delay can be used, but because of the wide range of sizes and heart rates encountered in pediatric CTA (i.e., 1–100 kg), a single recommendation for an empiric delay is not possible. A range of delays could be determined depending on the rate of administration.

One of two methods is generally used for individualized determination of the scan delay in pediatric CTA: test injection or bolus tracking. Bolus tracking is used more commonly and is straightforward. A region of interest is placed over the desired structure, and the examination triggers when this region reaches 100 to 150 HU (or by initiation of scanning based on visual appearance of enhancement during tracking), usually with a 7-second delay when the child is able to breath hold to allow for breath-hold instructions. The monitoring scan onset should be set to start shortly before the expected time of opacification of the structure of interest to minimize unnecessary radiation during monitoring. The monitoring CT parameters can be very low (e.g., 80–100 kVp and 10 mA) to further minimize dose.

Alternatively, a test bolus can be administered, and the arrival of contrast to the desired location (for cardiac CT, the right side versus the left side of the heart) can be used (Fig. 66.6). A test bolus of 10% of the total expected volume is administered. The arrival of the test bolus at the appropriate structure is timed, and this time is used to set the delay for the start of scanning after full-contrast bolus injection. In neonates, usually about 2 to 3 seconds is added to the arrival time of the test bolus for optimal enhancement, and up to 8 seconds may be added for teenagers.

Scan techniques include adjustment of technical parameters such as the number of detector rows, the thickness of detectors, the gantry cycle time, tube current (milliamperes [mA]), and peak kilovoltage (kVp). Parameters such as scan thickness and interval are adjustable after the scan volume is obtained.[5]

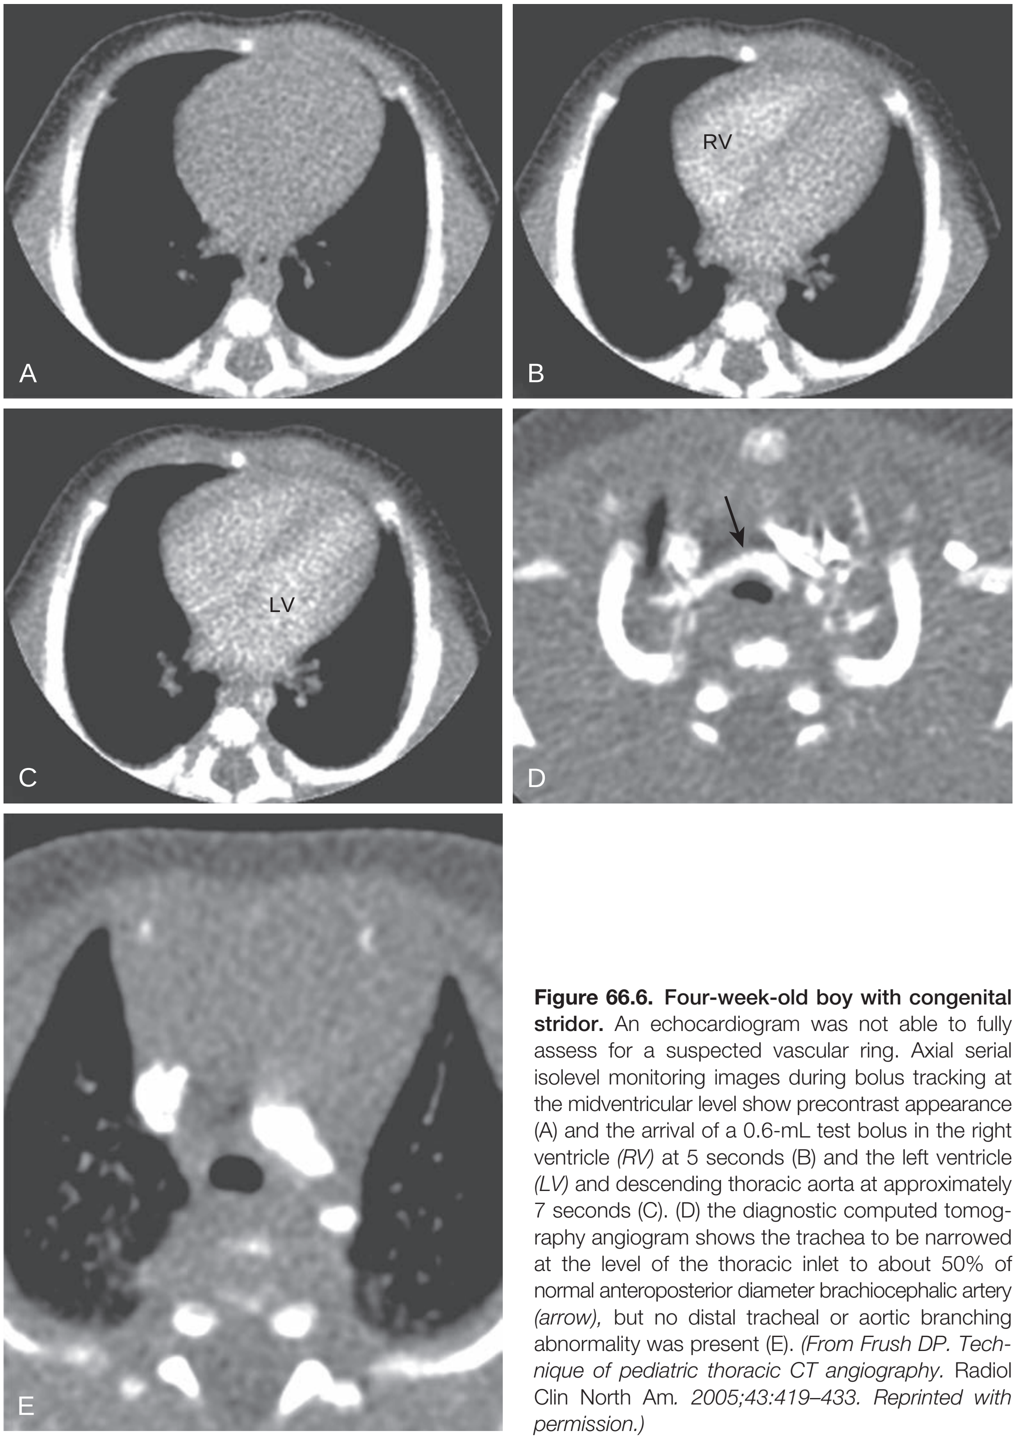

**Figure 66.6. Four-week-old boy with congenital stridor.** An echocardiogram was not able to fully assess for a suspected vascular ring. Axial serial isolevel monitoring images during bolus tracking at the midventricular level show precontrast appearance (A) and the arrival of a 0.6-mL test bolus in the right ventricle *(RV)* at 5 seconds (B) and the left ventricle *(LV)* and descending thoracic aorta at approximately 7 seconds (C). (D) the diagnostic computed tomography angiogram shows the trachea to be narrowed at the level of the thoracic inlet to about 50% of normal anteroposterior diameter brachiocephalic artery *(arrow),* but no distal tracheal or aortic branching abnormality was present (E). *(From Frush DP. Technique of pediatric thoracic CT angiography.* Radiol Clin North Am*. 2005;43:419–433. Reprinted with permission.)*

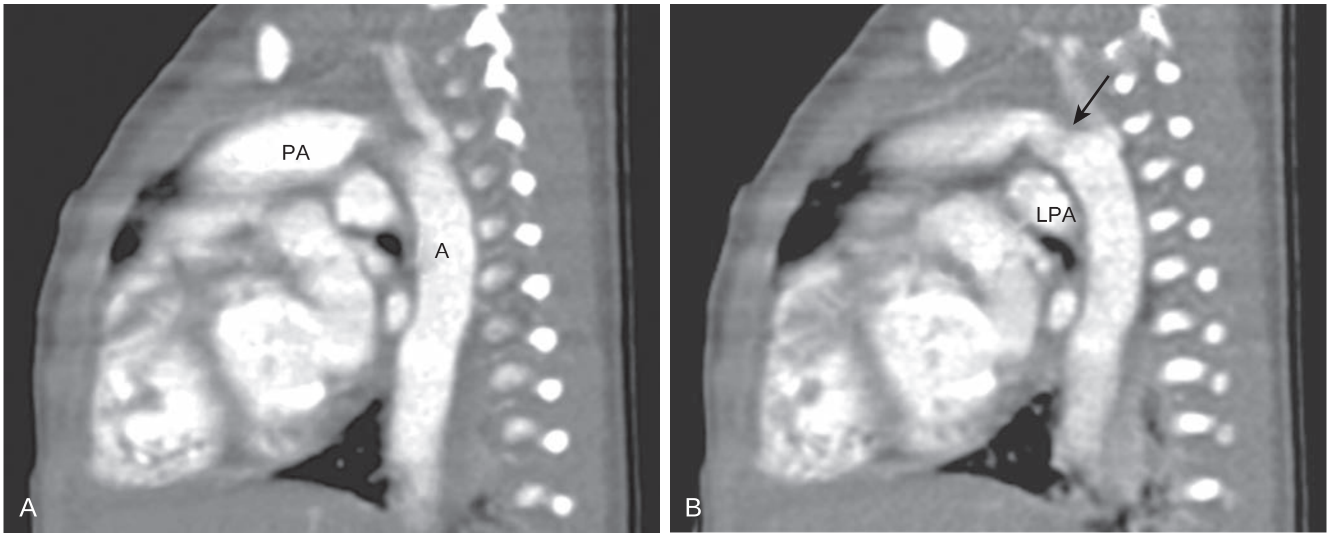
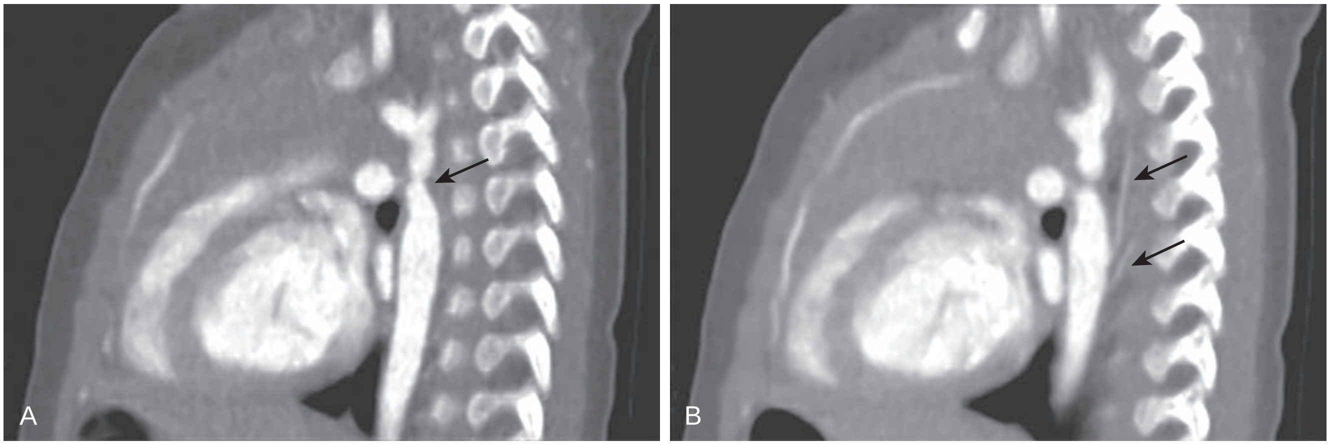
The isotropic images obtained with 64-slice and higher MDCT scanners provide excellent multiplanar reformations and three-dimensional evaluation, which show complicated anatomy in a way to which clinical care providers (e.g., cardiac surgeons) are accustomed (e-Figs. 66.7–66.9). The thinnest detector option should be chosen for pediatric CTA, because thinner slices improve the quality of reformations. The fastest gantry cycle time is recommended to minimize motion artifact and to obtain the fastest scanning time possible, which is important in children who may be anxious or otherwise fidgety. Pitch, essentially representing table speed (mm/sec) divided by effective collimation (mm), generally is in the range of 1.5 for nongated, single-source CTA.

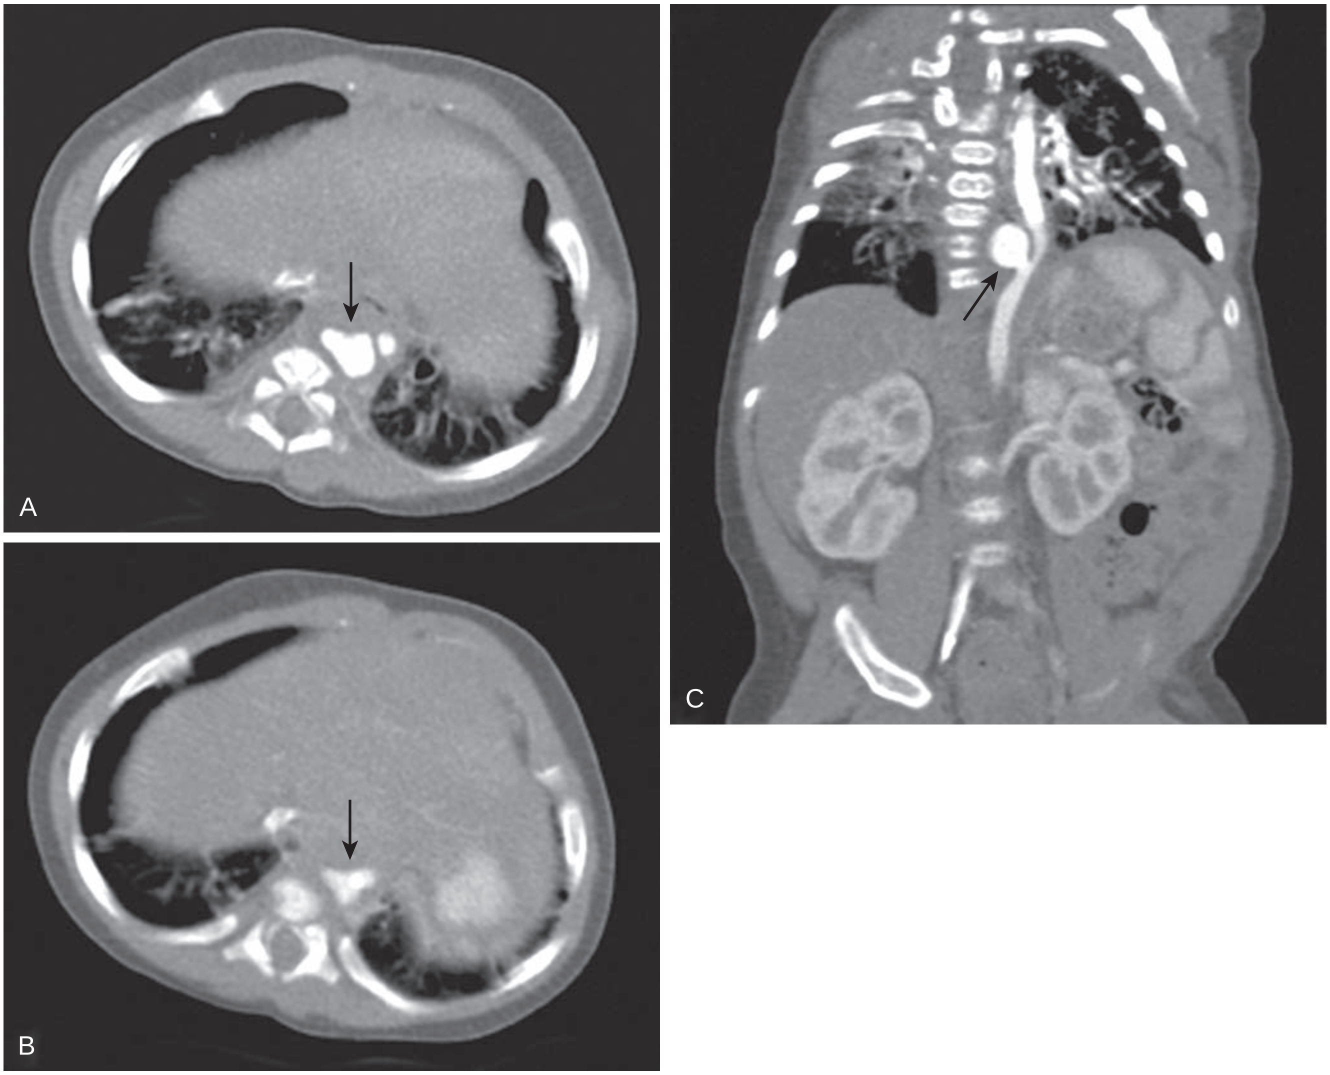
Tube current, including tube current modulation technology,[25] varies depending on patient size. Automatic radiation dose modulation (either automatic exposure control or automatic tube current modulation, and newer kVp modulation) are features of all modern MDCT scanners. Although the features differ among vendors, the principle of dose modulation is to dynamically control the tube current throughout the scan based on the patient's body habitus and user settings, and with kVp modulation to include desired contrast quality. Although it is possible to reduce radiation dose using these features, pediatric-specific dose modulation is not widely available and reference data are lacking. Therefore dose modulation techniques should be used with caution in children.[24]



**e-Figure 66.7. Two-day-old infant boy with interrupted aortic arch identified by echocardiography.** Because the aortic branch anatomy was not well visualized, CTA was performed. The examination was performed at 80 kVp. (A and B) With sagittal reformation, the relationship between the large ductus arteriosus *(arrow)* connecting the main pulmonary artery *(PA)* and the aorta *(A)* is seen. *LPA,* Left pulmonary artery. *(From Frush DP, Herlong RJ. Pediatric thoracic CT angiography.* Pediatr Radiol. *2005;35:11–25. Reprinted with permission.)*



**e-Figure 66.8. Sagittal reformations of aortic coarctation in a 4-month-old infant boy.** (A) The location of the coarctation is well demonstrated *(arrow).* (B) Collaterals *(arrows)* are seen feeding the descending aorta distal to the coarctation. *(From Frush DP. Technique of pediatric thoracic CT angiography.* Radiol Clin North Am. *2005;43:419–433. Reprinted with permission.)*



**e-Figure 66.9. Descending thoracic aortic aneurysm in an infant, probably from an infected umbilical arterial catheter in the neonatal period.** Axial images (A and B, slightly inferior to A) show an irregularity of the aorta *(arrows).* (C) Coronal reconstruction shows an aneurysm *(arrow),* neck, and displacement of the adjacent aorta. The aneurysm was successfully occluded with a coil. *(From Frush DP, Yoshizumi T. Conventional and CT angiography in children: dosimetry and dose comparisons.* Pediatr Radiol. *2006;36:154–158. Reprinted with permission.)*

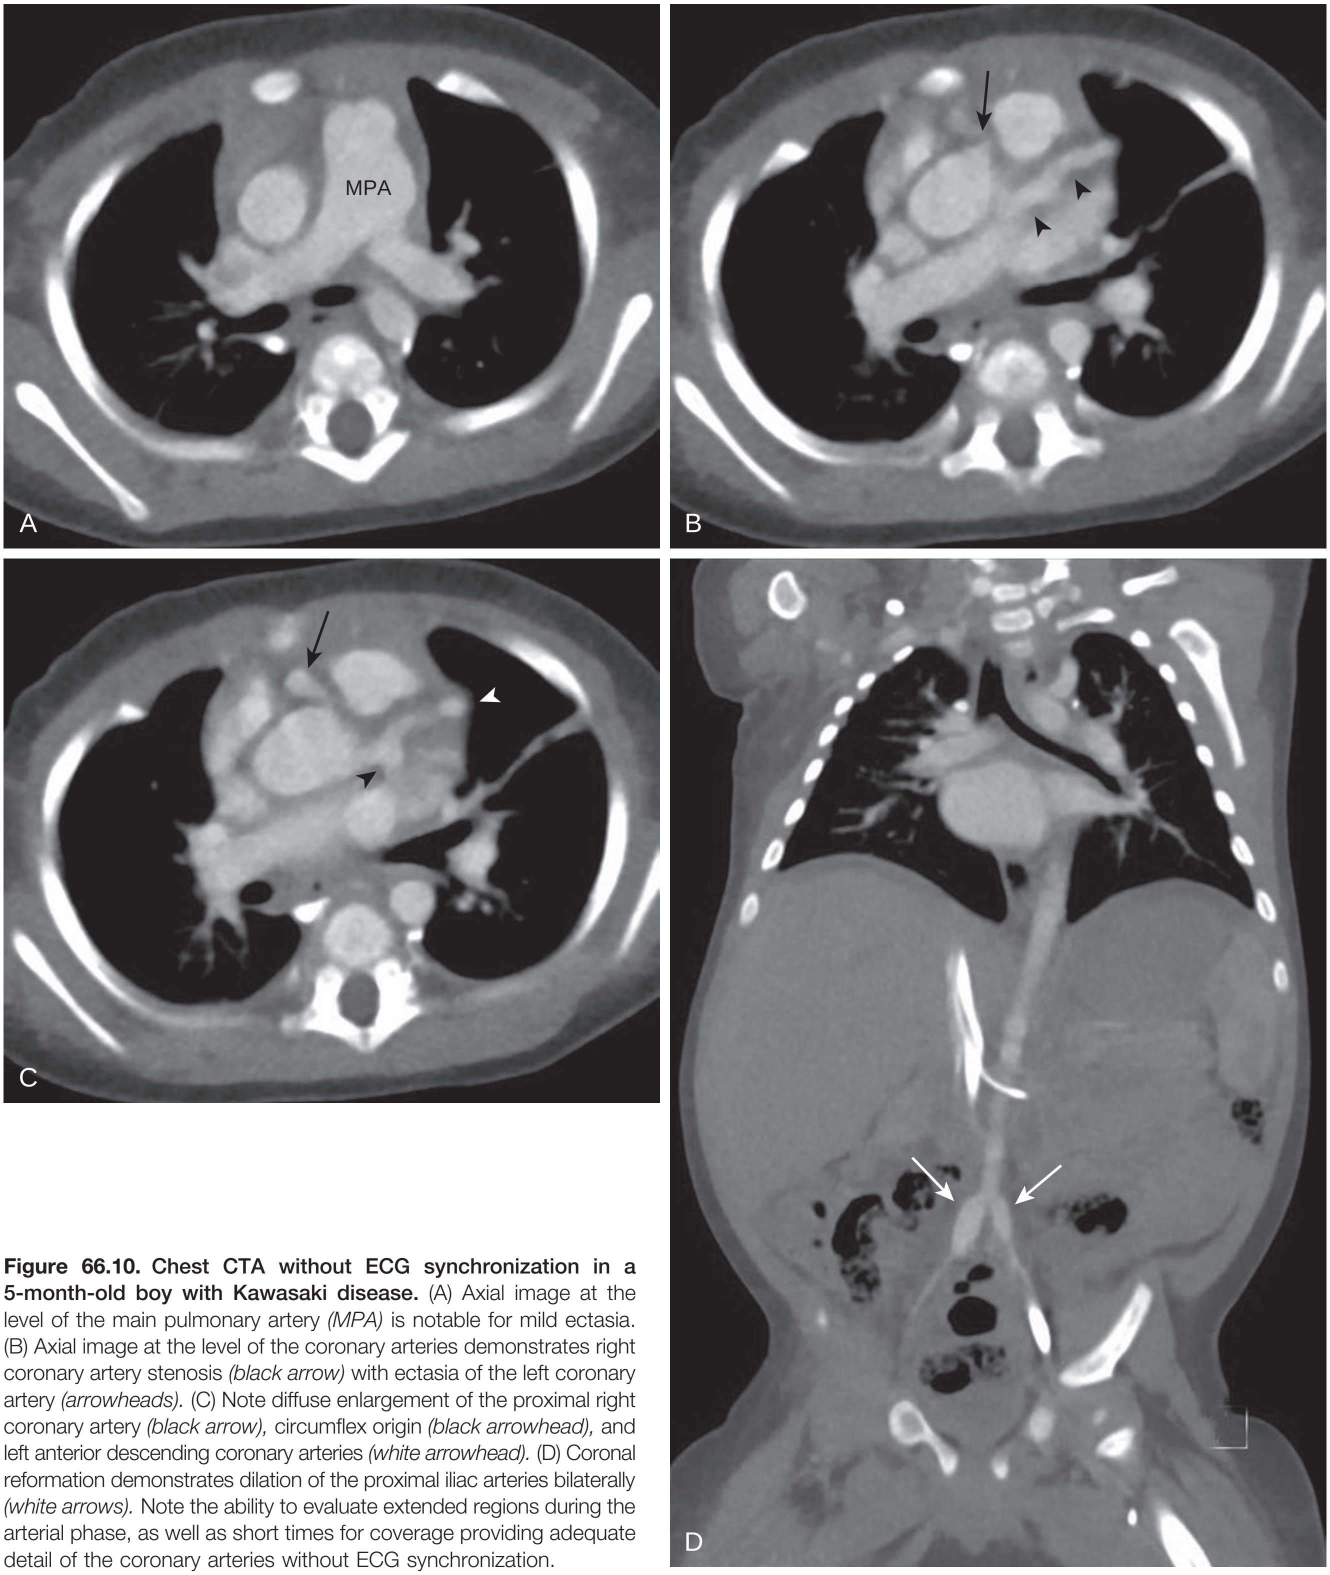


**Figure 66.10. Chest CTA without ECG synchronization in a 5-month-old boy with Kawasaki disease.** (A) Axial image at the level of the main pulmonary artery *(MPA)* is notable for mild ectasia. (B) Axial image at the level of the coronary arteries demonstrates right coronary artery stenosis *(black arrow)* with ectasia of the left coronary artery *(arrowheads).* (C) Note diffuse enlargement of the proximal right coronary artery *(black arrow),* circumflex origin *(black arrowhead),* and left anterior descending coronary arteries *(white arrowhead).* (D) Coronal reformation demonstrates dilation of the proximal iliac arteries bilaterally *(white arrows).* Note the ability to evaluate extended regions during the arterial phase, as well as short times for coverage providing adequate detail of the coronary arteries without ECG synchronization.

Because image contrast is relatively high in cardiothoracic CTA, consideration should be given to lowering the peak kilovoltage.[26] This step will improve image contrast and, although some increased noise occurs, the increase in contrast is greater than the increase in noise in small children, which produces an improved contrast-to-noise ratio and better image quality. Therefore 80 kVp (or 70 kVp, if available) (Fig. 66.10) should be used for newborns, infants, and young children, and 100 kVp for older children is acceptable. A value of 120 kVp can be used for larger children and adolescents. With advances in image processing time and storage and the availability of off-line workstations, evaluation of the pediatric heart and great vessels in multiple perspectives is now performed rapidly. Images should be reconstructed at the narrowest slice thickness possible (submillimeter) and at intervals

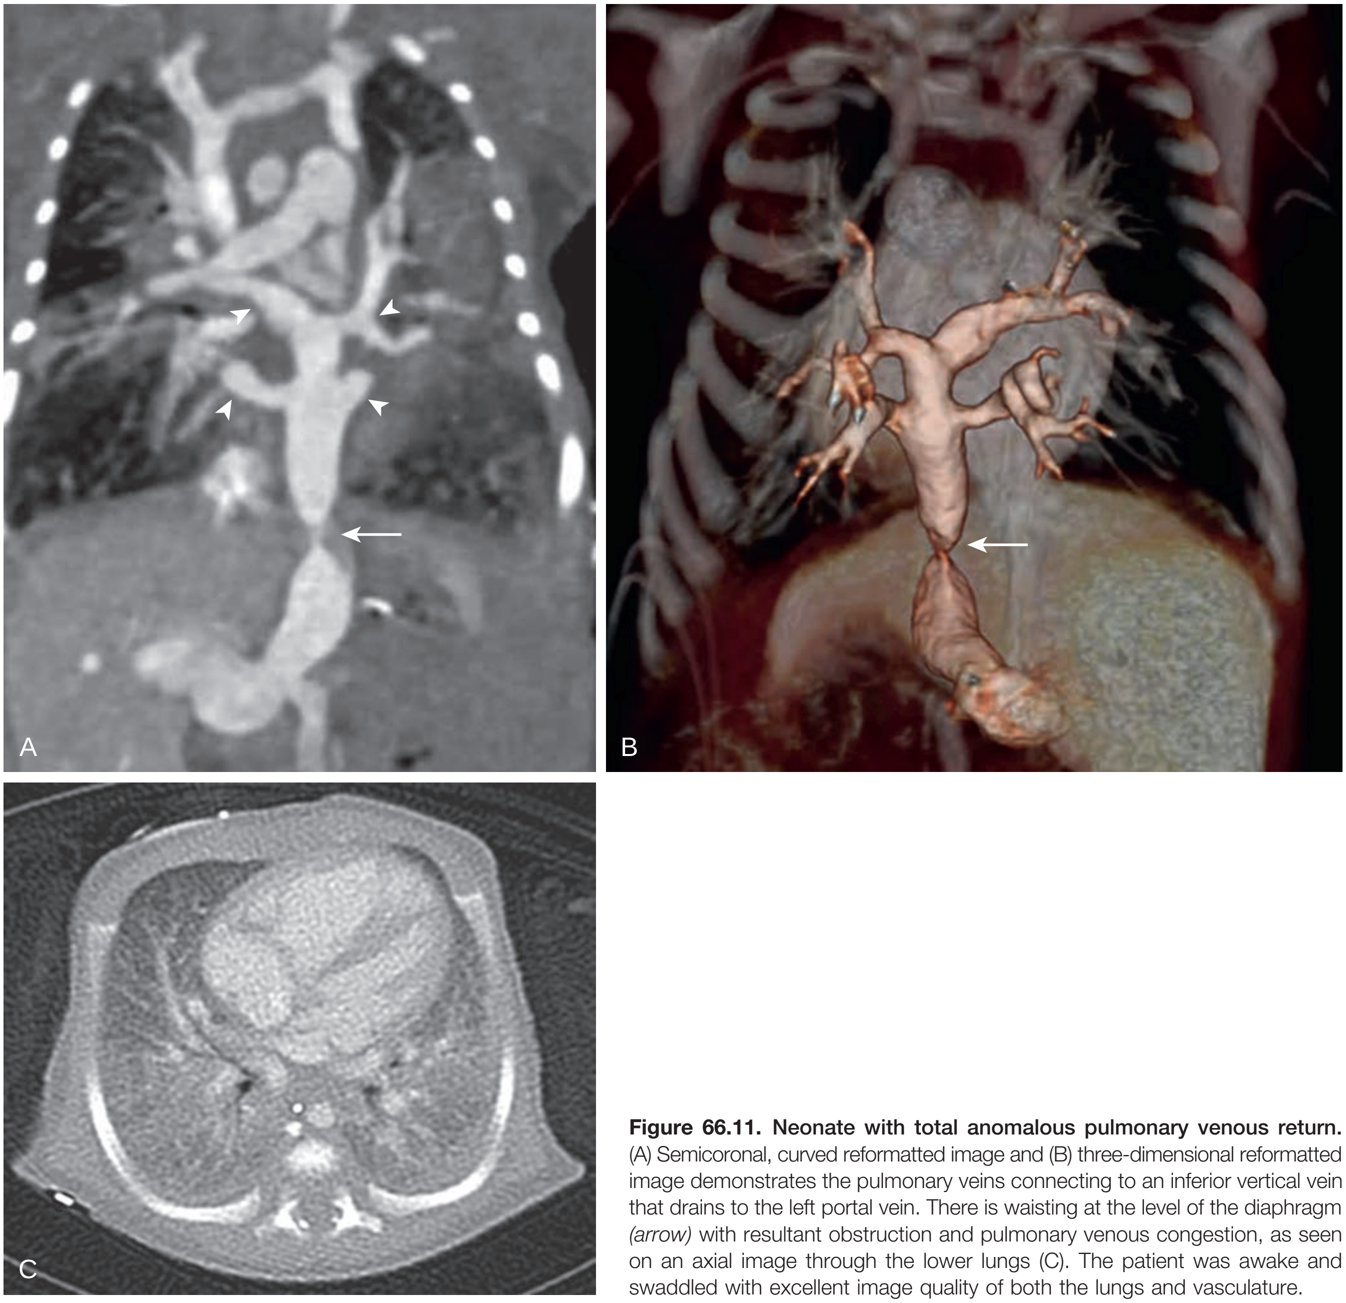

**Figure 66.11. Neonate with total anomalous pulmonary venous return.** (A) Semicoronal, curved reformatted image and (B) three-dimensional reformatted image demonstrates the pulmonary veins connecting to an inferior vertical vein that drains to the left portal vein. There is waisting at the level of the diaphragm *(arrow)* with resultant obstruction and pulmonary venous congestion, as seen on an axial image through the lower lungs (C). The patient was awake and swaddled with excellent image quality of both the lungs and vasculature.

just under the slice thickness. Iterative reconstruction techniques should be used routinely to improve image noise.[11,27]

The speed of modern CT scanners has obviated the need for cardiac gating in much of pediatric cardiovascular CT. As with adults, intracardiac anatomy is better displayed with use of ECG synchronization, although dual-source high-pitch and wide detector scanners can provide improved intracardiac detail compared with non–high-pitch and single-source scanners. However, ECG synchronization is still generally recommended for evaluation of the coronary arteries. As previously noted, when compared with retrospective ECG gating, prospective ECG gating reduces radiation dose. Limiting the z-axis coverage to the area of interest (i.e., the aortic root in evaluation of anomalous coronary origins) further decreases radiation dose. Technical considerations have been reviewed[18,28]; a detailed description of ECG-synchronized techniques is beyond the intent of this chapter. Even more than with the nongated angiographic technique, presence at the scanner by the imaging expert usually is necessary to determine contrast details, particularly with the timing bolus, and scan parameters (e.g., scan range, tube current, and peak kilovoltage), as well as performance of postacquisition processing. Dual-source design (i.e., two x-ray tubes) has improved temporal resolution (lessening the need for β-blockade to decrease heart rate, even to heart rates around 120 beats/min) (see Figs. 66.10 and 66.11).[29] Applying adult techniques to pediatric scanning can result in excessively high radiation dosages—reported to be as high as 30 millisieverts (mSv)—which is approximately 10 to 20 times the dose of a normal chest CT examination in a child. Dose and image quality for ECG-synchronized cardiac evaluation should reflect reduced-dosage techniques for other body applications in infants and children, with consideration of lower tube current and kilovoltage (see Fig. 66.6).

The use of bismuth breast shields to reduce breast dose has lowered radiation dose and maintained image quality for pediatric chest CT, although the benefit of shielding is debated given the availability of other techniques for dose reduction. The use of organ-based dose modulation, where the tube current is reduced over an arc to reduce surface dose such as for the breasts, has yet to be systematically studied in pediatric chest CT.

## CONCLUSION

CT evaluation of intrathoracic cardiovascular anatomy has increased dramatically in both adults and children during the past decade. In certain pediatric populations, including very young children, technical challenges need to be considered before and during performance of cardiac CT angiography. Considerations include proper patient preparation and individualization of scanning techniques to address the specific clinical questions, as well as considerations unique to that child (such as size). These considerations also will minimize radiation exposure. Despite these challenges, excellent cardiac angiographic evaluation can be obtained even in the most challenging cases.

### KEY POINTS

- Technique is critical for optimizing pediatric cardiovascular CTA.
- Pediatric CTA is less protocol driven than with adults.
- If performed properly, nongated and ECG-synchronized CT angiography in children can result in dose estimates at or below 1.0 mSv.
- Familiarity with clinical questions and anatomy with congenital disorders will afford the greatest potential for safe and high-quality pediatric examinations.
- Lower peak kilovoltage (e.g., 70, 80, and 100 kVp) can be used in CTA compared with other body imaging because of high-contrast vascular enhancement.

# Magnetic Resonance Imaging for Congenital Heart Disease

*Elizabeth F. Sheybani*

Cardiac magnetic resonance imaging (MRI) has become integral in the evaluation, treatment planning, and posttreatment surveillance of congenital and acquired heart disease. Although echocardiography remains the primary mode of evaluation for these children, cardiac MRI has the unique ability to accurately assess multidimensional anatomic, functional, volumetric, and flow data in even the youngest patients with congenital heart disease, and thus can be an invaluable supplement. The mainstays of cardiac MRI in congenital heart disease are electrocardiographic (ECG) gated balanced steady-state free-precession (b-SSFP) cine sequences for anatomic and functional evaluation and phase-contrast cine sequences for velocity and flow measurements. ECG and respiratory navigated magnetic resonance angiography (MRA) acquisitions, with or without gadolinium contrast, have become commonplace, as they allow offline reformats in any plane and three-dimensional (3D) image or model production.

## PULSE SEQUENCES

ECG-gated spin echo and gradient echo sequences are used for cardiac evaluation. Spin echo, or "black blood," imaging gives excellent contrast resolution between the endocardium or vessel wall and the blood-filled lumen (Fig. 67.1). Alternatively, on gradient echo (GRE) images, or "bright blood" images, the blood pool has high signal intensity. The GRE sequence balanced SSFP (b-SSFP) is the current mainstay of cardiac imaging. Balanced SSFP sequences are faster than (GRE) sequences and yield better contrast between myocardium and blood. By obtaining data during set phases of the cardiac cycle, b-SSFP cine images can be used for analysis of myocardial or valvular motion throughout the cardiac cycle. Although b-SSFP is ideally performed with the patient holding his or her breath, respiratory motion artifacts are minimized in sedated or uncooperative children by increasing the number of excitations. This technique is the preferred sequence for evaluating cardiac motion and quantifying cardiac function (Fig. 67.2).

## FUNCTIONAL EVALUATION

MRI is the reference standard for noninvasive cardiac functional assessment and is superior to echocardiography in assessing right ventricular function, particularly in patients with congenital heart disease.[1] This is an important consideration in evaluation of these children as they generally need serial and reproducible measurements of ventricular function to determine optimal timing of potential interventions.[2] A stack of short-axis cine images through the ventricles is obtained to measure ventricular volumes. Using postprocessing software, the operator defines the endocardial border on each slice, and the software then multiplies the resultant cross-sectional area by the slice thickness to obtain the ventricular volume. There is no consensus on inclusion or exclusion of the papillary muscles in the left ventricular volume or trabeculation in the right ventricular volume, so either method should be used with knowledge that the volumes can be affected by differences in postprocessing technique and similar methodology should be used when comparing studies.[3] End-diastolic and end-systolic phases are identified for calculation of ejection fraction and stroke volume. The additional application of pericardial contours allows determination of myocardial mass.

Because children vary in size, cardiac MRI measurements are reported as indexed values. These are obtained by dividing each measurement by the patient's body surface area. This allows more standardized comparisons as patients grow and across patient populations. There are reported normal values for left and right ventricular volumes in children, and these can be used for general reference but are based on small sample sizes.[3]

The right and left ventricular stroke volumes are the same in the structurally normal heart. Differences in stroke volumes are caused by shunts and/or valvular regurgitation. Using MRI, both shunt volumes and regurgitant fractions can be calculated from stroke volumes or flow data if there is an isolated single shunt lesion or regurgitation involving a single valve. If there are multiple abnormalities, more detailed evaluation is needed. Shunt fraction, or the pulmonary to systemic flow ratio (Qp:Qs), is determined by dividing the larger stroke volume by the smaller. The valvular regurgitant fraction is determined by dividing the regurgitant volume, which is the difference of ventricular stroke volumes, by the larger ventricle stroke volume (Fig. 67.3). The regurgitant volume may result from atrioventricular valve or semilunar valve insufficiency, or a combination of both.

$$\begin{aligned}&\mathrm{Qp} : \mathrm{Qs} =\\&\text{Ventricular stroke volume}_1/\text{Ventricular stroke volume}_2\end{aligned}$$

$$\begin{aligned}&\text{Valvular regurgitant fraction} =\\&(\text{Ventricular stroke volume}_1 - \text{Ventricular}\\&\text{stroke volume}_2)/\text{Ventricular stroke volume}_1\end{aligned}$$

where Ventricular stroke volume$_1$ is the larger of the two ventricular stroke volumes.

Phase-contrast imaging uses a GRE sequence to measure phase shift and produces both magnitude and directional information (Fig. 67.4). By setting an acquisition plane perpendicular to a vessel or valve of interest, phase-contrast imaging allows for accurate quantification of blood flow velocity. The pressure gradient across a stenosis can then be calculated from the blood flow velocity using the modified Bernoulli equation:

$$\Delta P = 4v^2$$

where $\Delta P$ is the peak instantaneous pressure gradient across the stenosis and $v$ is the velocity across the stenosis measured by flow analysis. Using postprocessing software, the velocity within each pixel of the targeted vessel can be multiplied by the vessel area and then summed across the cross section of the vessel across the cardiac cycle to generate the flow per beat within the vessel. Given the limitless scan plans of cardiac MRI, this method has proved superior to echocardiography for flow determinations and is used extensively in congenital heart disease to evaluate stenoses, shunt fractions, and collateral vessel burden.[4] More recently, 3D phase-contrast imaging (four-dimensional [4D] flow) has allowed

acquisition of a volumetric 3D flow dataset over the cardiac cycle, which can be postprocessed in any plane to yield velocity and flow data throughout the acquired volume.[5]

## MAGNETIC RESONANCE ANGIOGRAPHY

Contrast-enhanced magnetic resonance angiography (CE-MRA) is performed after injection of a gadolinium chelate bolus. The technique relies on T1 shortening of blood and requires rapid imaging. A spoiled gradient sequence with a short echo time is used. Conventionally, CE-MRA has high spatial and low temporal resolution and is performed during suspended respiration. More recently, high-temporal resolution, free-breathing, time-resolved CE-MRA has proved to be feasible in children with higher heart rates by using k-space undersampling techniques and parallel imaging.[6] In contrast to conventional CE-MRA, time-resolved MRA achieves greater temporal resolution but lower spatial resolution by oversampling the center of k-space (contrast) compared with the periphery (edge detail). Portions of k-space are shared across measurements with resulting high temporal resolution. Before contrast material is injected, a mask volume is obtained. The contrast material is then injected and the scan is initiated. The precontrast mask is subtracted from each subsequent volume to obtain a series of maximum-intensity projection images over time (Video 67.1). CE-MRA datasets can be used to create 3D volume renderings and multiplanar reformations (Fig. 67.5).

Balanced steady-state free-precession imaging (b-SSFP) is a respiratory- and cardiac-gated, fat-suppressed, 3D MRA sequence used for cardiac and extracardiac anatomy imaging. It provides high resolution because it is ECG gated, and there is excellent delineation of intracardiac anatomy and the coronary arteries (Fig. 67.6 and Video 67.2).[7] Given its high spatial resolution, this technique is used in children with complex congenital heart disease where 3D assessment, either with multiplanar or volumetric reformatted images or printed models, is critical for treatment planning. Because this technique can be performed without contrast, it can be useful in evaluating patients with severe renal dysfunction who cannot undergo testing with gadolinium-based contrast agents because of the risk of developing nephrogenic systemic fibrosis and to minimize gadolinium-based contrast agent exposure to decrease gadolinium deposition in the brain.[8,9,10]

## PERFUSION AND LATE GADOLINIUM ENHANCEMENT

First-pass contrast-enhanced perfusion images, with or without the concomitant administration of vasodilators, provide assessment of myocardial perfusion reserve. Myocardial perfusion is acquired by rapid imaging during multiple cardiac cycles over time, which allows visualization of a contrast bolus through the heart. A perfusion defect is suggestive of a stenosed arterial supply to that territory. Recent studies in children have shown that stress perfusion imaging is feasible and has reasonable sensitivity, specificity, and positive and negative predictive values for coronary disease when compared with coronary angiography.[11-13]

Late gadolinium enhancement of the myocardium is assessed 10 to 20 minutes after administration of an intravenous gadolinium-based contrast agent. An inversion pulse nulls the signal from normal myocardium, and abnormal myocardium appears bright on the black background of normal myocardium. Late gadolinium enhanced images provide information about abnormal myocardium in both ischemic and nonischemic cardiomyopathies, including myocarditis, and may help characterize cardiac masses and infiltrative diseases. Late gadolinium enhancement is seen due to increased extracellular distribution of contrast in abnormal tissues, whether from scarring (infarction), fibrosis (cardiomyopathy), inflammation (myocarditis), or infiltrative disease (amyloid, sarcoid). Regardless of the etiology, the presence of extensive late gadolinium enhancement portends a poor prognosis.[14]

### Preoperative and Postoperative Imaging

MRI is performed as a complement to echocardiography for preoperative evaluation of cardiovascular anomalies and function. Most intrinsic cardiac anomalies do not require MRI for initial diagnosis or treatment, although patients with complex anatomy can be difficult to fully evaluate with echocardiography, so these patients may benefit from cardiac MRI. However, cardiac MRI is performed more commonly in children after surgical repair or palliation than before surgery for preoperative diagnosis.

To assess cardiac anatomy and morphology, a combination of multiplanar spin echo and b-SSFP imaging usually is performed. Long- and short-axis b-SSFP cine imaging of the ventricles and

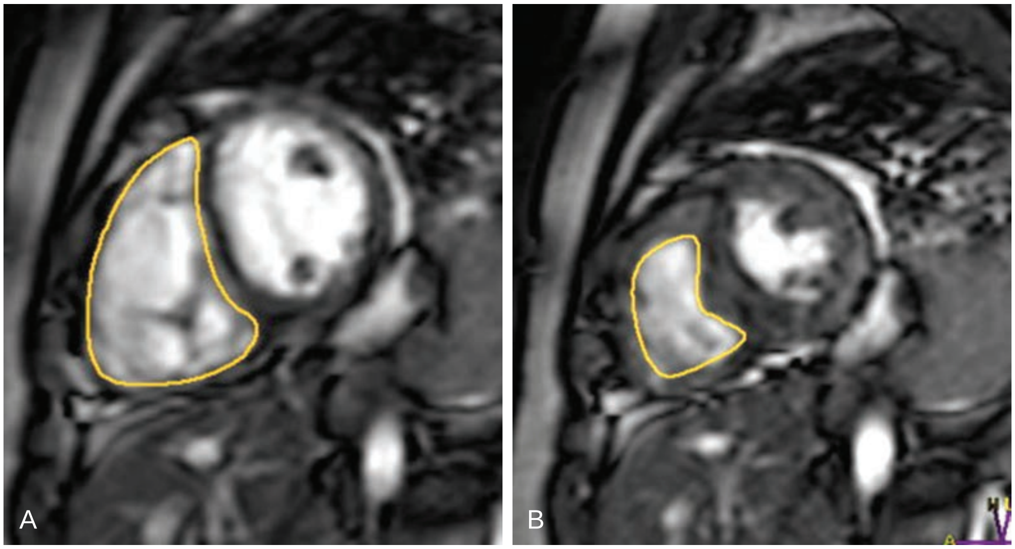

**Figure 67.3. Pulmonary regurgitation.** Endocardial right ventricular contours are drawn on a short-axis steady-state free-precession MRI in end-diastole (A) and end-systole (B) in a patient with a history of pulmonary stenosis after a pulmonary valvectomy and now with pulmonary regurgitation. The calculated pulmonary regurgitant fraction was calculated to be 37% by right and left ventricular stroke volume differences.

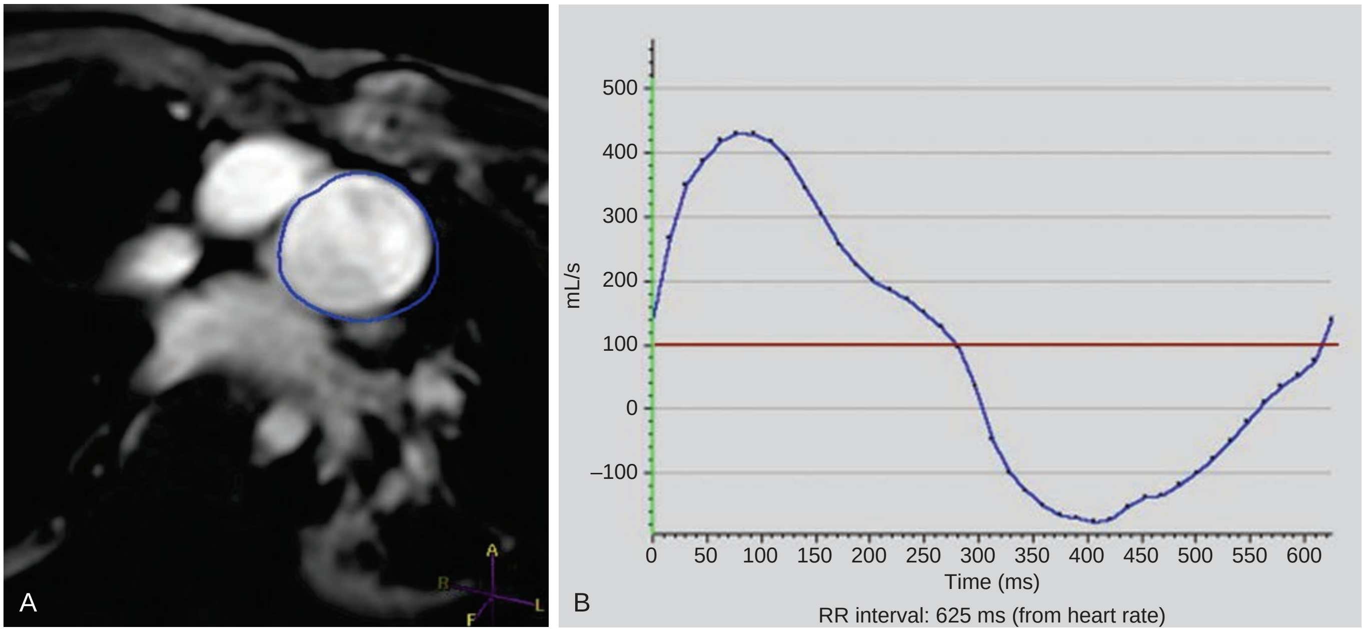

**Figure 67.4. Tetralogy of Fallot.** Phase-contrast velocity mapping of the pulmonary artery in a 15-year-old with a history of tetralogy of Fallot after patch augmentation of the subpulmonary outflow tract obstruction. The blue region of interest is around the pulmonary outflow tract (A). The flow curve demonstrates moderate pulmonary regurgitation with a calculated regurgitant fraction of 34% (B).

outflow tracts should be obtained for ventricular functional and volumetric analysis and to detect flow disturbances associated with septal defects or regurgitant valves. Phase-contrast imaging of the valves and pertinent vessels allows for blood flow velocity and vascular blood flow assessment. Extracardiac vascular evaluation is generally performed with CE-MRA. A spin echo dark blood sequence complements CE-MRA by allowing visualization of vessel walls. Vascular rings are well delineated by CE-MRA but require additional spin echo imaging to identify the degree of associated airway compression.

Because children with congenital heart disease often have complex anatomy, an organized segmental approach is necessary for image acquisition and interpretation. This includes determination of visceral situs and cardiac position, atrial relationship, atrioventricular and ventriculoarterial connections, and great arterial relationship (see Chapter 63). Potential abnormalities at each level should be assessed, including the number and connections of pulmonary veins, septal defects or additional shunt lesions, pulmonary artery or aortic anomalies, valvular abnormalities, and vascular dilation and stenoses.

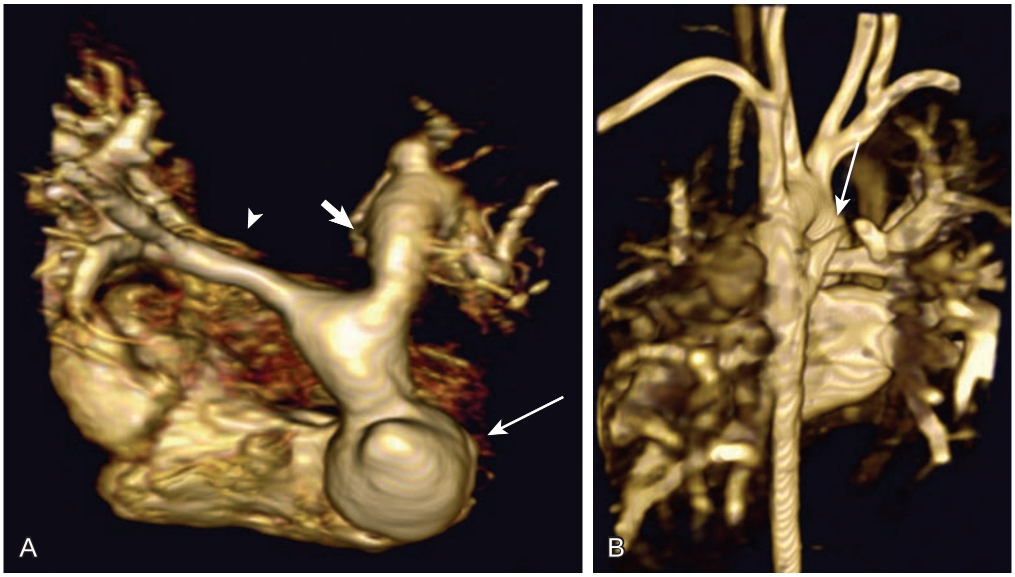

**Figure 67.5. Tetralogy of Fallot after patch augmentation for right ventricular outflow tract obstruction.** Three-dimensional volume-rendered MRI of the pulmonary artery and branches (A) from a superior-to-inferior view. A pseudoaneurysm of the right ventricular outflow tract is seen *(long arrow).* Hypoplasia of the right pulmonary artery is present *(arrowhead),* along with ectasia of the left pulmonary artery *(short bold arrow).* A posterior image of the chest (B) in the same patient shows a major aortopulmonary collateral artery to the upper lobe segment of the right lung *(arrow).*

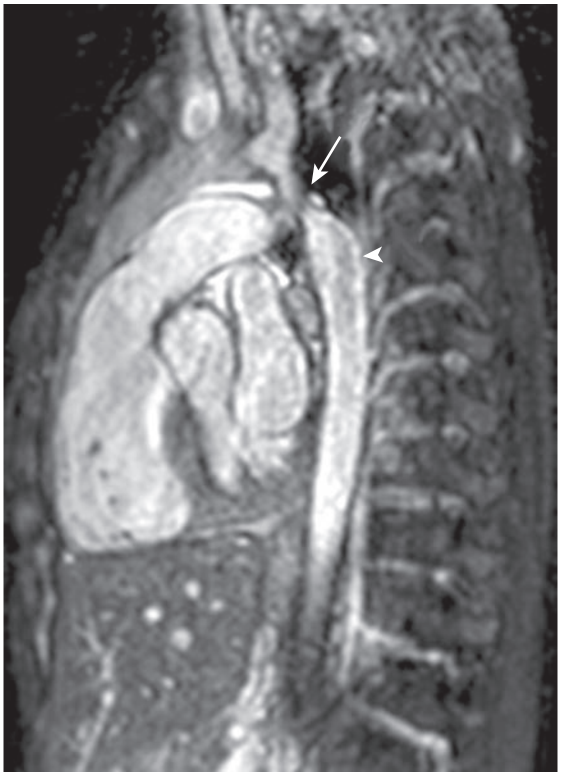

**Figure 67.6. Aortic coarctation in a 3-year-old.** A three-dimensional noncontrast b-SSPP 3D MRA of the chest was performed. The *arrow* points to a focal area of high-grade stenosis in the postductal aorta, and the *arrowhead* shows the turbulent flow distal to the coarctation (see Video 67.3).

### KEY POINTS

- Cardiac MRI is an excellent supplement to echocardiography in congenital and acquired heart disease given its ability to produce 3D images and accurately assess volumetrics, function, and flow.
- Time-resolved MRA produces better temporal resolution than conventional contrast-enhanced MRA. The shorter acquisition time makes it an ideal choice for pediatric cardiovascular imaging.
- The b-SSFP noncontrast 3D MRA technique gives excellent intracardiac and coronary artery detail and avoids exposure to gadolinium-based contrast agents.

## PEDIATRIC CARDIAC CATHETERIZATION

### Introduction

Pediatric cardiovascular catheterization laboratories today involve a variety of complex diagnostic and interventional procedures for congenital abnormalities using multiple imaging tools to improve procedural outcome and patient safety. Preprocedure imaging to map the complex anatomy is more routinely performed, including modalities such as computed tomography (CT), cardiac magnetic resonance imaging (cardiac MRI), and three-dimensional (3D) model creation to plan the interventional procedure. Many centers are also using 3D rotational angiography to outline anatomy and important stenoses in the laboratory. In addition, intracardiac echocardiography remains a frequently used modality to guide septal closures, assess paravalvar leaks during transcatheter valve implantation, and assess mitral valve anatomy or appendage anatomy during structural interventions. Consequently, the pediatric cardiovascular catheterization laboratory has evolved to diagnostic procedures using an assortment of imaging modalities to assess complex congenital abnormalities before surgery and interventional procedures that permit therapeutic options that often preclude surgery.[1]

### Procedural Techniques

Catheterizations are performed with the Seldinger technique in the femoral vein and/or artery. Alternative venous access includes the internal jugular, subclavian, or transhepatic approaches. Arterial access also may be obtained via the arteries of the upper extremities or the carotid artery, but these approaches typically are either emergent conditions, secondary to occluded standard vessels, or anatomy deemed inadequate due to a small vessel diameter relative to the sheath required for the procedure. Anticoagulation is managed with heparin, 80 to 100 U/kg or 5000 U in patients greater than 50 kg, for an activated clotting time goal of 200 to 280 seconds, depending on the procedure to be performed. Antibiotics are administered to patients who receive an implanted device or are at risk for endocarditis based on the American Heart Association guidelines. Baseline hemodynamics (including pressures and oxygen saturations) and angiography are obtained in room air. Subsequently, relative blood flows and vascular resistances are calculated. The ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs) is calculated according to the following formula: $Qp/Qs = [(AO_2 - MVO_2)/(PVO_2 - PaO_2)]$, where $AO_2$ is the aortic oxygen saturation, $MVO_2$ is the mixed venous oxygen saturation, $PaO_2$ is the pulmonary arterial saturation, and $PVO_2$ is the pulmonary venous saturation. These data then determine whether additional information or interventions are necessary, as well as whether the patient is a future surgical or transplant candidate.

## CONGENITAL ABNORMALITIES OF THE RIGHT SIDE OF THE HEART

### Pulmonary Valve Stenosis

Valvar pulmonary stenosis is found in 8% to 10% of patients with congenital heart disease (see Chapter 74). Balloon pulmonary valvuloplasty has supplanted surgical valvotomy as the treatment of choice. The recommended balloon-to-annulus ratio is between 100% and 140%.[2] The reported success rate is greater than 90% with complications occurring in less than 1%.[3] Hemodynamic measurements include the right ventricular (RV) pressure compared with systemic arterial pressure and the peak-to-peak systolic pressure gradient across the pulmonary valve. The guideline recommendations for balloon pulmonary valvuloplasty is the presence of at least moderate pulmonary valve stenosis defined as peak instantaneous pressure gradient of ≥36 mm Hg by echocardiography.[4] We use as a guideline the “rule of 50,” which is defined as a peak RV systolic pressure of more than 50 mm Hg, a peak RV systolic pressure more than 50% of the systemic systolic pressure, or a peak-to-peak systolic gradient across the pulmonary valve of more than 50 mm Hg. An end-hole catheter is used to obtain a pressure from the pulmonary artery to the body of the right ventricle to assess the severity and location of any stenoses.

RV angiography in the anteroposterior view angled cephalad and in the lateral view is performed to provide information about location and severity of pulmonary valve stenosis. The valve annulus is measured digitally. The angiographic diagnosis of dysplastic pulmonary valve stenosis is confirmed when the valve leaflets are markedly thickened and severely immobile. For patients who meet the hemodynamic criteria, balloon pulmonary valvuloplasty is performed using a standard technique and deemed successful if the estimated peak RV pressure is less than 50 mm Hg, less than 50% of the peak systemic pressure, and less than 50 mm Hg peak-to-peak gradient across the pulmonary valve (guidelines state less than 40 mm Hg). Also, procedures are deemed successful only if there is a stable saturation with a closed ductus arteriosus and no immediate operative intervention is necessary before discharge from the hospital.

### Tricuspid Valve Stenosis

Bioprosthetic valves in the tricuspid position are amenable to transcatheter valve implantation.[5] Data are limited, but limited experience using the internal jugular approach has shown promising results (e-Fig. 68.1). Further data and clinical studies are necessary.

### Postoperative Right Ventricular Outflow Tract Derangements

Nearly 5,000 babies are born each year in the United States with some form of RV outflow tract derangement, and many of these patients require surgery early in life.[1] As these patients return with either hemodynamically significant RV outflow stenosis, regurgitation, or a combination, they are now candidates for a transcatheter pulmonary valve replacement.

Currently there are two Food and Drug Administration (FDA)–approved transcatheter pulmonary valves available for patients with hemodynamically abnormal RV outflow tracts, including either free pulmonary insufficiency and RV volume overload or RV outflow obstruction with RV hypertension and RV systolic or diastolic failure. The two valves are the Sapien XT[6] (Edwards Lifesciences, Irvine, CA) and the Melody valve[7] (Medtronic, Minneapolis, MN). The transcatheter pulmonary valve has replaced many patients’

## Abstract:

Pediatric cardiovascular catheterization laboratories involve a variety of complex diagnostic and interventional procedures for congenital abnormalities using multiple imaging tools to improve procedural outcome and patient safety. Preprocedure imaging to map the complex anatomy is more routinely performed, including modalities such as computed tomography (CT), cardiac magnetic resonance imaging (cardiac MRI), and three-dimensional (3D) model creation to plan the interventional procedure. Many centers are also using 3D rotational angiography to outline anatomy and important stenoses in the laboratory.

The pediatric cardiovascular catheterization laboratory has evolved to diagnostic procedures using an assortment of imaging modalities to assess complex congenital abnormalities before surgery and interventional procedures that permit therapeutic options that often preclude surgery.

need for a reoperation. Consequently, patients who often required two to four surgeries before an adult age can be treated with a nonsurgical valve technique (e-Fig. 68.2).

## Pulmonary Artery Stenosis

Since the introduction of high-pressure balloons (>30 atmospheres), pulmonary artery angioplasty has a success rate of more than 70%. Patients with severely hypoplastic pulmonary arteries with multiple stenoses that are refractory to high-pressure angioplasty may be amenable to cutting balloon angioplasty.[8] Cutting balloons are now FDA approved for pulmonary artery angioplasty with balloons 4 to 8 mm in diameter going to 7 to 8 atmospheres. Cutting balloon angioplasty often is followed by standard angioplasty (8–12 atm) for the best final result. Balloon-expandable stents have improved results in proximal vessels, eliminating the need for surgery in most patients (e-Fig. 68.3), but they are of limited value in distal pulmonary vessels. Furthermore, stents are contraindicated in noncompliant vessels that cannot be expanded using high-pressure balloons. Although balloon catheters, as well as stents, have not specifically been approved by the FDA as a treatment for pulmonary artery stenoses, these techniques have become the mainstay of treatment for distal vessel obstruction.

# CONGENITAL ABNORMALITIES OF THE LEFT SIDE OF THE HEART

## Aortic Valve Stenosis

Valvar aortic stenosis results from fusion of the aortic valve leaflets, creating either a unicuspid or bicuspid apparatus with functionally a one- or two-leaflet aortic valve. This is the most common congenital heart lesion, occurring in 1% to 2% of the population (see Chapter 73). Valvar aortic stenosis can be classified into two groups: group 1 has disease that is severe enough that it presents at birth or within 1 to 2 years of age (10%–15%), and group 2 has disease that is not diagnosed until after age 2 years and will progress much more slowly.[9,10] Morbidity, mortality, and the need for intervention are significantly skewed toward group 1. As with pulmonary stenosis, noninvasive imaging techniques have advanced to the point that nearly all anatomic and functional information about the valve may be obtained without catheterization. Fusion of the right and left coronary cusps is more significantly associated with coarctation of the aorta[11] compared with fusion of the right and noncoronary cusp. All bicuspid aortic valve patients are at risk for aortic root enlargement, and 8% to 10% may have a cerebral aneurysm. Catheterization is performed for valves that clearly merit intervention or when symptoms and imaging findings are incomplete or confounding.[12]

Aortic valve stenosis is classified into the following categories: trivial, mild, moderate, severe, and critical. Critical aortic stenosis is not defined by a specific pressure gradient or valve orifice size but on the basis of physiologic manifestations. If the stenosis is such that the patient is unable to produce and maintain an adequate cardiac output, the stenosis is critical. Patients in this group may have a low valve gradient due to decreased cardiac function and low cardiac output. Although controversy may exist with regard to the most beneficial treatment method for this patient population, most centers have adopted balloon valvuloplasty as the initial treatment of choice. Balloon valvuloplasty has demonstrated a reduction in gradient and resultant valve regurgitation with a shorter course in the cardiac intensive care unit and a shorter hospital stay compared with surgical valvotomy.

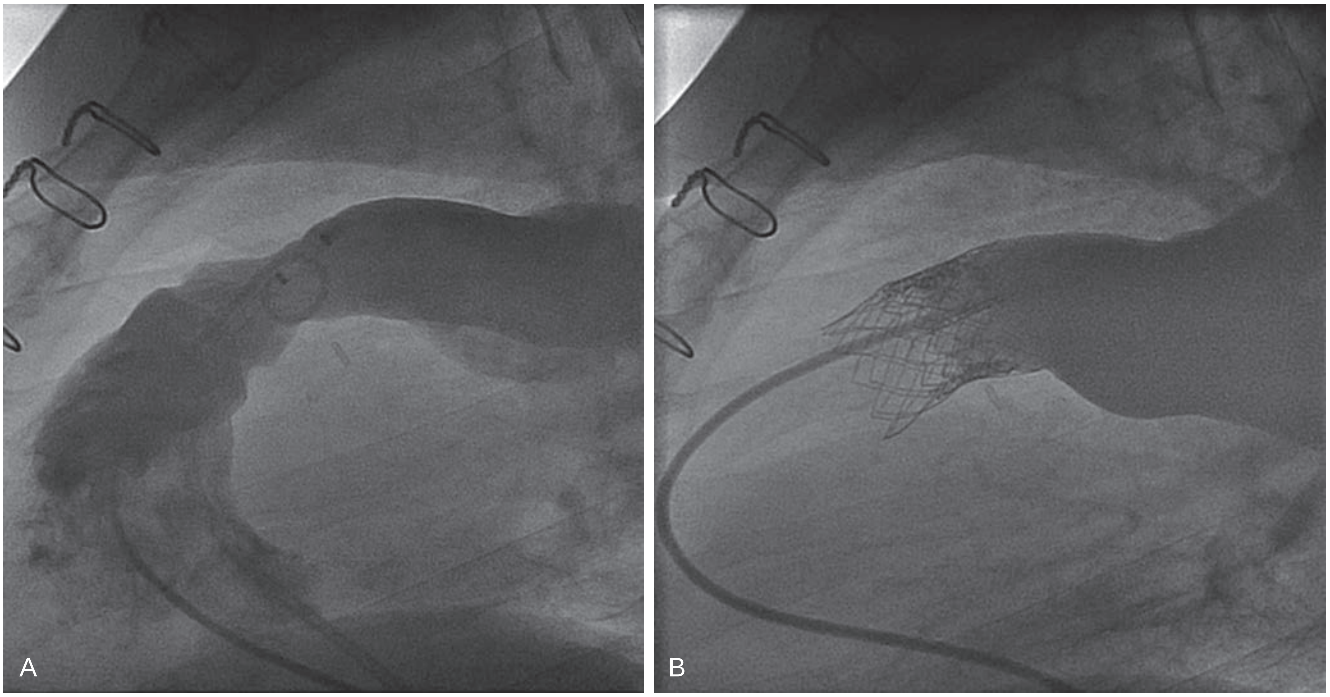
However, balloon valvuloplasty has been associated with an increased rate of reintervention compared with surgical valvotomy as a result of recurrent stenosis or worsening regurgitation. Given that residual aortic valve disease, especially regurgitation, may progress over time, the recommendation for the valvuloplasty technique is more conservative, with a smaller maximal balloon diameter (80% to <100% of the annulus) than that recommended for the pulmonary valve (100%–140%). The valve may be approached retrograde from the aorta, with arterial access usually from the femoral or carotid via a surgical cutdown. Our preference is to approach the aortic valve prograde by crossing an existing atrial communication or by performing a transseptal puncture to access the left side of the heart. Once in the left ventricle, angiography is performed to measure the valve annulus and identify landmarks for valvuloplasty. Many centers have adopted rapid right or left ventricular pacing at the time of balloon inflation. This rapid pacing transiently reduces cardiac output and the shearing force transmitted to the balloon as it is inflated across the valve annulus. The goal is to reduce the balloon shear force motion on the fragile valve leaflets and prevent excessive damage and subsequent regurgitation. Repeat angiography and echocardiography after inflation are essential to evaluate the success of the valvuloplasty and monitor for regurgitation or other complications. The differentiation between noncritical stenosis categories is made by noninvasive echocardiographic measurements of valve area and Doppler gradient. A normal valve area is 2 $cm^2/m^2$. Mild obstruction is consistent with valve areas less than 2 $cm^2/m^2$ but greater than 0.7 $cm^2/m^2$, and severe obstruction is consistent with valve areas less than 0.5 $cm^2/m^2$. Mean echocardiographic Doppler gradients are good predictors of the peak-to-peak pressure gradient measured at catheterization. Gradients less than 25 mm Hg are considered trivial, those 25 to 50 mm Hg are mild, those 50 to 75 mm Hg are moderate, and those greater than 75 mm Hg are severe.[12] These measurements are made with the understanding that the cardiac function and cardiac output are normal. Catheterization is not recommended for trivial or mild stenosis. Moderate and severe stenoses are approached with primary balloon valvuloplasty using the techniques previously described.

## Coarctation of the Aorta—Angioplasty and Stent Placement

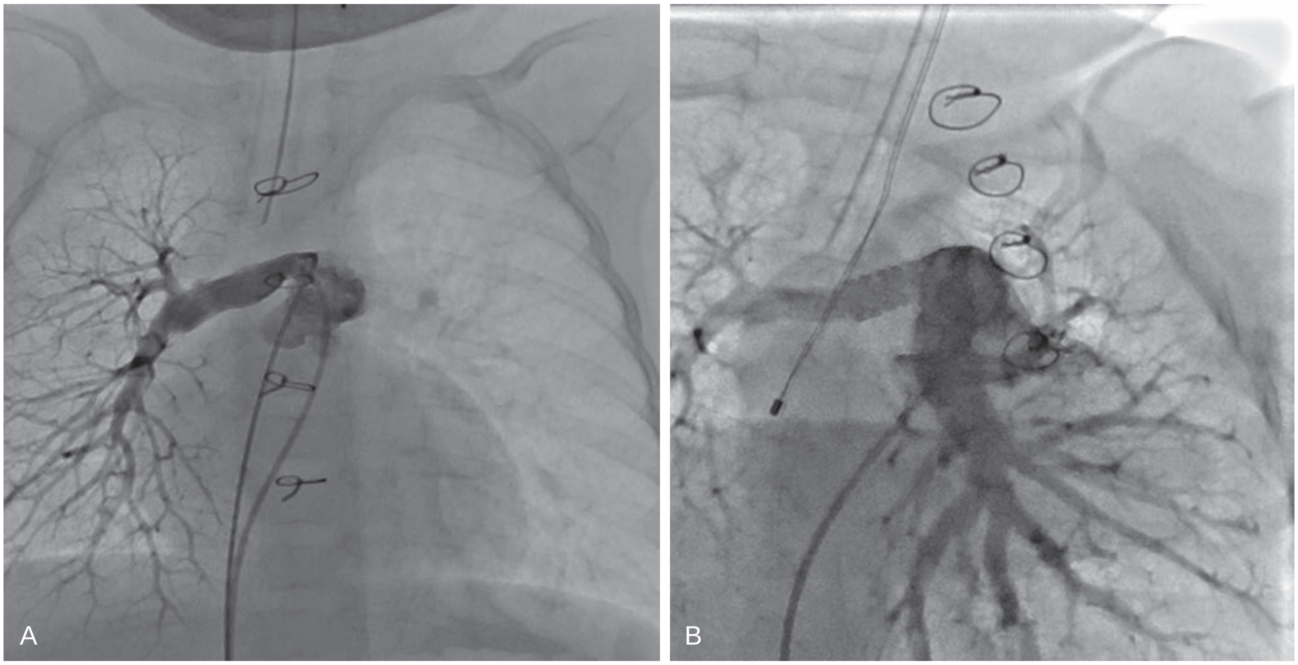
Often, aortic obstruction after an end-to-end surgical repair at the isthmus is a result of aortic narrowing within the transverse arch. These obstructive lesions are further defined as either the proximal transverse arch between the innominate artery and left carotid artery or the distal transverse arch, defined as the region between the left carotid artery and the left subclavian artery. Although few data exist regarding stent angioplasty within the distal transverse aortic arch, general experience has been that this procedure is safe and effective. A sheath is placed in the femoral artery and an arterial monitoring catheter is placed in the right upper extremity. A 4-Fr sheath is used to advance a 4-Fr pigtail catheter from the right radial artery to the proximal transverse aortic arch. This catheter is used to monitor pressures during stent angioplasty of the distal transverse arch from the femoral artery and to perform cine angiograms to determine appropriate stent placement distal to the takeoff of the left carotid artery.

Transcatheter stent angioplasty for postoperative recoarctation of the aorta at the isthmus has been demonstrated to be safe and effective.[14] The technique usually involves a femoral arterial approach. Recently, the coarctation of the aorta stent trial (COAST) resulted in an FDA approval for a bare metal stent (CP stent, NuMED, Hopkinton, NY) for coarctation of the aorta and COAST II resulted in FDA approval of a Gore-Tex–covered stent (CP Covered Stent, NuMED, Hopkinton, NY) for coarctation of the aorta (Fig. 68.4).

An exchange length wire is placed in the ascending aorta or right subclavian artery. An angioplasty balloon is used with a maximum diameter that is equal to or less than the diameter of the normal aortic segments adjacent to the stenotic region and/or the diameter of the descending thoracic aorta at the diaphragm. The stent is mounted on the angioplasty balloon and passed through



**e-Figure 68.2. Right ventricular outflow tract evaluation.** (A) Lateral projection fluoroscopy and cine angiography of a patient with truncus arteriosus post–right ventricular outflow tract reconstruction. Angiography shows free pulmonary insufficiency and supravalvar narrowing. (B) Lateral projection fluoroscopy and cine angiography of a patient with tetralogy of Fallot post–right ventricular outflow tract revision with a 26-mm Sapien XT valve. Angiography in the main pulmonary artery demonstrates no pulmonary insufficiency or stenosis.



**e-Figure 68.3. Pulmonary artery stenosis.** (A) Anterior-posterior projection fluoroscopy and cine angiography demonstrating a proximal right pulmonary artery stenosis. (B) Caudal right anterior oblique projection fluoroscopy and cine angiography demonstrating a successful balloon stent angioplasty of the right pulmonary artery.

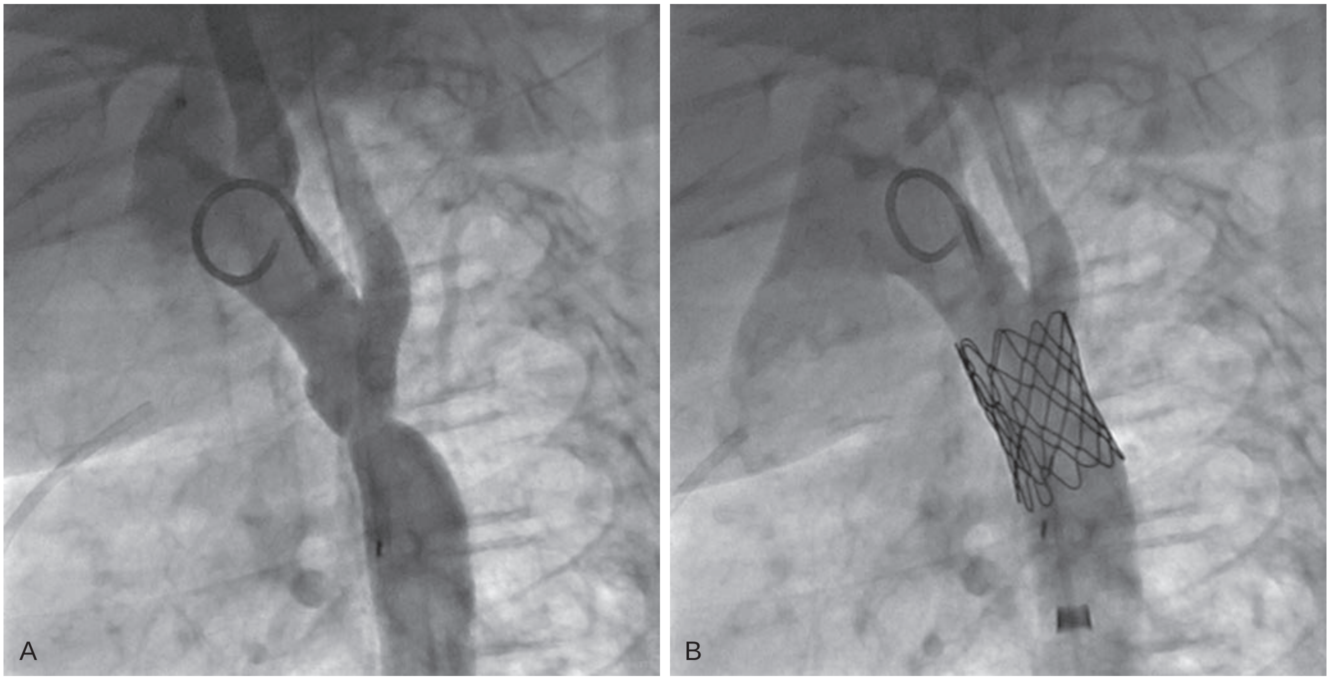


**Figure 68.4. Aortic coarctation.** (A) Lateral projection fluoroscopy and cine angiography of a patient with Turner's syndrome, bicuspid aortic valve, and coarctation of the aorta demonstrates severe native stenosis of the aorta at the isthmus. a sheath at least 1 to 2 Fr larger than that required by the balloon. The stent length is dependent on the lesion length but is usually 28 to 45 mm. The stent is fully dilated in most cases, but at times it is deemed safer to serially dilate the lesion over two procedures.

## SEPTAL AND VASCULAR CLOSURE DEVICES

### Secundum Atrial Septal Defect

Although atrial septal defect (ASD) diagnosis rarely requires cardiac catheterization, today many patients undergo cardiac catheterization for therapeutic device closure.[14] These patients require assessment of associated anomalies such as abnormalities of pulmonary venous connections. A step-up in oxygen saturations in the right atrium and pulmonary arteries is characteristic for an ASD, and the degree of left-to-right shunting or the pulmonary to systemic blood flow ratio (Qp:Qs) can be determined. The ideal age or timing for elective ASD closure is 2 to 5 years of age or within 6 to 12 months of diagnosis. Rarely, a child with an ASD presents with severe congestive heart failure and requires intervention in the first year of life.

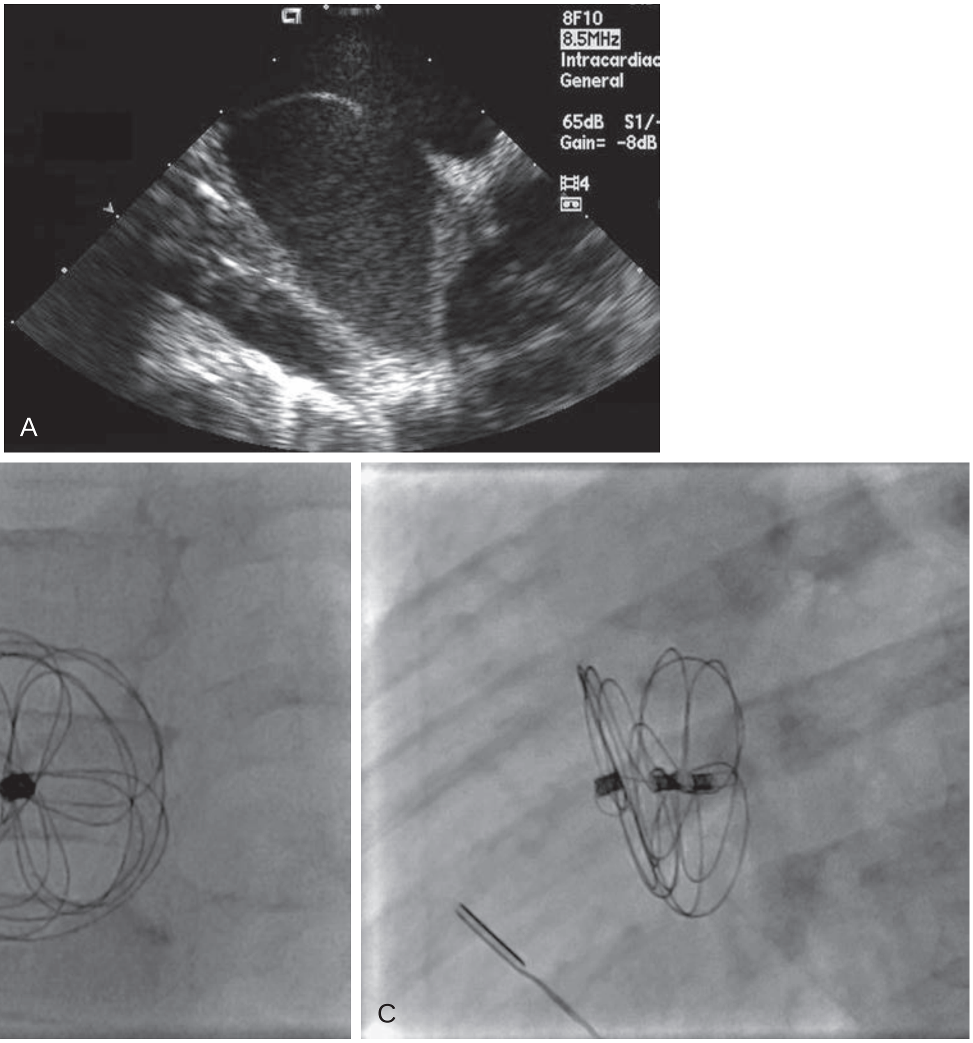
Percutaneous ASD closure has been established as a safe and effective alternative to operative repair. The technique involves transcatheter delivery of a device in its retracted state via the femoral vein under fluoroscopic and echocardiographic guidance. Echocardiographic guidance can be transthoracic in young children and transesophageal, intracardiac, or even 3D in older children and adults. The most commonly available devices today consist of a double-disc design made of nickel and titanium (Nitinol) with deployment of the first disc on the left atrial aspect of the septum followed by deployment of the second opposing disc on the right atrial wall. The expanded discs are tightly approximated, thus closing the defect. The device becomes endothelialized during the next 3 to 6 months while the patient is treated with antiplatelet medications. Relative contraindications include some defect diameters too large in relation to body weight; the absence of adequate septal tissue margins, especially the posterior inferior septum near the atrioventricular valves; and close proximity to vital cardiac structures.

The world experience of transcatheter ASD closure using the FDA-approved Amplatzer Septal Occluder (St. Jude Medical, St. Paul, MN) has been reported with a greater than 97% immediate success rate.[15] The occlusion rate reached 100% by 3 years. An overall 2.8% adverse event rate was found, and no procedural deaths occurred. Several studies regarding comparisons of device occlusion versus surgical closure have been performed prospectively. These reports include the Amplatzer (St. Jude Medical, St. Paul, MN) and Helex (W. L. Gore & Associates, Flagstaff, AZ) devices. Findings include shorter hospital stays, less discomfort, and shorter convalescence in patients undergoing successful device closure. Hospital costs are similar. Regression of right ventricular dilation was similar for both groups of patients; however, it was dependent on the patient's age at the time of closure, with greater regression after earlier intervention and before puberty. Most recently, the Gore Septal Occluder (GSO) device (W. L. Gore & Associates, Flagstaff, AZ) reached FDA approval and is routinely use to close ASD with diameters up to 17 to 18 mm (e-Fig. 68.5).[16]

Procedural adverse events are uncommon but include embolization into the right or left atrium, pulmonary artery, left ventricle, and aorta; stroke as a result of a clot or air embolization; and bleeding complications.[14] Both acute and late embolization have been reported, and thus it is critical for the radiologist to be familiar with the location of the interatrial septum on radiography to ascertain correct device position in the anteroposterior and lateral chest radiograph.

### Patent Ductus Arteriosus

The first transcatheter closure of a persistently patent ductus arteriosus (PDA) was performed by Portsmann in 1967. Since that time a number of different PDA closure devices have been studied, some of which



**e-Figure 68.5. Atrial septal defect.** (A) Intracardiac echocardiography (Biosense Webster, Diamond Bar, CA) from the right atrium demonstrates a secundum atrial septal defect in a 4-year-old child. (B) Anterior-posterior projection fluoroscopy demonstrates a well-positioned 30-mm Gore Septal Occluder device in a secundum atrial septal defect. (C) Lateral projection fluoroscopy demonstrates a well-positioned 30-mm Gore Septal Occluder device in a secundum atrial septal defect.

are no longer available. The goal of the procedure has always been to achieve 100% closure of the PDA without obstruction of either adjoining blood vessel (i.e., the aorta and the left pulmonary artery) with minimal risk of complications. The difficulty is that the PDA exhibits extreme variability in size and shape. Krichenko and colleagues[17] classified the PDA into five anatomic types based on the lateral aortic angiogram. The most common (type A) ductus is conical with a narrowed pulmonary arterial end and large aortic ampulla. Other types include those with a narrowed aortic end, narrowing at both ends, and a tubular configuration.

There has been great success since the first coil closure of a PDA in 1992. As expected, the recommended technique for coil embolization is variable, depending on the size and shape of the PDA. The vessel can be approached from the venous or arterial side, and the coils may be deployed "free hand" or secured with a bioptome or modified catheter. Smaller coils, such as the Flipper coil (Cook Medical, Bloomington, IN), are attached to a delivery system and are released once they are verified to be in the proper position.

A more recent addition to the interventional cardiologist's armamentarium for PDA closure is the Amplatzer Duct Occluder and the Amplatzer Duct Occluder II (St. Jude Medical, St. Paul, MN).[18] Both devices are self-expanding wire mesh devices attached to a delivery cable and deployed through a long sheath from the venous system (e-Fig. 68.6). The device has a retention skirt to occupy the aortic ampulla and tapers slightly to the pulmonary artery end. The device is filled with a polyester mesh that stimulates thrombus formation within the lumen of the PDA. The shape of the device and self-expanding properties exert radial force on the walls of the PDA, holding the device in place until endothelialization occurs. The device has excellent closure rates approaching 100% at 1 month after the procedure. The main limitation is the size and bulky nature of the device. The PDA must have an aortic ampulla adequate to accommodate the retention skirt without creating aortic obstruction. Furthermore, the device can create left pulmonary artery stenosis by compressing adjoining structures once it is released.

More recently, the Nit Occlude (pfm medical, Carlsbad, CA) reached FDA approval for PDA closure.[19] This device is deployed through a 4-Fr system making it a preferred technique in smaller children (e-Fig. 68.7).

### Other Abnormal Vessels

Accessory blood vessels are of concern for the interventional radiologist and interventional cardiologist. These accessory blood vessels may include aortopulmonary or venovenous collaterals, arteriovenous fistulae and malformations, surgically placed shunts, and transhepatic access tracts. Techniques for closure are similar to those described for the PDA, predominately involving Gianturco (Cook Medical, Bloomington, IN) and similar coils, the Amplatzer Duct Occluder (St. Jude Medical, St. Paul, MN), or the Amplatzer Vascular Plug (St. Jude Medical, St. Paul, MN). The vascular plug is similar to the duct occluder in that it is a self-expanding wire mesh design. It differs in that it is cylindrical in shape with no retention skirt, no tapering through its length, and no polyester mesh interior fabric. The device has excellent occlusion results but has been unsuccessful in short arterial vessels, such as aortopulmonary collaterals and the PDA. It is thought that the lack of occlusive material through the center of the device does not provide enough restriction to arterial blood flow to stimulate thrombosis and occlude the vessel.

## PEDIATRIC ELECTROPHYSIOLOGY

### Introduction

With regard to imaging, the clinical practices of the pediatric radiologist and pediatric electrophysiologist intersect in two ways: Both subspecialists are interested in detailed internal anatomy, and both subspecialties have evolved toward performing therapeutic procedures. In particular, advances in imaging have helped improve outcomes of catheter ablation for nearly every tachyarrhythmia.

This section is divided into two parts: (1) items of interest to the radiologist pertaining to activities in the electrophysiology laboratory, especially newer imaging technologies to guide catheter ablation and radiation exposure risks during catheter ablation; and (2) cardiac rhythm device therapy and special concerns in the radiology department.

### Catheter Ablation in Children

#### History and Indications

Curative therapies for pathologic tachyarrhythmias began with open-chest surgery for Wolff–Parkinson–White syndrome in 1968 followed by transvascular catheter delivery of alternating current in the radiofrequency range (about 550 kHz) in 1987 in adults[20] and in 1994 in children[21] for common forms of supraventricular tachycardia (SVT). The importance of complex electroanatomic correlation within the cardiac chamber walls was first applied to atrial and ventricular tachycardias post–congenital heart surgery in the late 1990s[22] and in adults having paroxysmal atrial fibrillation starting with the seminal discovery by Haissaguerre in 1998 that repetitive pulmonary vein discharges are its source.[23] Since 2000, technical advances in catheter design have enabled the creation of larger lesions—necessary for transmural arrhythmia substrates—and have brought about the use of cryoenergy, with its greater safety profile when substrates are proximate to vital structures such as the coronary arteries and atrioventricular node. Owing to improved outcomes and safety profiles, almost no tachyarrhythmia substrate is now considered exempt from catheter ablation. Accordingly, current indications to perform catheter ablation in children and after congenital heart surgery are more liberal[24] (e-Box 68.1) compared with those from 2002.[25]

#### Technical Considerations

The guiding principle of electrophysiologic testing and catheter ablation involves coupling of anatomic structures to electrical phenomena. As a result of improvements in electroanatomic mapping systems, the anatomic shell of the structurally normal heart may now be accurately created with minimal or no fluoroscopy.[26,27] In patients with normal cardiac anatomy and SVT, multielectrode catheters are typically positioned in the right ventricle, right atrium, coronary sinus, and His bundle region of the tricuspid valve annulus, with one for mapping and ablation (e-Fig. 68.8). These anatomic sites are accessed from a combination of femoral, internal jugular, and subclavian venous approaches. However, in some patients with complex congenital cardiovascular anomalies (e.g., interrupted inferior vena cava in some patients with heterotaxy), in those whose surgical procedure segregated the systemic venous return from the heart (e.g., cavopulmonary connection or extracardiac conduit in patients having single ventricle physiology), and in those who have lost venous access due to multiple prior procedures, some or all of these venous sites will not allow access to the heart. In these instances, alternate approaches may include transhepatic venous,[28] transthoracic,[29] or transbaffle.[30] Furthermore, occasional arrhythmia substrates are primarily epicardial, requiring transpericardial access. Transthoracic or intracardiac echocardiography[31] may aid in understanding anatomic details and in the positioning of catheters.

Electroanatomic mapping systems currently use a combination of magnetic field–based and impedance-based technologies to derive accurate 3D reconstructions of the cardiac chambers and associated structures. Simultaneous acquisition of local electrical signals provides a rapid display of tachycardia substrates in real

## e-BOX 68.1 Indications for Ablation Procedures in Pediatric and Adolescent Patients

### INDICATIONS FOR ABLATION PROCEDURES IN PEDIATRIC PATIENTS WITH NARROW-COMPLEX SVT (AVNRT/AVRT/AET/NAFAT/ATRIAL FLUTTER) WITHOUT CONGENITAL HEART DISEASE

**Class I**

1. Ablation is recommended for documented SVT, recurrent or persistent, associated with ventricular dysfunction in larger* patients (LOE: C).
2. Ablation is recommended for documented SVT, recurrent or persistent, when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used before ablation depends on patient size)† (LOE: C).
3. Ablation is recommended for documented SVT, recurrent or persistent, when the family wishes to avoid chronic antiarrhythmic medications in larger* patients (LOE: C).
4. Ablation is recommended for recurrent acute hemodynamic compromise (hypotension or syncope) from SVT in larger* patients (level of evidence [LOE]: E).
5. Ablation is effective for recurrent SVT requiring emergency medical care or electrical cardioversion for termination in larger* patients (LOE: C).

**Class IIa Ablation Can Be Useful for the Following:**

1. Recurrent clinical symptoms clearly consistent with paroxysmal SVT in larger* patients, and one of the following: evidence for involvement of an atrioventricular (AV) accessory pathway; inducible SVT (LOE: C).
2. Slow pathway modification in larger* patients with a history of documented SVT, when SVT is not inducible at electrophysiologic testing but evidence for dual AV nodal physiology with or without single AV nodal echos is demonstrated (LOE: C). Cryotherapy should be considered for slow pathway modification (LOE: B).

**Class IIb Ablation May Be Reasonable for the Following:**

1. Slow pathway modification in larger* patients with clinical symptoms clearly consistent with paroxysmal SVT but not documented, when SVT is not inducible at electrophysiologic testing but evidence for dual AV nodal physiology with or without single AV nodal echos is demonstrated (LOE: C). Cryotherapy should be considered for slow pathway modification (LOE: B).
2. Recurrent clinical symptoms clearly consistent with paroxysmal SVT in smaller* patients, and one of the following at electrophysiology study: evidence for involvement of an AV accessory pathway; inducible SVT (LOE: C). Medical therapy should be considered before ablation (LOE: C). Cryotherapy should be considered for slow pathway modification (LOE: B).
3. Recurrent acute hemodynamic compromise (hypotension or syncope) from SVT in smaller* patients (LOE: C).
4. Intermittent symptomatic SVT that is nonsustained (<30 seconds) in larger* patients (LOE: C).

### INDICATIONS FOR ABLATION PROCEDURES IN PEDIATRIC PATIENTS WITH INAPPROPRIATE SINUS TACHYCARDIA

**Class IIb Ablation May Rarely Be Reasonable for the Following:**

1. Inappropriate sinus tachycardia when autonomic causes such as postural orthostatic tachycardia syndrome have been ruled out, and medical therapy is either not effective or is associated with intolerable side effects (LOE: C).

### INDICATIONS FOR ABLATION PROCEDURES IN PEDIATRIC PATIENTS WITH WPW PATTERN (SEE SVT INDICATIONS FOR PATIENTS WITH WPW PATTERN AND AVRT; SEE CHD INDICATIONS FOR PATIENTS WITH WPW AND CHD)

Predictors of high risk for cardiac arrest in WPW pattern include the following:

- A shortest preexcited RR interval during atrial fibrillation, or during incremental atrial pacing ≤250 msec
- Multiple accessory pathways

**Class I Ablation Is Recommended for the Following:**

1. WPW pattern after resuscitated cardiac arrest (LOE: B).
2. WPW pattern with syncope when there are predictors of high risk for cardiac arrest (LOE: B).

**Class IIa Ablation Can Be Useful for the Following:**

1. WPW pattern with ventricular dysfunction presumed due to dyssynchrony in larger* patients, or when medical therapy is either not effective or is associated with intolerable side effects† in smaller* patients (LOE: B). (Note: This indication was Class IIb in the prior guidelines for asymptomatic WPW.)
2. WPW pattern without symptoms, when there are predictors of high risk for cardiac arrest in larger patients* (LOE: C).
3. WPW pattern with syncope, without predictors* of high risk for cardiac arrest in larger* patients (LOE: C).
4. WPW pattern without symptoms in larger* patients when the absence of WPW pattern is a prerequisite for participation in personal or professional activities (LOE: E).

**Class IIb Ablation May Be Reasonable for the Following:**

1. WPW pattern without symptoms in larger* patients with predictors of low risk for cardiac arrest, as patient/family choice (LOE: E).

### INDICATIONS FOR ABLATION PROCEDURES IN ADOLESCENT PATIENTS WITH ATRIAL FIBRILLATION (AF), WITH OR WITHOUT CHD

**Class I**

None

**Class IIa Ablation Can Be Useful For the Following:**

1. An SVT substrate identified as the initiating event for AF, using either ambulatory ECG monitoring or invasive electrophysiologic evaluation. It is reasonable to ablate possible provocative SVT substrates, including a single ectopic focus within a larger pulmonary vein, or isolation of a single pulmonary vein orifice for an ectopic focus/foci initiating AF (LOE: C).

**Class IIb Ablation May Rarely Be Considered for the Following:**

1. Empiric wide area circumferential isolation of all pulmonary veins in the absence of a documented triggering focus or arrhythmia, as is performed in adults with paroxysmal AF, in adolescent pediatric patients when AF is recurrent; requires repeated DC cardioversion; and medical therapy is either not effective or is associated with intolerable side effects.† The procedure should be undertaken by or with the direct assistance of a clinician experienced in the technique (LOE: C).

### INDICATIONS FOR ABLATION PROCEDURES IN PEDIATRIC PATIENTS WITH JUNCTIONAL ECTOPIC TACHYCARDIA (JET)

**Class I**

1. Ablation is recommended for persistent or recurrent idiopathic JET, or congenital JET associated with ventricular dysfunction, when medical therapy is either not effective or is associated with intolerable side effects† (LOE: C).

## e-BOX 68.1 Indications for Ablation Procedures in Pediatric and Adolescent Patients—cont'd

2. When ablation of JET is being performed, cryotherapy is the preferred first choice due to the high risk of AV block. Radiofrequency energy should be used with extreme caution, after a detailed discussion with the family/patient concerning the high risk of AV block and potential need for permanent pacing (LOE: C).

**Class IIa Ablation Can Be Useful for the Following:**

1. Persistent or symptomatic recurrent idiopathic JET, or congenital JET in larger* patients, when medical therapy is either not effective or is associated with intolerable side effects† (LOE: C).

**Class IIb Ablation May Be Reasonable for the Following:**

1. Persistent or symptomatic recurrent idiopathic JET, or congenital JET in larger* patients, as an alternative to chronic antiarrhythmic therapy that has been effectively controlling the arrhythmia (LOE: C).
2. Persistent or symptomatic recurrent idiopathic JET, or congenital JET in smaller* patients, when medical therapy is either not effective or is associated with intolerable side effects† (LOE: C).

### INDICATIONS FOR ABLATION PROCEDURES IN PEDIATRIC PATIENTS WITH VENTRICULAR ARRHYTHMIAS WITHOUT CONGENITAL HEART DISEASE

**Class I**

1. Ablation is recommended for frequently ventricular ectopy or tachycardia, predominantly from a single focus, thought to be causing ventricular dysfunction, when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used depends on patient size†), or as an alternative to medical therapy in larger* patients (LOE: C).
2. Ablation is effective for recurrent or persistent symptomatic intrafascicular verapamil-sensitive reentrant VT, idiopathic outflow tract VT, or VT with hemodynamic compromise, when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used depends on patient size†), or as an alternative to medical therapy in larger* patients (LOE: C). (Notes: Additional consideration should be used for tachycardia origins in proximity to a coronary artery, e.g., aortic sinus; outflow tract VT was a Class IIa indication in the prior pediatric guidelines for ventricular arrhythmias.)

**Class IIa Ablation Can Be Useful for the Following:**

1. Frequent ventricular ectopy with correlated symptoms in larger* patients (LOE: C).

**Class IIb Ablation May Be Reasonable for the Following:**

1. Accelerated idioventricular rhythm with correlated symptoms in larger* patients (LOE: C). (Note: This indication was Class IIa in the prior pediatric guidelines for ventricular arrhythmias.)
2. Recurrent/frequent polymorphic ventricular arrhythmia when there is a suspected triggering focus, arrhythmia, or substrate that can be targeted (LOE: C).

### INDICATIONS FOR ABLATION PROCEDURES IN PATIENTS WITH CONGENITAL HEART DISEASE

**Class I**

1. Ablation is recommended for recurrent or persistent SVT related to accessory AV connections or twin AV nodes in CHD patients, when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used depends on patient size†), or as an alternative to medical therapy, in larger* patients (LOE: B).
2. Ablation is effective for patients with WPW pattern and high-risk or multiple accessory pathways, as commonly encountered in Ebstein's anomaly, in larger* patients with CHD (LOE: C).
3. Ablation is effective for recurrent symptomatic atrial tachycardia in patients with CHD presenting outside the early postoperative phase (>3–6 months), when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used depends on patient size†), or as an alternative to medical therapy in larger* patients (LOE: B).
4. Ablation is recommended for adjunctive therapy to an ICD in patients with CHD and recurrent monomorphic VT, a VT storm, or multiple appropriate shocks that are not manageable by device reprogramming or drug therapy (LOE: C).

**Class IIa Ablation Can Be Useful for the Following:**

1. Sustained monomorphic VT in patients with CHD causing symptoms or hypotension, when medical therapy is either not effective or is associated with intolerable side effects (medical therapy used depends on patient size†), or as an alternative to medical therapy in larger* patients. The decision whether or not to have an ICD as adjunctive therapy should follow the ACHD guidelines (LOE: B).
2. Recurrent or persistent AVNRT, when medical therapy is either not effective or is associated with intolerable side effects in larger* patients with moderate or complex CHD (mild CHD can be managed as narrow [usual] complex SVT) (LOE: C).
3. Substrates that have a reasonable likelihood of contributing to tachyarrhythmias in the postoperative period, in the absence of other indications, when impending congenital heart surgery will result in restriction of vascular or chamber access following surgery (LOE: C).
4. Substrates that have a reasonable likelihood of contributing to tachyarrhythmias in the postoperative period, in the absence of other indications in larger* patients with Ebstein's anomaly before anticipated cardiac surgery (LOE: C). (Note: This was a Class IIb indication in the prior ACHD guidelines.)
5. Recurrent asymptomatic atrial tachycardia presenting outside the early postoperative phase (>3–6 months), in larger* patients with CHD who are at increased risk of thromboembolic events or worsening heart failure, or in smaller* patients when medical therapy is either not effective or is associated with intolerable side effects (LOE: C).
6. Frequent ventricular ectopy, predominantly from a single focus, thought to be contributing to deteriorating ventricular function in larger* patients with CHD, or in smaller* patients when medical therapy is either not effective or is associated with intolerable side effects (LOE: C). (Note: This was a Class IIb indication in the prior ACHD guidelines.)

**Class IIb Ablation May Be Reasonable for the Following:**

1. SVT with acute hemodynamic compromise in smaller* patients with CHD (LOE: E).
2. Creation of complete AV block with permanent pacing in patients with atrial tachyarrhythmias refractory to all medications and substrate targeted catheter ablation, who are not candidates for surgical therapy (LOE: B).

### INDICATIONS FOR CATHETER ABLATION IN SMALLER CHILDREN*

**Class I Ablation is Recommended for the Following:**

1. Documented SVT, recurrent or persistent, when medical therapy is either not effective or is associated with intolerable side effects (LOE: C).

Continued

### e-BOX 68.1 Indications for Ablation Procedures in Pediatric and Adolescent Patients—cont'd

2. WPW pattern after resuscitated cardiac arrest (LOE: B).
3. WPW pattern with syncope when there are predictors of high risk for cardiac arrest (LOE: B).
4. Persistent or recurrent idiopathic JET, or congenital JET associated with ventricular dysfunction, when medical therapy is either not effective or is associated with intolerable side effects† (LOE: C).

When ablation of JET is being performed, cryotherapy is the preferred first choice due to the high risk of AV block. Radiofrequency energy should be used with extreme caution, after a detailed discussion with the family/patient concerning the high risk of AV block and potential need for permanent pacing (LOE: C).

5. Ventricular ectopy or tachycardia with ventricular dysfunction, when medical therapy is either not effective or is associated with intolerable side effects (LOE: C).
6. Recurrent or persistent SVT related to accessory AV connections or twin AV nodes in patients with CHD, when medical therapy is either not effective or is associated with intolerable side effects (LOE B).
7. Ablation is effective for recurrent symptomatic atrial tachycardia presenting outside the early postoperative phase (>3–6 months) in patients with CHD, when medical therapy is either not effective or is associated with intolerable side effects (LOE B).
8. Pediatric cardiovascular surgical support should be available in-house during ablation procedures for smaller patients* (LOE: E).

**Class IIa Ablation Can Be Useful for the Following:**

1. WPW pattern with ventricular dysfunction presumed due to dyssynchrony when medical therapy is either not effective or is associated with intolerable side effects† (LOE: B).
2. Recurrent sustained monomorphic VT causing symptoms or hypotension despite antiarrhythmic drug therapy in patients with CHD (LOE: B).
3. Recurrent asymptomatic atrial tachycardia presenting outside the early postoperative phase (>3–6 months), in patients with CHD who are at increased risk of thromboembolic events or worsening heart failure, when medical therapy is either not effective or is associated with intolerable side effects (LOE: C).
4. Substrates that have a reasonable likelihood of contributing to tachyarrhythmias in the postoperative period in the absence of other indications, when impending congenital heart surgery will result in restriction of vascular or chamber access after surgery (LOE: C).
5. Frequent ventricular ectopy thought to be contributing to deteriorating ventricular function in patients with CHD, when medical therapy is either not effective or is associated with intolerable side effects (LOE: C).

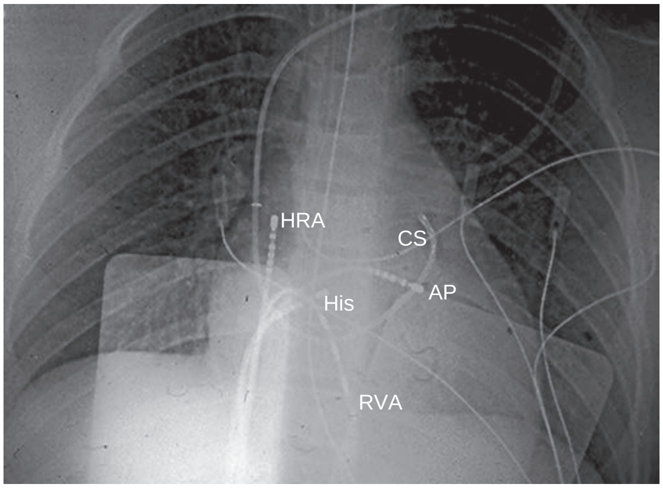
**Class IIb**

1. Recurrent clinical symptoms clearly consistent with paroxysmal SVT, and one of the following at electrophysiology study: evidence for involvement of an AV accessory pathway; inducible SVT (LOE: C). Medical therapy should be considered before ablation (LOE: C). Cryotherapy should be considered for slow pathway modification (LOE: B).
2. When ablation is indicated, cryoablation can be useful to avoid the higher risks of complications with RF ablation (LOE: C).
3. Recurrent acute hemodynamic compromise (hypotension or syncope) from SVT (LOE: C).
4. Persistent or symptomatic recurrent idiopathic JET, or congenital JET, when medical therapy is either not effective or is associated with intolerable side effects† (LOE: C).
5. Polymorphic ventricular arrhythmia when there is a suspected triggering focus, arrhythmia, or substrate that can be targeted (LOE: C).
6. Creation of complete AV block with permanent pacing in patients with atrial tachyarrhythmias refractory to all medications and substrate targeted catheter ablation, who are not candidates for surgical therapy (LOE: B).

---

*In general, smaller patients are less than approximately 15 kg, and larger patients are greater than approximately 15 kg.

†The precise definition of "medical therapy that is either not effective or is associated with intolerable side effects" is left up to the practitioner and family to decide. However, in general, the threshold for ineffectiveness and intolerability should be higher in smaller patients. For example, failure or intolerability of a beta-blocker alone might be adequate in the larger patient, but not in the smaller patient, unless there were additional circumstances. In the smallest patients, failure or intolerability of drug combinations from multiple classes, including membrane-stabilizing agents, with adequate loading time, would be required before the decision for ablation.



**e-Figure 68.8. Electrophysiology testing.** Anterior-posterior projection of a chest fluorograph during a radiofrequency catheter ablation procedure in a teenager with Wolff–Parkinson–White syndrome and a left lateral accessory pathway. Standard multipole electrode catheters are positioned in the high right atrium *(HRA),* across the tricuspid valve in the His bundle region *(His),* in the right ventricular apex *(RVA),* in the coronary sinus *(CS),* and at the mapped location of the accessory pathway *(AP)* along the mitral valve.

time. Isochronal activation maps, isopotential (voltage) maps, and customized rendering of derived electrophysiologic features are afforded by these systems.

The CARTO system (Biosense Webster, Diamond Bar, CA) was originally only a magnetic field–based system, wherein a low-energy, triple-source transmitter located on a position pad mounted beneath the patient identified the receiver, which was mounted in the tip of the specialized mapping/ablation catheter using a global positioning system technology (e-Fig. 68.9). This system was handicapped by the necessity that only proprietary catheters be used. The Ensite system (St. Jude Medical, St. Paul, MN) was originally only an impedance-based system, wherein three pairs of skin surface patches served as low-energy transmitters in the x-y-z axes. Using continuous impedance measurements, the electrodes from any nonproprietary electrode catheters were the receivers. This system suffered from impedance drift, with spatial inaccuracies introduced by long procedure durations and changes in chest and lung water. Both systems have adopted technologies from the other, and both now use both magnetic field– and impedance-based features. These companies have also evolved catheter designs that enable simultaneous acquisition of multiple endocardial sites. Finally, both of these systems have the capacity to merge previously obtained CT or MRI scans of the patient's heart chambers with the real-time anatomic renderings.

This technology has been of greatest value in the mapping and ablation of atrial or ventricular muscle reentrant tachycardias whose substrates are within the wall of a chamber and are defined by areas of slow conduction related to scar or structural conduction boundaries, such as venous ostia or valve annuli. Nonreentrant tachycardias are mapped and ablated by identifying sites of earliest activation.

## Radiation Exposure

As electroanatomic mapping system technology has become the workhorse for electrophysiologic procedures, fluoroscopy has taken on an adjunctive role. In published series of children undergoing these procedures, fluoroscopy duration fell from 61.5 minutes in 1994 to 38.3 minutes in 2004.[32] In the modern era, groups using either the CARTO or Ensite systems now report mean fluoroscopy times less than 5 minutes and total absorbed radiation doses less than 60 mGy.[26,27] Complete elimination of fluoroscopy has been reported for 31% to 54% of cases.[26,27] When fluoroscopy is necessary, adherence to the ALARA (As Low As Reasonably Achievable) principle is paramount. Most operators limit x-ray exposure by reducing frame rates to 15 and even 7.5 frames/sec and by minimizing the use of magnification.

Data on actual x-ray exposure during catheter ablation procedures comes largely from adult series, in which thermoluminescent dosimeters and/or anthropomorphic radiologic phantoms were used.[33-37] Considering fluoroscopy times ranging from 41 to 60 minutes, a single procedure has been estimated to carry a risk of fatal malignancy in 0.03% to 0.13% of individuals and to result in birth defects in 0.00012%.[34,35,37] These figures are approximately equivalent to 1% and 0.1% of the spontaneous incidences, respectively. Geise and colleagues[38] reported that radiation doses to exposed skin were 6.2 to 49 mGy/min in nine children, which calculated to total doses of 0.09 to 2.35 Gy.

# DEVICE THERAPY IN CHILDREN

## Fundamentals of Pacing Hardware

Bradycardia devices (i.e., pacemakers) and antitachycardia devices (i.e., implantable cardioverter-defibrillators [ICDs]) require two basic hardware components, the pulse generator and conductors (primarily, "leads"). The pulse generator consists of an energy source (battery), microcircuitry, titanium alloy housing, and a plastic connector block for conductor attachment. In addition, the ICD contains capacitors to store deliverable energy. The lead consists of one (unipolar) or two (bipolar) wires, a nonconducting insulation, one or more connector pins that insert into the pulse generator connector block, and a fixation end that attaches to myocardium (via a tiny screw, fish hook, plaque, or other device). Transvenous bipolar leads generally have a radiodense distal electrode and a slightly more proximal "ring" electrode, whereas the unipolar lead has only a distal electrode. Epicardial leads are mostly unipolar, but bifurcated plaque electrodes and in-line bipolar leads also exist. In addition, the ventricular lead for an ICD may have one or two additional insulated conductors that are exposed on the outer surface of the lead (so-called coils) and participate in the shock field. Arrays and patches may be necessary to optimize cardioversion or defibrillation and are inserted in subcutaneous or intrapericardial sites. Figs. 68.10 and 68.11 illustrate the radiographic appearance of this hardware. Entirely subcutaneous cardioverter-defibrillators are now available for larger patients (at least 40 kg) not requiring bradycardia pacing (e-Fig. 68.12), and transvenous leadless pacemakers are being inserted into older adults requiring only ventricular bradycardia pacing.

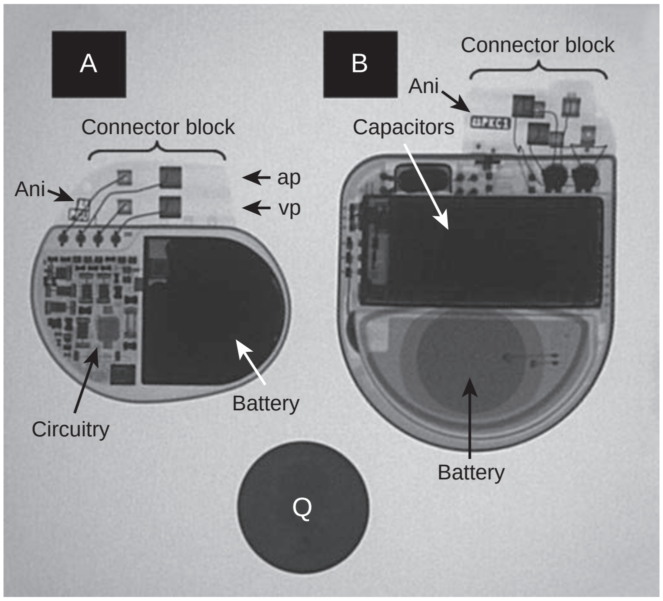


**Figure 68.10. Pacemaker components.** (A) Fluoroscopic image of a modern dual-chamber pacemaker and implantable cardioverter-defibrillator. (B) *Ani,* Alphanumeric identifier; *ap,* atrial port (the portion of the connector block that accepts the connector pin of the atrial lead); *Q,* quarter (for size comparison); *vp,* ventricular port (the portion of the connector block that accepts the connector pin of the ventricular lead).

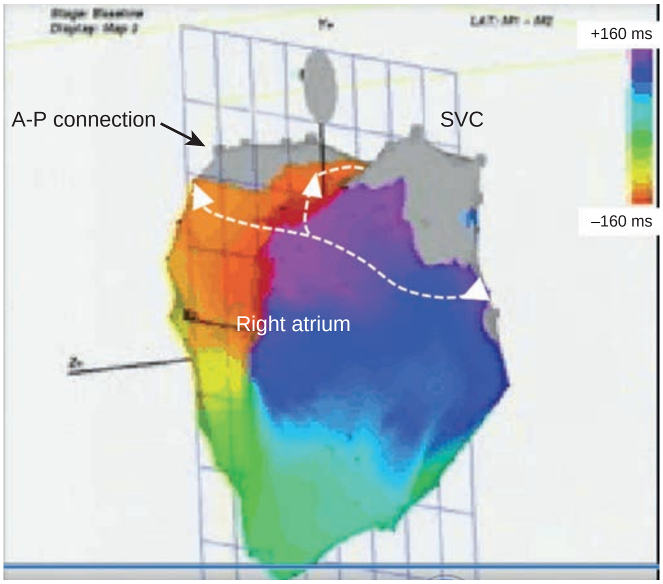
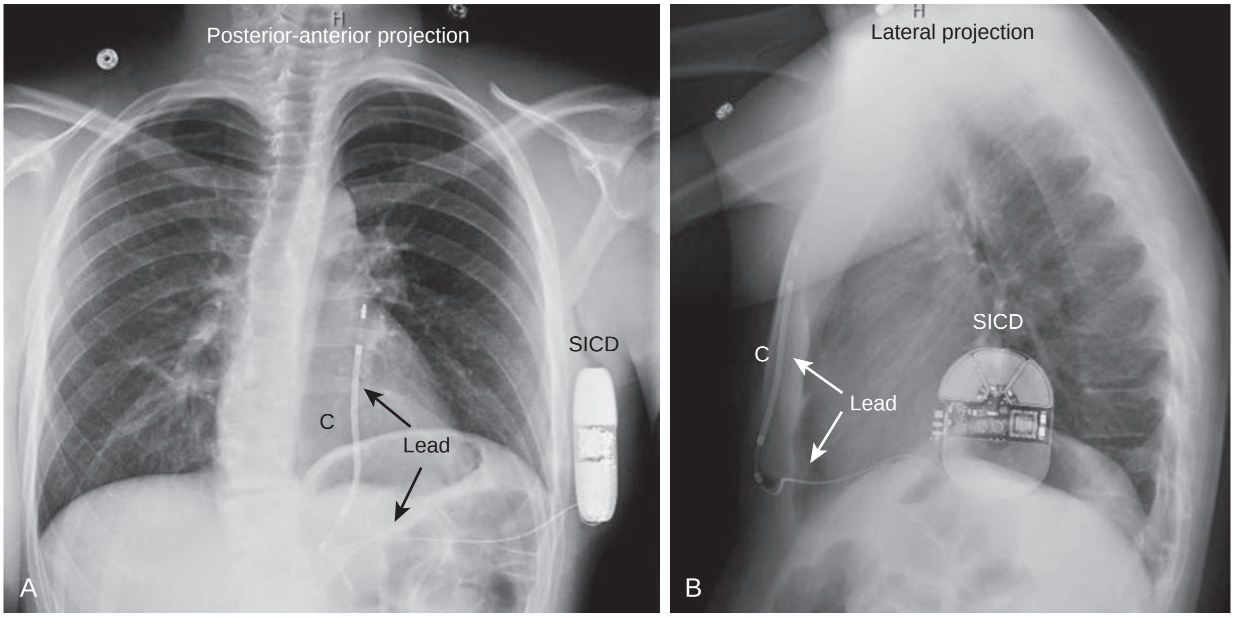
## Radiography of Pacing Systems

The radiologist will be called on to interpret radiographs from children with devices immediately after device implantation, during routine follow-up, and when component failure is suspected.

A systematic approach will enable the radiologist to interpret the appearance of the hardware. The first step is to identify the location of the pulse generator. When the device is infraclavicular, the conductors usually are transvenous. Epicardial leads are generally tunneled to a subcutaneous abdominal device, but subcostal and flank locations (especially in premature infants) also may be used. Hybrid systems use a combination of transvenous, epicardial, and/or subcutaneous conductors, configured to accommodate restricted venous access, and/or a preexisting lead that is considered valuable, and/or an optimized shock vector in the case of ICDs. The pulse generator will be positioned in a location optimal to



**e-Figure 68.9. Electrophysiology mapping.** Left posterior oblique projection of an electroanatomic map of the right atrium following atriopulmonary-style Fontan operation in a 34-year-old man who was born with tricuspid atresia. This is an isochronal depiction of atrial flutter in which slow conduction is identified by color-coded local activation timing (*broken line* and *arrowheads*) defined by endocardial electrograms that were obtained by point-to-point contact registration using the CARTO system. Areas of scar are *gray*. *A-P,* Atriopulmonary connection; *SVC,* superior vena cava.



**e-Figure 68.12.** Posterior-anterior and lateral chest radiographs from a 17-year-old boy who suffered idiopathic ventricular fibrillation during cross-country competition. Visualized is a completely subcutaneous implantable cardioverter-defibrillator *(SICD)* and lead. The shock coil *(C)* is parasternal, and the device is slightly posterior to straight lateral. Precise location of all hardware is paramount.

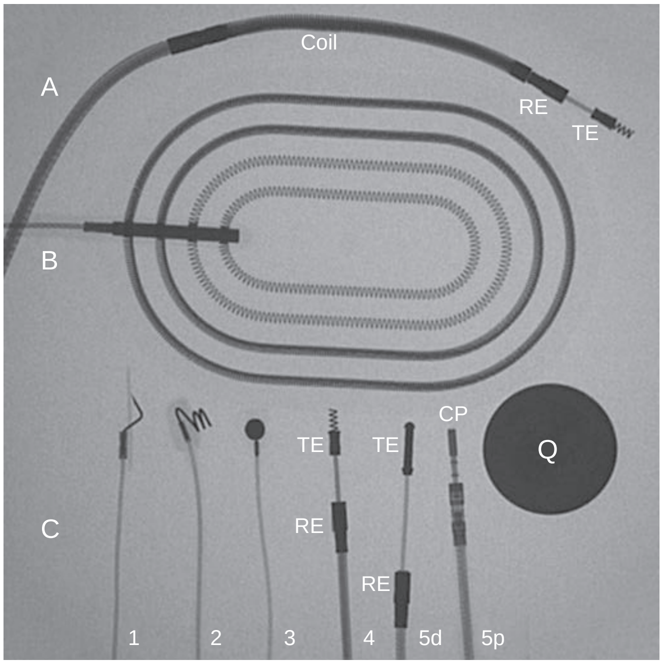


**Figure 68.11. Fluoroscopic images of several types of conductors used for cardiac device therapy in children and teenagers.** (A) A transvenous, active fixation, bipolar, ventricular lead used with implantable cardioverter-defibrillators (ICDs) and containing a coil for participation in shock delivery. (B) A patch, which is placed in the subcutaneous location, and is used with ICDs for participation in shock delivery. (C) A variety of leads used with either pacemakers or ICDs. *1,* The distal (cardiac) end of a unipolar, epicardial active fixation (stab-on or fish hook) lead. *2,* The distal end of a unipolar, epicardial active fixation (screw-in) lead. *3,* The distal end of a unipolar, epicardial passive fixation (plaque, suture-on) lead. *4,* The distal end of a bipolar, transvenous active fixation lead (with a retractable screw). *5d* and *5p* illustrate the distal (cardiac) and proximal (connector block of pacemaker) ends of a bipolar, passive fixation lead, respectively. *CP,* Connector pin; *Q,* quarter (for size comparison); *RE,* ring electrode; *S,* screw; *TE,* tip electrode.

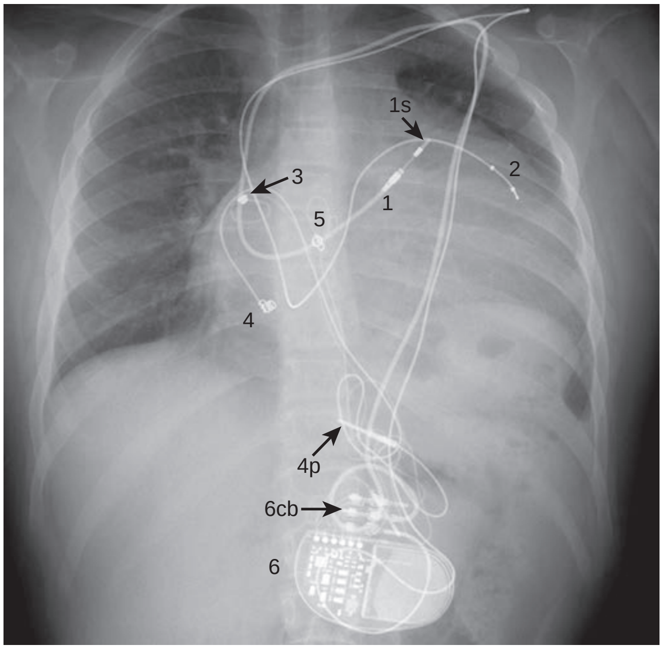

**Figure 68.13.** Posterior-anterior chest radiograph from an 11-year-old girl who underwent repair of an atrioventricular septal defect and who has postoperative heart block, severe mitral regurgitation, and left ventricular dysfunction. *1,* A transvenous, bipolar, active fixation (*1s,* screw) lead positioned in the right ventricular outflow tract. *2,* A transvenous, bipolar, passive fixation lead positioned in the posterolateral cardiac vein via the coronary sinus for the purpose of synchronizing ventricular activation. *3,* An epicardial, unipolar, passive fixation (plaque electrode) lead positioned on the right atrium. *4,* An epicardial, unipolar, active fixation (screw-in) lead positioned on the right atrium, abandoned, with the proximal end (*4p,* connector pin) in the abdominal pacemaker pocket. *5,* An epicardial, unipolar screw fragment positioned on the right ventricle. *6,* Pacemaker (*6cb,* pacemaker connector block).

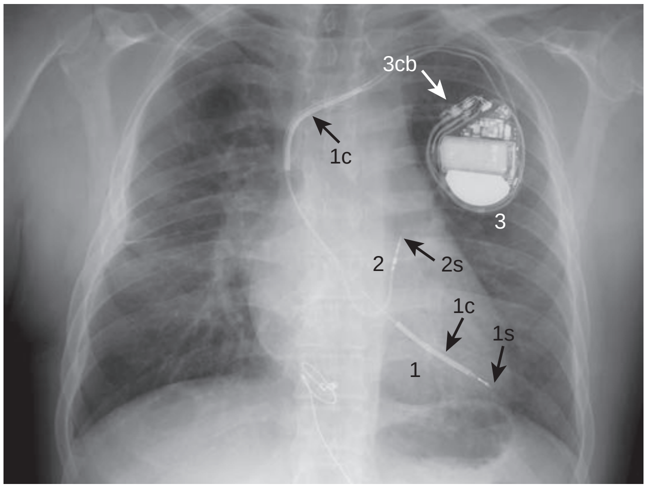
the complex configuration of the conductors. The second step is to describe each conductor, including the type (e.g., lead, lead with coils, array, or patch), its course from the pulse generator to the heart or other thoracic site, its form of attachment to the heart in the case of leads, and whether the lead is unipolar or bipolar. Magnification of the lead tip may be required. The third step is to correlate the congenital and surgical anatomy with lead locations and courses. Understanding the appropriateness of the course of each lead often requires some knowledge of the surgical anatomy. Figs. 68.13 and 68.14 and e-Fig. 68.15 illustrate the radiographic appearance of patients who have complex cardiac device therapy. Finally, leads attached to both right and left ventricles suggest an attempt at ventricular resynchronization as a result of ventricular dysfunction. The left ventricular lead may be transvenous to the cardiac venous system or epicardial surface of the heart.

In children undergoing chronic device therapy, symptoms suggestive of device malfunction may develop, such as syncope, skeletal muscle twitching, hiccoughs, new onset of fatigue, palpitations, and, in the case of ICDs, inappropriate shocks. Radiographic abnormalities that may suggest the etiology include lead conduction fracture, lead dislodgement (especially if symptoms occur soon after implantation), lead stretch as a result of somatic growth, and connector pin separation from pulse generator. Transvenous leads usually fracture beneath the clavicle, but epicardial leads may fracture anywhere along their length. A caveat: The Medtronic model 4968 (Medtronic, Minneapolis, MN) bifurcated, epicardial, double-plaque lead always has the appearance of near-fracture at the union of the two conductors (Fig. 68.16). Finally, the radiologist may be called on to identify the type of implanted device (i.e., the manufacturer and model number) that is in a patient. Each pulse generator has a radiodense alphanumeric identifier (often its model number) that can be referenced in any of the major companies' device encyclopedias (see Fig. 68.10).

## Caring for Children With Devices While in the Radiology Department

Cardiac devices became interactive with the first inclusion of demand circuitry, which was developed in 1965 to allow sensing of intrinsic electrical activity. We now communicate with these devices for purposes of reprogramming, functional testing, and telemetry using a computerized programmer and radiofrequency signals. Despite various forms of protective shielding and electronic filters, all devices may be affected by certain sources of electromagnetic interference (EMI) that may be present in the radiology department. It should be emphasized that ionizing radiation used for diagnostic procedures usually is not a source of EMI. High-dose x-rays during CT, only when applied directly to the device, can rarely result in oversensing.[39] This effect theoretically can inhibit a device, resulting in loss of output. However, the effect is transient and reverses as the beam moves away from the devices.



**e-Figure 68.15.** A posterior-anterior chest radiograph from a 19-year-old who had a Senning operation for d-transposition of the great arteries, sinus node dysfunction, and a history of ventricular tachycardia. *1,* A transvenous, active fixation lead that is attached to the left ventricular apex (systemic venous ventricle) by a retractable screw *(1s).* The lead contains two coils *(1c)* that will participate in possible shock delivery. *2,* A transvenous, bipolar, active fixation lead that is attached to the roof of the left atrium (systemic venous atrium) by a retractable screw *(2s).* *3,* An implantable cardioverter-defibrillator (ICD) (*3cb,* ICD connector block).

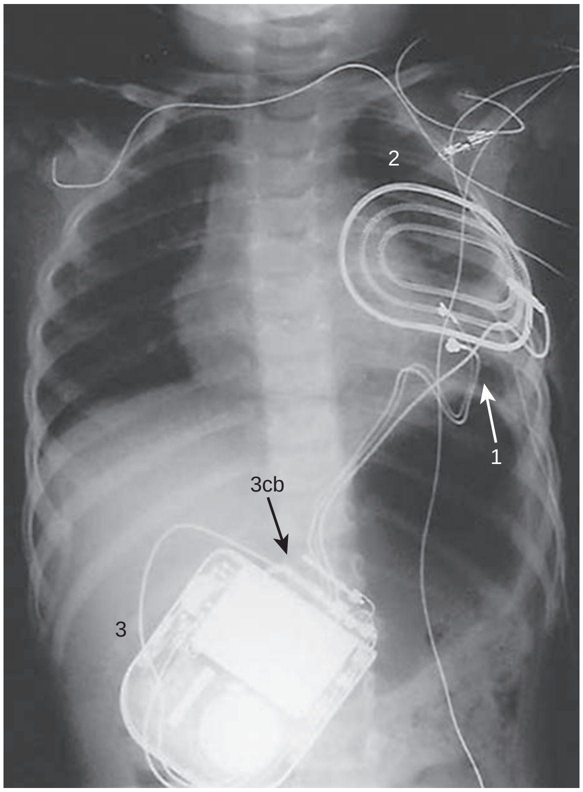


**Figure 68.14.** A posterior-anterior chest radiograph from a 3-month-old male infant with ventricular tachycardia associated with Brugada syndrome. *1,* An epicardial, bifurcated (hence, bipolar), passive fixation (plaque electrodes) lead positioned on the left ventricle for purposes of ventricular pacing and sensing. *2,* A patch placed posteriorly and in a subcutaneous location for participation in possible shock delivery. *3,* An implantable cardioverter-defibrillator (ICD) in a subcutaneous pocket over the left abdomen (*3cb,* ICD connector block).

Repeated high-dose radiation therapy may damage the silicone and silicone oxide insulation necessary for the complementary metal oxide semiconductor chip technology of cardiac devices. Device manufacturers have provided guidelines to minimize risk of damage to ICDs resulting from radiotherapy.[40] Occasionally, the device may even have to be repositioned away from the treatment field. EMI-device interactions may result from MRI, defibrillation, electrocautery, peripheral nerve stimulation, transcutaneous electrical nerve stimulation, diathermy, radiofrequency ablation, and lithotripsy. Untoward responses by the device may include oversensing, noise reversion, power-on reset, permanent circuit failure, and damage to the lead-tissue interface, causing a permanent rise in the stimulation threshold. A glossary of these terms appears in e-Box 68.2. Some of these potentially harmful medical procedures, specific responses to EMI, and ways to prevent these responses appear in e-Table 68.1.[41] For older devices, MRI theoretically may cause device malfunction as a result of static magnetic, gradient, and radiofrequency fields and may cause tissue heating at the conductor-cardiac interface. MRI conditional devices and conductors are now available from all of the major manufacturers for up to 1.5-T field strength.

## SUMMARY

Cardiac catheterization for congenital heart disease has evolved from its early days when it was exclusively a diagnostic tool to a dynamic and continuously growing field of therapeutic interventional procedures for children and adults with cardiac abnormalities. Clinicians and industry have a history of working together to push the field forward and find novel solutions to difficult problems while making the products to accomplish these goals smaller and safer. The interventional cardiologist and cardiothoracic surgeon have truly become an organized team in the treatment of once uniformly fatal conditions to offer longer and better quality of life to a diverse group of medically complex and rewarding patients.

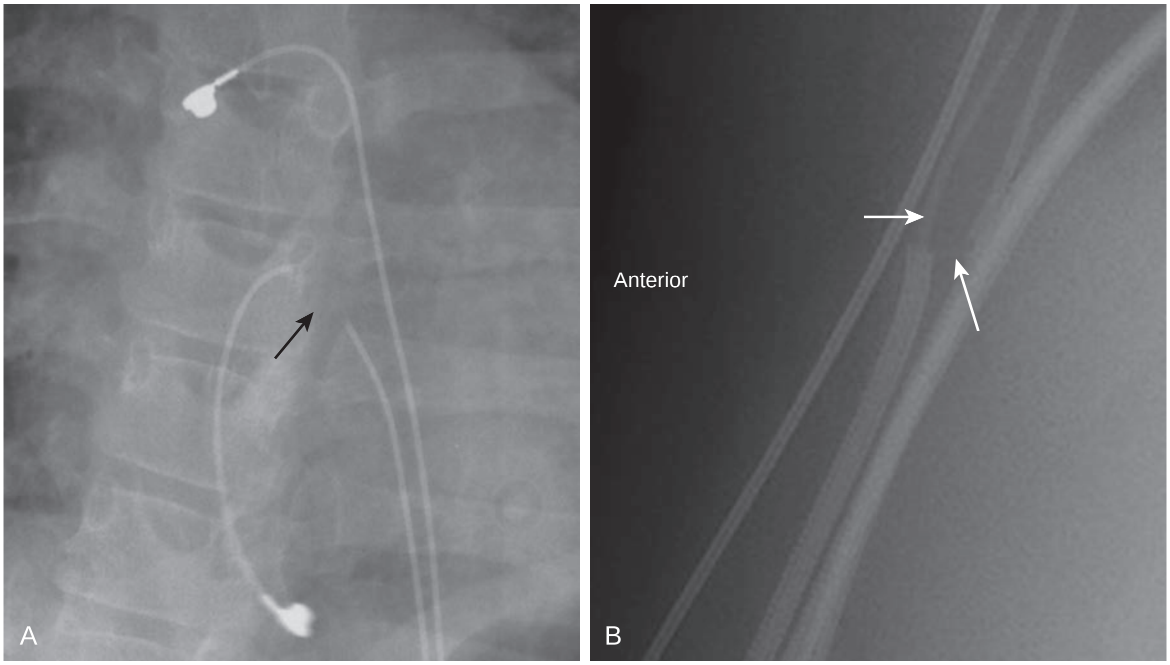

**Figure 68.16.** (A) Posterior-anterior projection of the chest showing an epicardial lead fracture *(arrow).* (B) Lateral projection of the upper abdomen in a different child showing a pseudofracture in the Medtronic 4968 epicardial lead. The proximal conductors are identified by *white arrows* just superior to their union at the bifurcation. The *lower arrow* identifies the smallest caliber component of the conductor. This image shows the normal appearance of this lead.

### e-BOX 68.2 Glossary of Terms Applicable to Electromagnetic Interference–Cardiac Device Interactions

**Activity sensor:** A pacing device component that responds to a physiologic or nonphysiologic patient parameter (e.g., motion or minute ventilation) to provide a faster pacing rate.

**Asynchronous mode:** A mode of operation in which the pacemaker is insensitive to incoming signals from the chamber being paced.

**Backup mode:** A pacing mode typically similar to that observed when the device battery has reached critical depletion; usually VVI (see below).

**DDD mode:** Dual-chamber mode of operation in which pacing and sensing occur in both the atrium and ventricle; atrioventricular synchrony is thus maintained from the lower programmed rate to the upper P-wave tracking (sensing) rate.

**Inhibition:** A pacemaker response in which a stimulus is withheld in response to a sensed event.

**Noise reversion mode:** A pacing mode that is activated when electrical noise is sensed. The mode usually consists of fixed-rate pacing for one pacing cycle, but in some devices this mode may continue as long as the electrical noise is sensed, and normal pacemaker function resumes when the noise is no longer sensed.

**OOO mode:** A programmable mode in some devices in which no chambers are sensed and no chambers can be paced; in essence, the device is off.

**Oversensing:** When the sensing circuitry of a pacemaker senses noncardiac electrical activity (such as electromagnetic interference) and interprets it as cardiac activity; this may result in inappropriate inhibition (see above) or inappropriate pacing, depending on the underlying programmed pacing mode.

**Pacing mode:** A programmable feature of all cardiac devices that defines the cardiac chamber or chambers that can be paced and sensed from and how the device will respond to a sensed intrinsic electrical event; the mode is abbreviated using an internationally recognized three- to five-letter code.

**Pacing threshold:** The minimum programmable energy output required to result in a propagated response by the cardiac chamber of interest; this value is dependent on complex lead, tissue, and metabolic interactions.

**Power-on reset:** The phenomenon in which older bradycardia pacemakers may change from an asynchronous mode to inhibition of pacing as a consequence of electromagnetic interference during MRI scanning.

**Reed switch:** A magnetically activated component of most pacemakers that "closes" when exposed to certain magnetic fields. This action typically results in asynchronous pacing (see above), thus ensuring pacemaker output in the presence of possible electromagnetic interference–induced oversensing (see above) and inappropriate inhibition.

**Sensing threshold:** The minimum cardiac chamber electrogram amplitude that can still be identified by the pacemaker circuitry as an intrinsic electrical event; this value depends on complex lead orientation, tissue, and metabolic interactions.

**VDD mode:** A dual-chamber mode of operation in which pacing can only occur in the ventricle but sensing can occur in both chambers.

**VOO mode:** A single-chamber mode of operation that is asynchronous, and only pacing occurs in the ventricle at the programmed rate, irrespective of the intrinsic ventricular rate.

**VVI mode:** A single-chamber mode of operation in which both pacing and sensing occur in the ventricle; intrinsic ventricular beats are sensed by the pacemaker, resetting the lower-rate timing circuitry and thus avoiding competitive pacing.

**e-TABLE 68.1** Potential Sources, Effects, and Prevention of Electromagnetic Interference During Medical Procedures That May Be Performed in the Radiology Department

| Procedure | Possible Effects | Prevention of Untoward Effects |
|---|---|---|
| Cardioversion/ defibrillation | Reprogramming to backup mode; local tissue-lead damage (increasing pacing and sensing thresholds) | Paddles should be greater than 4–6 inches from the device; patches should be placed in the anterior-posterior orientation; cardiologist should reevaluate the device afterward |
| Diathermy | Oversensing and inhibition; heating and destruction of device components (if placed directly over the device) | Avoid application directly over the device |
| Electrocautery | Oversensing and inhibition (if brief); noise reversion mode (if prolonged); reprogramming to backup mode; inappropriate tachycardia recognition (ICD) | Place a ground patch distant from the device; use bipolar cautery; never apply cautery within 4–6 inches of device; program to asynchronous mode during duration of procedure (or tape a magnet over the device); program tachycardia recognition "off" (ICDs) |
| Extracorporeal shock wave lithotripsy | Oversensing and inhibition; noise reversion mode; malfunction of reed switch; activity sensor-driven pacing; inappropriate tachycardia recognition (ICDs) | Synchronize lithotripter to patient's R wave; maintain focal point of lithotripter greater than 6 inches from device; program pacemaker to VVI or VOO modes for duration of procedure; program tachycardia recognition "off" (ICDs); cardiologist should reevaluate device afterward |
| Magnetic resonance imaging (MRI nonconditional) | Reed switch closure and reversion to asynchronous mode; theoretical (from RF scanning):<br>• Rapid pacing (>300)<br>• Heating of conductors with local lead tissue damage<br>• Oversensing and inhibition (pacers)<br>• Inappropriate tachycardia recognition (ICDs)<br>• Backup mode<br>Power-on reset | If not pacemaker dependent:<br>• Program output to less than pacing threshold<br>• Program to OOO mode<br>• Avoid procedure, if possible; explant device first<br>If pacemaker-dependent:<br>• Continuous rhythm monitoring during procedure with transcutaneous backup pacing available |
| Transcutaneous electrical nerve stimulators | Oversensing and inhibition; reprogramming; rapid ventricular pacing if VDD or DDD modes; inappropriate tachycardia recognition (ICDs) (all rare) | Probably safe, if a bipolar cardiac device; avoid stimulation using vector parallel to leads; program tachycardia recognition "off" (ICDs) |

*ICD,* Implantable cardioverter-defibrillator; *RF,* radiofrequency.

## KEY POINTS

- Electrophysiologic testing in children has benefitted greatly from magnetic field- and impedance-based technologies to aid in mapping of tachycardia substrates. This has reduced the duration of ionizing radiation required to image electrode catheters in the heart. Uncomplicated electrophysiologic studies that include catheter ablation are now commonly performed with less than 5 minutes of fluoroscopy time and, in some institutions, using no fluoroscopy at all.
- Cardiac implantable electronic devices remain an important treatment option for young patients with serious bradycardic conditions, patients at high risk for sudden cardiac arrest from ventricular tachyarrhythmia, and occasional patients with severely reduced ventricular systolic function. The weak link in these systems remains the electrical conductors, so-called “leads”. Periodic radiographic analysis is required for all such systems, and this is even more important in very young patients and those having congenital heart disease, because the incidence of lead malfunction is higher in those groups. An understanding of the radiographic appearance of this equipment as well as a working knowledge of any associated congenital heart disease, especially post-operative anatomy, is important.
- Cardiac implantable electronic devices (CIEDs) are variably affected by large electromagnetic fields as may be required during certain diagnostic and therapeutic procedures, especially diathermy, electrocautery, extracorporeal shock wave lithotripsy, transcutaneous electrical nerve stimulation, and magnetic resonance imaging. Effects may include suppression of electrical output, inappropriate identification of tacharrhythmias, thermal heating of myocardium, and actual reprogramming. The radiologist in concert with the electrophysiology team should carefully plan these procedures, sometimes with on site involvement of the cardiologist. These issues are becoming more common, since all of the newest CIEDs are MRI conditional.

# Surgical Considerations for Congenital Heart Disease

*Asvin M. Ganapathi and Andrew J. Lodge*

Congenital cardiac defects may be categorized in a variety of ways. One approach is to separate them based on the presence or absence of cyanosis at the time of presentation. Cyanotic lesions are either associated with shunting of deoxygenated blood into the systemic arterial circulation or with severely reduced pulmonary blood flow. These lesions include transposition of the great arteries, tetralogy of Fallot (TOF), truncus arteriosus, total anomalous pulmonary venous connection, and hypoplastic left heart syndrome (HLHS). Acyanotic lesions include obstructions to left ventricular outflow, such as aortic stenosis or coarctation of the aorta, and defects with shunting of blood from the systemic circulation to the pulmonary circulation, including atrial, ventricular, and atrioventricular (AV) septal defects and patent ductus arteriosus (PDA). Often a combination of lesions exists, and associated anomalies must be thoroughly identified by preoperative imaging studies. This chapter will review the pathophysiology and clinical and imaging evaluation of patients with congenital heart disease as they relate to surgical planning. Discussion will reference treatments, particularly with regard to choice of surgical approach, along with intraoperative and postoperative considerations pertinent for radiologists.

## GENERAL CONSIDERATIONS

Many congenital heart defects are fatal or can lead to long-term complications or a shortened life expectancy if not corrected surgically. Due to advances in congenital heart surgery, anesthesia, critical care, and diagnostic imaging, many defects can be treated effectively with consistently improving results. Although some congenital heart defects are effectively and permanently treated with one operation, many require subsequent interventions and long-term follow-up, including the use of different imaging modalities.

## SURGICAL APPROACHES

Surgery for congenital heart disease is most commonly performed via a median sternotomy with an anterior midline thoracic incision. After exposure of the sternum, a sternal saw is used to split the sternum and a retractor is placed to expose the operative field within which the pericardial sac is contained (Fig. 69.1). This incision offers excellent access to all of the structures of the heart, which is useful when multiple lesions are present or if a complicated repair must be performed.

Less invasive incisions such as a partial median sternotomy or a minithoracotomy can also be utilized. In the case of a partial median sternotomy, the skin incision is kept small and only the upper or lower sternum is divided (e-Fig. 69.2). Depending on the necessary exposure, thoracotomy incisions can be anterior, lateral, or posterior (e-Fig. 69.3) and, in the current era, these incisions are performed by dividing the intercostal muscles and leaving the ribs intact.

The type of lesion being repaired determines the choice of surgical incision. Straightforward repair of extracardiac lesions such as aortic coarctation, vascular rings, or PDA generally can be performed through a left thoracotomy. With refined techniques, even intracardiac repairs requiring cardiopulmonary bypass (CPB) such as an atrial septal defect (ASD) or mitral, tricuspid, and aortic valve operations can be done through minimally invasive incisions. In addition, interest has developed in performing relatively straightforward operations, including some heart valve surgery, using thoracoscopic or robotic techniques. In these cases, several very small incisions and specially designed instruments are used to perform the procedure (e-Fig. 69.4). Advantages touted include an improved cosmetic result and potentially shorter recovery times inside and outside the hospital.

For most complex congenital heart defects, such as repair of an AV septal defect or a cyanotic defect, a median sternotomy is used. This allows better exposure of both intracardiac and extracardiac structures that need to be repaired. For example, the repair of TOF might involve incisions in both the right atrium and the pulmonary artery to close the ventricular septal defect (VSD) and relieve the right ventricular outflow obstruction. In some cases in which a very small pulmonary annulus or significant infundibular stenosis is present, the incision might even need to be extended to the right ventricular cavity (Fig. 69.5).

The choice of surgical approach also is important in the case of staged operations. Lesions that commonly require multiple operations include HLHS, TOF, and truncus arteriosus. A patient with HLHS generally will undergo three operations for complete palliation, and the need for a repeat sternotomy carries both operative and radiographic implications. Imaging of the chest can help with operative planning because redo median sternotomy incisions carry a risk of damage to the thoracic contents as a result of the formation of postoperative adhesions. For example, the aorta or other structures can be found very close to the sternum (e-Fig. 69.6) and might be damaged upon entry to the chest during the sternotomy. This sometimes necessitates the emergent institution of CPB or alternative, peripheral cannulation (discussed later).

Other scenarios influencing operative planning and the choice of incision include the presence of multiple lesions or when a palliative procedure, instead of complete repair, is indicated. For example, many congenital heart defects can occur together, such as coarctation of the aorta and VSD. In this case, a surgical procedure that might have been accomplished through a thoracotomy incision for isolated coarctation (e-Fig. 69.7) would necessitate a median sternotomy to address both lesions.

The incision used for surgery has a variety of clinical and radiographic consequences. Patients who have had median sternotomy incisions often will have steel wires re-approximating the sternum, although in children, sutures that are not radio-opaque often are used. Occasionally, chest wall deformities may develop in children who have sternotomy incisions as the children grow. Children who have had surgery for congenital heart disease also are at higher risk for developing scoliosis than the general population (e-Fig. 69.8). Thoracotomy incisions can produce distortion of the ribs on the side that has been operated upon and also can lead to scoliosis.[1] In the current era, ribs usually are not cut or sectioned during thoracotomy procedures, but sometimes inadvertent rib

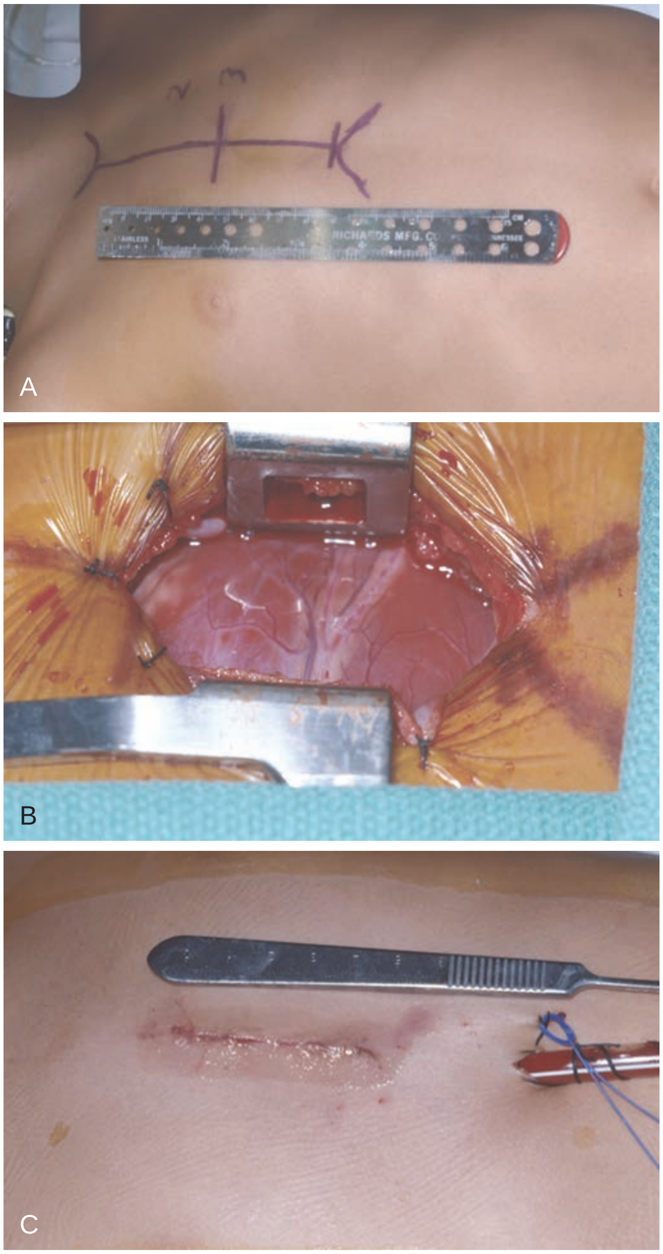
## Abstract:

Congenital cardiac defects may be categorized in a variety of ways. One approach is to separate them based on the presence or absence of cyanosis at the time of presentation. Cyanotic lesions are either associated with shunting of deoxygenated blood into the systemic arterial circulation or with severely reduced pulmonary blood flow. These lesions include transposition of the great arteries, tetralogy of Fallot (TOF), truncus arteriosus, total anomalous pulmonary venous connection, and hypoplastic left heart syndrome (HLHS). Acyanotic lesions include obstructions to left ventricular outflow, such as aortic stenosis or coarctation of the aorta, and defects with shunting of blood from the systemic circulation to the pulmonary circulation, including atrial, ventricular, and atrioventricular (AV) septal defects and patent ductus arteriosus (PDA).

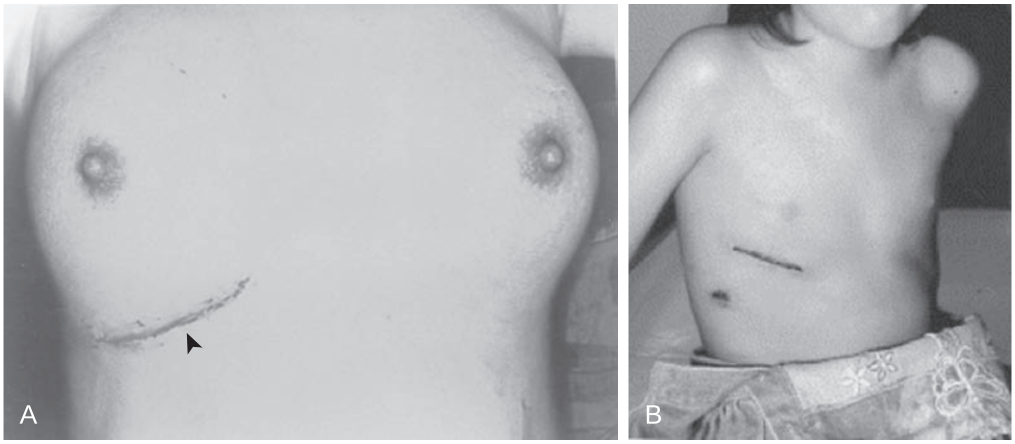
Congenital cardiac defects may be categorized in a variety of ways. One approach is to separate them based on the presence or absence of cyanosis at the time of presentation. Cyanotic lesions are either associated with shunting of deoxygenated blood into the systemic arterial circulation or with severely reduced pulmonary blood flow. These lesions include transposition of the great arteries, tetralogy of Fallot (TOF), truncus arteriosus, total anomalous pulmonary venous connection, and hypoplastic left heart syndrome (HLHS). Acyanotic lesions include obstructions to left ventricular outflow, such as aortic stenosis or coarctation of the aorta, and defects with shunting of blood from the systemic circulation to the pulmonary circulation, including atrial, ventricular, and atrioventricular (AV) septal defects and patent ductus arteriosus (PDA). Often a combination of lesions exists, and associated anomalies must be thoroughly identified by preoperative imaging studies. This chapter will review the pathophysiology and clinical and imaging evaluation of patients with congenital heart disease as they relate to surgical planning. Discussion will reference treatments, particularly with regard to choice of surgical approach, along with intraoperative.

## Keywords:

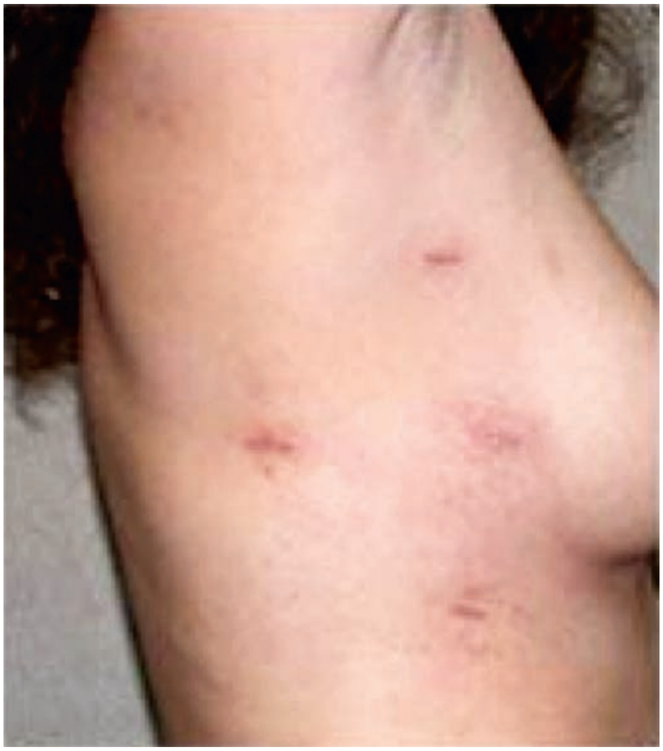
congenital heart disease
cardiac surgery



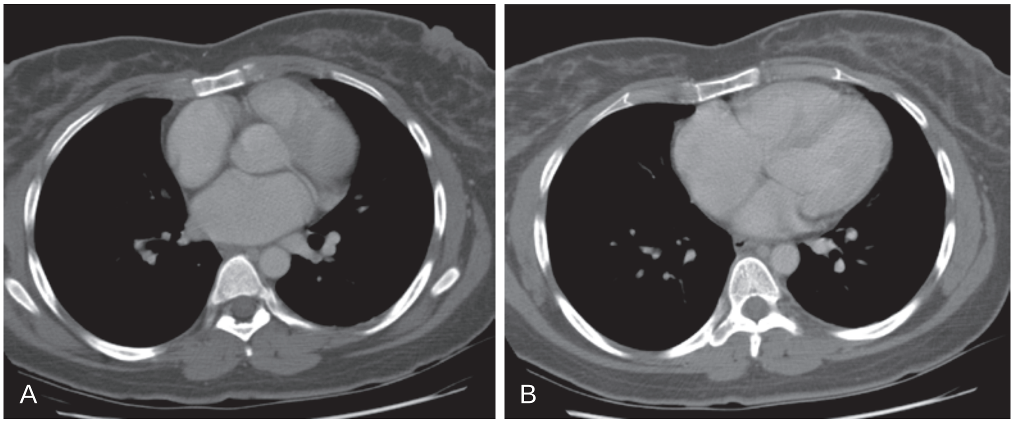
**e-Figure 69.2. Partial lower median sternotomy.** (A) With the patient supine and the head to the left of the picture, the skin is marked preoperatively to show the length of the entire sternum, the second and third intercostal spaces (2 and 3), and the planned incision between the horizontal lines. In small children, a skin incision approximately 4 cm long can be used. (B) The exposure created with this incision is shown. Compared with Fig. 69.1, less of the pericardial contents are immediately obvious. (C) The closed incision after repair of an atrial septal defect. A chest tube and pacing wires are seen exiting the skin caudal to the incision.



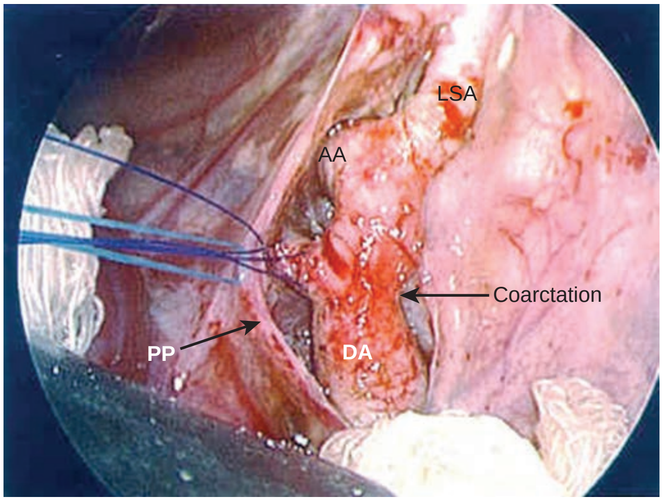
**e-Figure 69.3. Anterior right thoracotomy incisions for minimally invasive heart surgery.** (A) Frontal and (B) Right oblique views of the thorax. The incisions are generally made in the inframammary crease. These incisions sometimes are preferred, particularly for female patients.



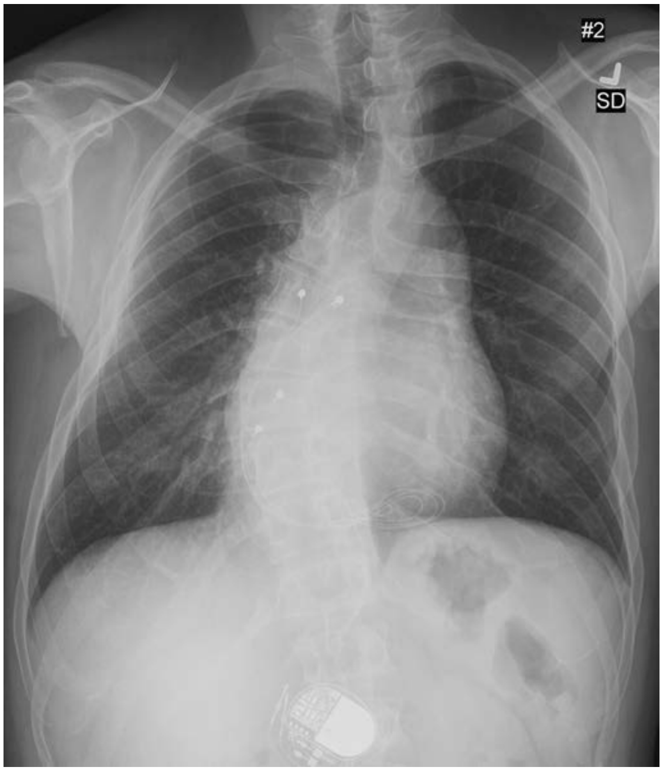
**e-Figure 69.4.** Incision sites for robotic ports used in atrial septal defect repair.



**e-Figure 69.6. Axial computed tomography images of a patient with previously repaired tetralogy of Fallot.** (A) The right atrium and right ventricular outflow tract are in close proximity to the anterior chest wall. (B) A more caudal image showing close proximity of the right atrium and ventricle to the anterior chest wall.



**e-Figure 69.7. Intraoperative photograph during repair of aortic coarctation.** The parietal pleura *(PP)* has been opened to expose the aorta. This flap of tissue contains the vagus and recurrent laryngeal nerves. The sutures are around the ductus arteriosus. The coarctation is visible as a subtle indentation externally. The internal diameter will be substantially smaller. *AA,* Aortic arch; *DA,* descending aorta; *LSA,* left subclavian artery.



**e-Figure 69.8. Scoliosis after CHD.** Frontal chest radiograph shows significant scoliosis in a patient with complex CHD who underwent multiple cardiac surgeries as a child.

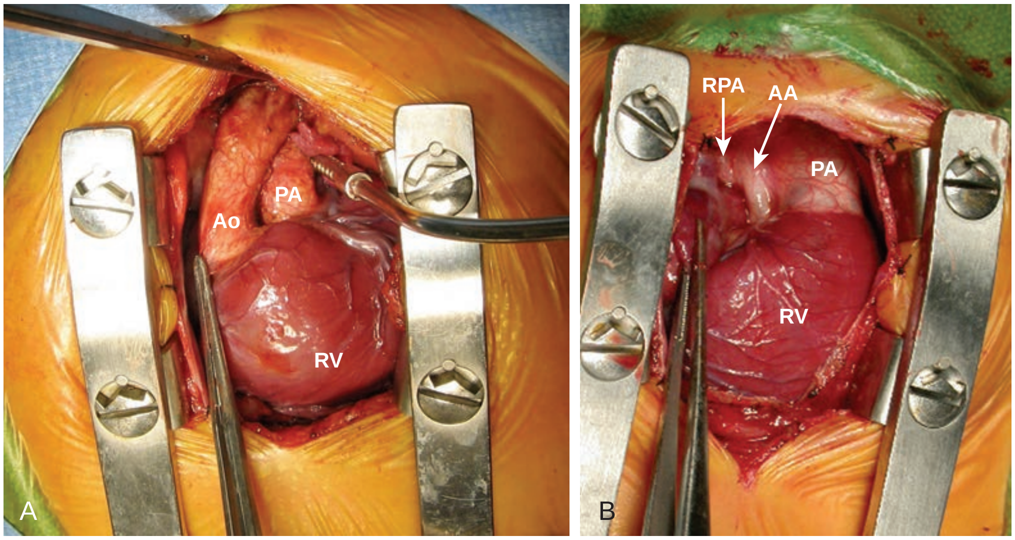


**Figure 69.1. Median sternotomy.** (A) A sternal retractor is in place in a patient with transposition of the great arteries. The pericardium has been opened and sutured to the margins of the incision to expose the heart. The aorta *(Ao)* arises from the right ventricle *(RV)* and the pulmonary artery *(PA)* from the left ventricle. The left coronary artery and some of its branches also are seen. Note that the left ventricle, which is a posterior structure, is not well exposed. (B) Similar exposure in a patient with hypoplastic left heart syndrome. The main *PA* is large and the ascending aorta *(AA)* is diminutive. The right pulmonary artery *(RPA)* is visible emerging from behind the aorta. The right atrial appendage is being grasped with a forceps. The right ventricle *(RV)* is also exposed. The cut pericardial edge, which is sutured to the skin edge, is more easily seen in this picture.

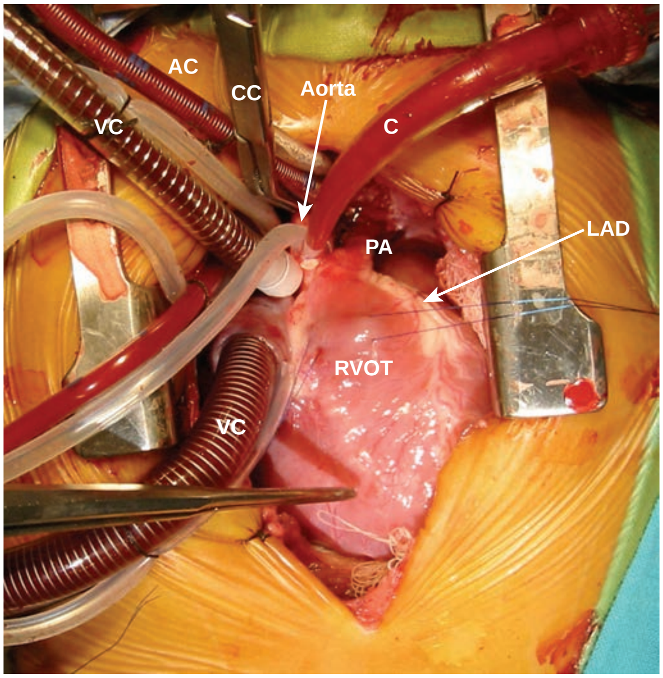

**Figure 69.5. An intraoperative photograph of an infant with tetralogy of Fallot (TOF) demonstrates a typical setup for cardiopulmonary bypass.** The patient's head is toward the top of the picture. A cross-clamp *(CC)* has been applied to the aorta between the arterial cannula *(AC)* and the cardioplegia catheter *(C)*. Venous cannulae *(VC)* are positioned in the superior vena cava and right atrium. The surface of the right ventricle is visible, and sutures are present in the right ventricular infundibulum *(RVOT)*. The diminutive main pulmonary artery *(PA)*, which is typical of patients with TOF, is seen. The left anterior descending coronary artery *(LAD)* is seen at the left lateral margin of the field. The left ventricle typically is not visible without retraction through a median sternotomy because it is a posterior structure.

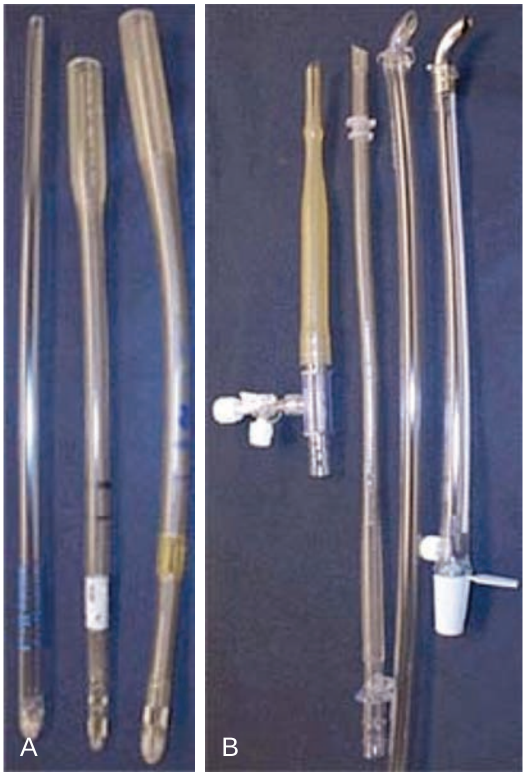
fractures can occur, which would be noted on the postoperative chest radiograph.

## CARDIOPULMONARY BYPASS AND EXTRACORPOREAL MEMBRANE OXYGENATION

Most congenital heart operations are performed using CPB to support the circulation. The principal components of the system are a blood pump (commonly a roller or centrifugal pump) and an artificial lung (oxygenator) (Fig. 69.9). CPB is established by the placement of arterial and venous cannulae (e-Fig. 69.10), usually in the ascending aorta and right atrium, however, the femoral, iliac, or axillary arteries can serve as alternatives for arterial cannulation, and in surgeries necessitating opening of the heart, venous cannulation is accomplished by separate superior and inferior vena cavae cannulae. CPB facilitates cardiac surgery by emptying the heart of blood, allowing ventilation to be stopped, and, if necessary, arresting the heart with cardioplegia, a potassium-rich solution circulated through the coronary vasculature after clamping the aorta between the coronary arteries and the CPB arterial inflow. The evolution of this technology has reduced CPB-related complications and morbidity such as the systemic inflammatory response, catastrophic air embolism, myocardial injury, and pulmonary dysfunction.[2,3]

Some surgery on extracardiac structures, such as modified Blalock-Taussig shunts and pulmonary artery banding, can be performed without CPB if the patient remains hemodynamically stable. In these cases, CPB generally is readily available should circumstances change. Sometimes extracorporeal circulatory support is necessary after surgery to allow for recovery of the heart over an extended period or as a bridge to transplant in the case of an unsuccessful repair. In these cases, a modified CPB circuit is used for extracorporeal membrane oxygenation (ECMO) (Fig. 69.11). Chest radiography can be used to assess the position of ECMO cannulas (Fig. 69.12). ECMO can be continued for days to weeks if necessary. However, a recent registry study demonstrated that the majority of survivors were on ECMO for 8 days or less.[4]



**e-Figure 69.10. Cannulae used for cardiopulmonary bypass.** (A) Examples of venous cannulae. (B) Examples of arterial cannulae.

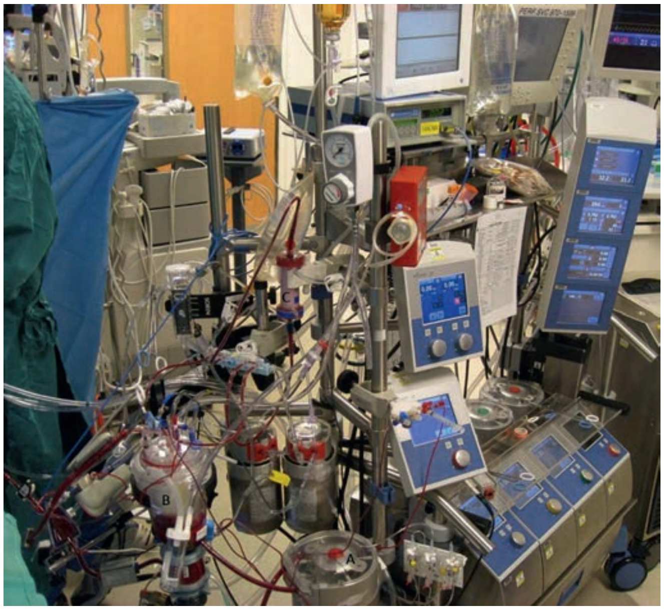


**Figure 69.9. Pediatric cardiopulmonary bypass (heart-lung) machine.** The roller pump, the reservoir with oxygenator below, and hemofilter are visible. The blood tubing connecting the components can be seen. Below the oxygenator is a temperature coil to which water lines are attached, allowing control of the patient's body temperature. Some of the monitoring equipment for the apparatus can be seen to the right of the image.

Survival rates in patients who require ECMO after surgery range from 38% to 53%.[5]

## CIRCULATORY ARREST AND REGIONAL CEREBRAL PERFUSION

In very complex cases such as those involving small neonates or complex aortic arch reconstruction, it occasionally is desirable to temporarily stop the entire circulation for a period. This technique, termed "deep hypothermic circulatory arrest" (DHCA), uses total body cooling to approximately 18°C, thus allowing the circulation to be safely suspended for up to 30 to 45 minutes. The safety of circulatory arrest and its effect on long-term neurologic outcome are controversial. The landmark Boston Circulatory Arrest Study suggested that neurodevelopmental abnormalities became significantly more prevalent after 41 minutes of DHCA.[6] However, it should be noted that data from other studies suggest that DHCA has little or no effect.[7–9] One limitation of all of these studies is the relatively small sample size.

Examples of operations in which patients possibly may be subjected to DHCA include the Norwood procedure for HLHS or repair of total anomalous pulmonary venous connection. As techniques have evolved, the use of DHCA has decreased, and many surgeons prefer to use regional cerebral perfusion, a technique that uses selective arterial inflow at a lower rate to the innominate or carotid artery and thereby limits periods of total ischemia. One advantage of this technique is blood flow not only to the brain but also to subdiaphragmatic organs.[10] There is wide variation in the use and technique of regional cerebral perfusion.[11]

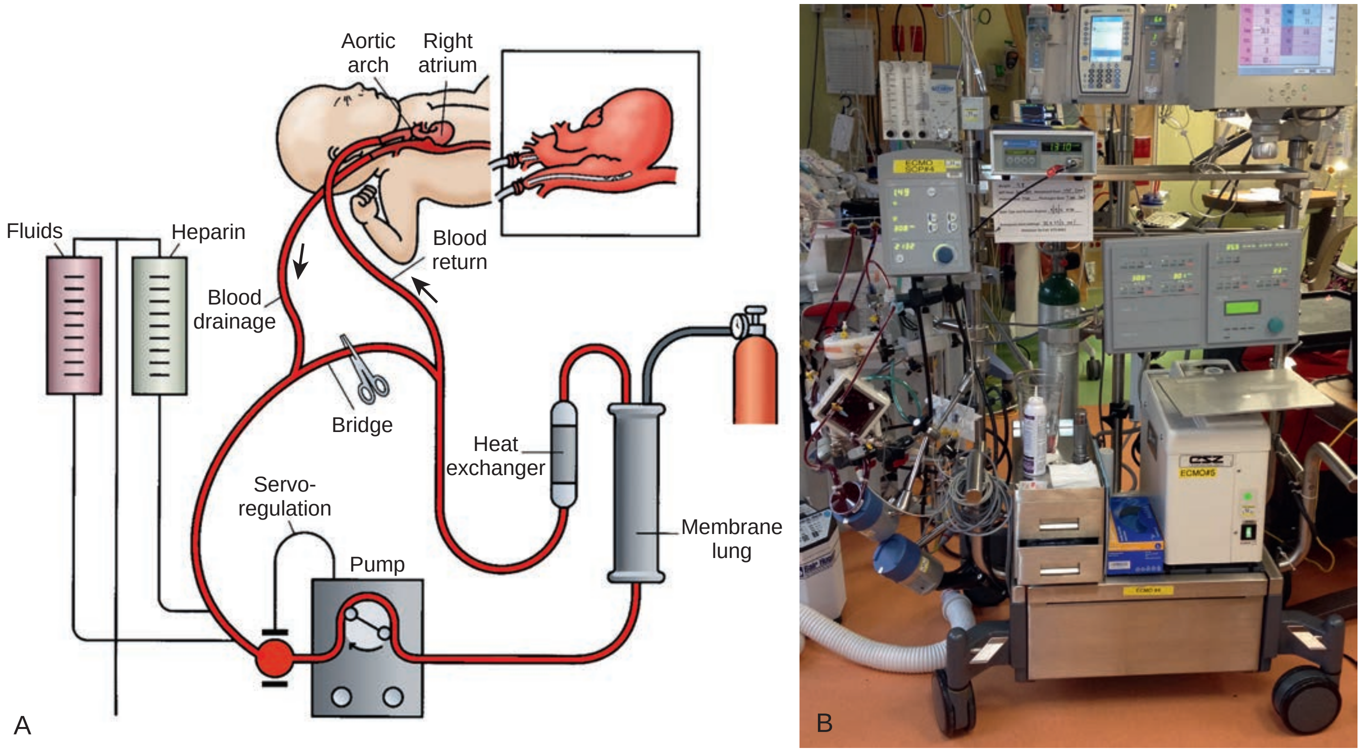

**Figure 69.11. Extracorporeal membrane oxygenation (ECMO).** (A) A schematic diagram of an ECMO circuit. (B) An actual ECMO circuit in clinical use. *(A, from* http://www.nichd.nih.gov/publications/pubs/images/Efig1p26.gif*. Accessed April 2, 2012.)*

## CHEST RADIOGRAPHY

Chest radiographs are useful both before and after cardiac surgery. From a preoperative standpoint, the chest radiograph can be used for diagnostic purposes, because many lesions have characteristic findings, as well as a means to determine the severity of disease by indicating evidence of congestive heart failure, pulmonary edema, or atrial/generalized cardiac enlargement. These findings may influence medical management before surgery or help to predict the postoperative course. In addition, a chest radiograph provides an important baseline to which to compare postoperative films. However, in some centers, the use of preoperative chest radiography in otherwise healthy children is being questioned as it may not be cost effective.

Chest radiographs are the most common radiographic study obtained after heart surgery, and are obtained immediately upon arrival at the recovery room or intensive care unit (e-Fig. 69.13). These images are used to verify the positioning of central venous lines, chest tubes, the endotracheal tube, sternal wires, and prostheses, as well as to assess the degree of lung expansion and to rule out unsuspected pleural effusions or pneumothoraces. In small children with limited percutaneous vascular access, pressure monitoring lines sometimes are inserted directly into the cardiac chamber (and later removed at the bedside). The most common points of insertion, in decreasing order of frequency, are the right atrium, left atrium (usually via the right superior pulmonary vein; less often via the left atrial appendage), and pulmonary artery.

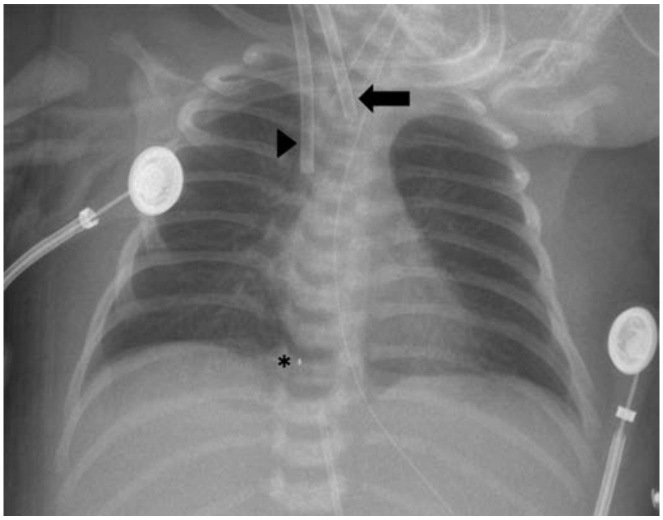

**Figure 69.12. Positioning of ECMO cannulas in infant.** ECMO cannulas (arterial and venous marked by *arrow* and *arrowhead* respectively) in a child. A radiopaque marker *(asterisk)* is noted at the bottom of the venous cannula indicating its depth.

Obtaining and interpreting the immediate postoperative film in a timely fashion is critical because delays can be life-threatening. For instance, mediastinal widening—a new or enlarging opacity in the vicinity of the aorta after the repair of coarctation of the aorta—may represent postoperative bleeding. An unsuspected pneumothorax can be life threatening if it is not detected early. A pneumothorax may arise in the case of a patient who undergoes PDA ligation via a left thoracotomy but does not have a pleural drain left in at the end of the operation (a common scenario). If a patient has undergone a left thoracotomy, one might observe asymmetry of the lung fields because of congestion or atelectasis of the right lung paired with hyperinflation of the left lung (e-Fig. 69.14). This asymmetry occurs because the patient is positioned with the right side down for an extended period and the left lung is partially or completely collapsed during the procedure for surgical exposure purposes. Many patients have mild pulmonary edema or small pleural effusions related to the inflammatory response to CPB. These findings generally resolve with diuretic treatment. Many current valve prostheses also are visible on a chest radiograph because of the presence of radiopaque material in the sewing ring, stent, or the valve itself. However, some bioprosthetic valves, including homografts and autografts, will not be apparent on radiographs (Table 69.1).

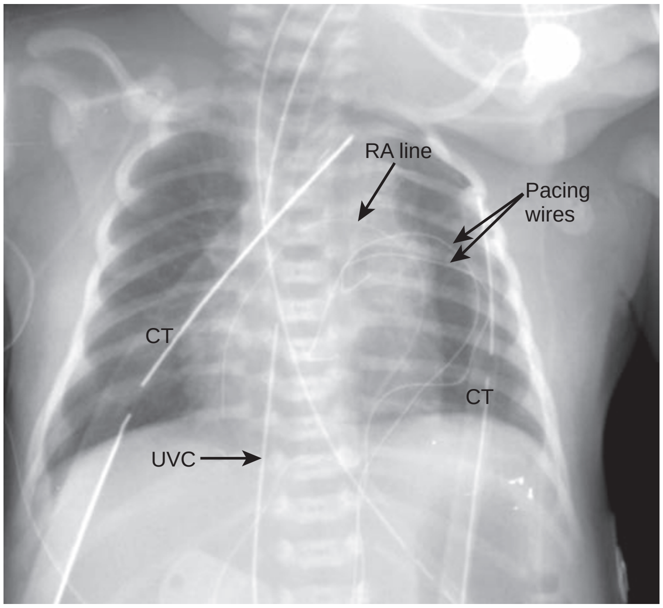
Daily chest radiographs frequently are obtained for patients after cardiac surgery. Posterior-anterior and lateral films generally are preferred for patients who are stable enough to travel to the radiology department, including patients with indwelling appliances such as chest tubes. However, it is common practice to obtain daily portable films while the patient requires intensive care unit monitoring. Neonates and infants who remain intubated with small bore endotracheal tubes are at risk for the development of atelectasis, which can be a major impediment to clinical care. The presence, extent, and distribution of atelectasis and the position of the endotracheal tube are critically important elements of the chest radiograph that may require daily assessment. Follow-up radiographs generally are obtained immediately after the removal of pleural chest tubes, but they are not routinely necessary after the removal of intracardiac lines, pacing wires, and pericardial (mediastinal) drains. Although these radiographs primarily are used to observe if a pneumothorax is present after removal of the chest tube, they also can help identify other conditions such as pleural or pericardial effusions.

## OTHER CONSIDERATIONS

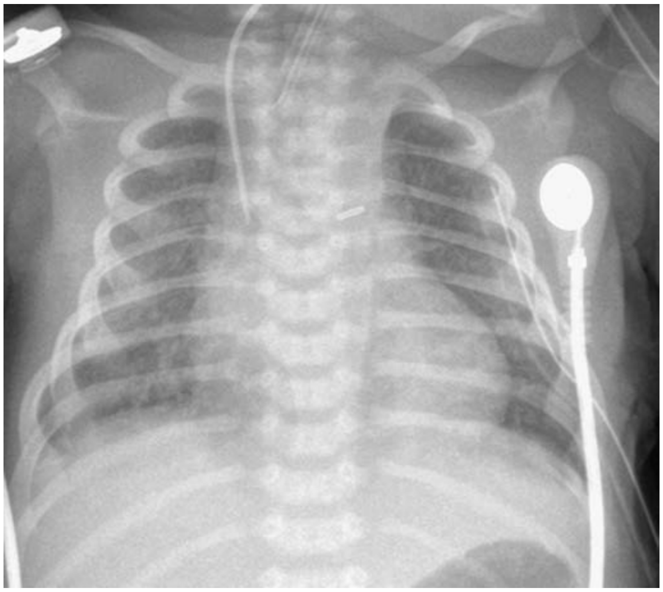
Imaging studies performed or interpreted by radiologists are important in many other situations in the evaluation and surgical management of congenital heart disease. Many patients with complex congenital heart disease, particularly patients requiring intervention as neonates or infants, may have associated syndromes

**TABLE 69.1** Cardiac Valve Prostheses

| Prosthesis Type | Synonym | Definition | Characteristics |
|---|---|---|---|
| Bioprosthetic | Xenograft, heterograft | Manufactured valve; uses tissue from other species such as pig or cow | Does not require long-term anticoagulation; subject to structural deterioration |
| Mechanical | — | Manufactured valve, generally composed of metal and pyrolytic carbon | Requires long-term anticoagulation; the most durable prosthesis; magnetic resonance imaging compatible |
| Homograft | Allograft | Cryopreserved human valve or valved conduit | Included segment of aorta or pulmonary artery offers greater reconstructive potential; subject to structural deterioration; aortic valve particularly prone to calcification |
| Autograft | — | Patient's own tissue | Pulmonary autograft used to replace aortic valve in Ross procedure |
| Stentless | — | Bioprosthetic valve that does not have a rigid plastic or metal stent built in | Technically more difficult to implant; may have greater effective orifice area |



**e-Figure 69.13. Typical chest radiograph of a postoperative infant.** The tip of the endotracheal tube can be seen above the carina. A variety of other support equipment is labeled. The pacing wires can appear similar to the transthoracic pressure lines. The wires can be identified by their typical termination in a "J" configuration, whereas the pressure lines will be straight. Typically some redundant length of each is seen in the pericardial space. The right chest tube *(CT)* traverses the right pleural space and terminates in the pericardium/mediastinum. The right atrial *(RA)* line tip is near the RA-inferior vena cava junction. *UVC,* Umbilical vein catheter.



**e-Figure 69.14. Postoperative chest radiograph after aortic coarctation repair.** Hyperinflation of the left lung is observed with a central line noted in the right internal jugular vein and patchy opacities in the right lung likely related to atelectasis.

or anomalies. In these cases, it is common practice to obtain imaging studies such as an ultrasound of the brain and/or kidneys before surgery to establish baseline diagnoses. It has been increasingly recognized that neonates with complex congenital heart disease have brain pathology that exists even before neonatal surgical correction, and at some centers, preoperative magnetic resonance imaging (MRI) studies of the brain have become routine (e-Fig. 69.15). Brain imaging becomes important when considering ECMO or during the use of ECMO because findings of a severe neurologic insult may affect decision making.

Feeding problems in infants who undergo congenital heart surgery are common and involve the use of radiology services. In certain subsets of patients, such as those with HLHS, gastroesophageal reflux is particularly common. These patients may require diagnostic tests such as upper gastrointestinal series and gastric emptying studies to help establish a diagnosis or to plan for antireflux surgery. They also may require placement or repositioning of feeding tubes with fluoroscopic guidance.

Other studies may be required to aid in the assessment of postoperative complications. Renal insufficiency is relatively common in the postoperative period. Renal ultrasound with Doppler assessment of renal artery and vein flow may be helpful. Many patients who require prolonged ventilation have a confusing combination of lung and pleural space disease, and chest ultrasound can be very helpful in differentiating pathologic processes in the chest. Occasionally, image-guided drainage using ultrasound can be helpful in treating more complicated effusions. Infants who require ECMO and are at risk for ongoing coagulopathy require serial cranial ultrasound imaging procedures to assess for bleeding.

Imaging studies also have become increasingly useful for preoperative planning in complicated cases. CT and MRI play an increasingly important role in these situations. In patients who have had previous cardiac surgery and are at risk for injury to the heart with a repeat sternotomy, CT scans can be very helpful in risk assessment or surgical planning by showing the relationship of the heart and great vessels to the sternum. CT angiography also can be helpful in patients with aortic coarctation who have complex anatomy or late diagnosis, both for operative planning and assessing candidacy for stent placement. CT or CT angiography also are useful in the diagnoses or characterization of complicated pulmonary artery or vein anatomy, such as in patients who have had repair of anomalous pulmonary venous connections, TOF, or transposition of the great arteries. Cardiac MRI is being used more commonly for many of these same indications (e-Fig. 69.16). In addition, cardiac MRI can be used to evaluate intracardiac shunts and plan therapy, such as in the case of transcatheter device closure of ASD. MRI also has become quite useful for evaluating right ventricular function and pulmonary insufficiency in patients who have had repair of TOF (Videos 69.1 and 69.2). CT and MRI are the best imaging modalities for most vascular rings (e-Fig. 69.17). Some patients require cannulation of peripheral vessels for the institution of CPB but also may have had multiple heart catheterizations or cutdowns. In these cases, ultrasound imaging with Doppler can help establish the patency of peripheral vessels such as the femoral artery and vein.

## SUMMARY

Congenital heart disease can present with a variety of symptoms in patients at any age. Surgical and catheter-based techniques, as well as pediatric cardiac anesthesiology, have evolved during the past 30 years. Interventions are being performed at an earlier age and through smaller incisions, with improving short- and long-term survival. Diagnosis is established by echocardiography in most circumstances, although MRI and CT may be useful in a number of preoperative and postoperative circumstances. Management decisions are based on the overall clinical picture, which takes into consideration patient symptoms, physical findings, and results of imaging studies. Imaging studies performed and interpreted by radiologists during the preoperative and postoperative phases are critical for the successful treatment of these patients.

### KEY POINTS

- Incisions for pediatric cardiac surgery range from minimally invasive options such as small incisions for robotic procedures and thoracotomies to large midline, sternal incisions requiring splitting of the sternum.
- Radiographic studies are extremely important for both the diagnosis and operative planning of congenital heart disease. These studies consist primarily of chest radiographs, CT scans, and MRI. Echocardiography also plays a significant role in diagnosis.
- Chest radiographs are perhaps the most important study utilized in patients undergoing congenital heart surgery. They provide important diagnostic, preoperative, and postoperative information. Additionally, they serve to verify correct positioning of intraoperatively placed lines, chest tubes, and endotracheal tubes.
- Because many children with congenital heart disease have comorbidities involving other organ systems, radiographic studies for diagnosis and management of these processes are essential, such as renal and vascular ultrasound, brain imaging, and a variety of gastrointestinal studies.

## INTRODUCTION

Congenital abnormalities of the heart are the most common birth defects, occurring in approximately 8 of every 1,000 newborns.[1] Approximately 25% of those in whom an abnormality is identified have critical congenital heart disease (CHD) with risk for significant perinatal compromise or death.[2,3] Despite advances in imaging technology and technique, much CHD remains undetected until after birth.[4–8] Fortunately, routine prenatal cardiac screening has evolved from single-frame acquisition imaging of the four-chamber heart view to include delineation of the outflow tracts, an addition which significantly improves CHD detection.[9,10] Appropriate screening, when combined with fetal echocardiography when indicated, can readily identify and guide management for most cardiac abnormalities.

The complete fetal echocardiogram includes two-dimensional imaging, pulsed-wave and color Doppler interrogation, and M-mode imaging to completely assess fetal cardiac structure, function, and rhythm. Newer techniques may supplement the standard fetal echocardiogram and include tissue Doppler imaging, strain analysis, and three-dimensional imaging.[11,12] This chapter reviews (1) normal fetal cardiac anatomy, physiology, and rhythm assessment; (2) common congenital cardiovascular lesions and heart rhythm abnormalities; and (3) indications for interventions for fetal heart disease and outcomes.

## FETAL PHYSIOLOGY AND FLOW

An understanding of normal fetal cardiovascular anatomy and physiology is essential to interpretation of the fetal echocardiogram. The following are important differences between the fetal and postnatal circulation:

1. The right ventricular output exceeds that of the left ventricle, resulting in a slightly larger right atrium, tricuspid valve, right ventricle, pulmonary valve, and main pulmonary artery when compared with their left-sided counterparts.
2. The ductus venosus and foramen ovale are present; the ductus venosus shunts placental venous return to the right atrium and the foramen ovale directs this blood to the left atrium.
3. The ductus arteriosus is present, allowing deoxygenated systemic venous return to bypass the branch pulmonary arteries and be directed to the descending aorta and placenta.
4. The pulmonary vascular resistance is high, resulting in a relatively small proportion (approximately 10%) of the fetal cardiac output being directed toward the lungs.

## FETAL ANATOMIC AND FUNCTION ASSESSMENT

A complete fetal echocardiogram includes imaging of the atria, ventricles, atrioventricular and semilunar valves, foramen ovale, pulmonary veins, ductal and aortic arches, main and branch pulmonary arteries, and assessment of cardiac rhythm and function. Quantitative assessments of valve and vessel size should be compared with gestation-matched normative data. Pulsed-wave and color Doppler interrogation of each structure should be performed.

### Visceral/Atrial Situs and Cardiac Position

Proper identification of situs at the beginning of a fetal echocardiogram is of paramount importance for framing the rest of the examination. The positions of the viscera within the abdomen and the heart within the thorax should be identified. In normal abdominal situs, the liver is right-sided and the stomach is left-sided. The normal position of the heart within the thorax is on the left (levocardia); additional possibilities are dextrocardia and mesocardia, wherein the majority of the cardiac mass is rightward or midline, respectively. The direction of the cardiac apex should also be identified. The apex normally points leftward, but rightward or posterior-anterior orientations are possible.

Once abdominal situs and cardiac position have been determined, delineation of atrial morphology should follow (Fig. 70.1). The right atrium receives the coronary sinus and inferior vena cava, and its appendage is broad-based and triangular. The left atrium is characterized by the presence of septum primum, the "valve" of the foramen ovale and its appendage, which is slender and finger-like. The pulmonary veins usually connect to the left atrium, but there is significant variability of the pulmonary venous connections in CHD. Although "right" and "left" atria are typically in their usual right- and left-sided locations respectively, it is important to note that they may be inverted or ambiguous in nature.

### Right and Left Ventricles

The right and left ventricles should be identified by their distinguishing morphologic features. The right ventricle has a moderator band, attachments of its atrioventricular (tricuspid) valve to the ventricular septum (septophilic), an atrioventricular valve annulus apical to its left ventricular counterpart, and coarse trabeculations. The left ventricle, in contrast, has an atrioventricular (mitral) valve without attachments to the septum (septophobic), and appears smooth due to its fine trabeculations (see Fig. 70.1). As with the atria, although "right" and "left" ventricles are typically in their usual right- and left-sided locations, it is critical to note that other anatomic arrangements are possible, and ventricles may be left-right inverted (ventricular inversion) and, rarely, may assume a superior-inferior relationship. Ventricular function may be qualitatively assessed in both a four-chamber transverse view and a short-axis view. Calculation of left ventricular shortening fraction (left ventricular end diastolic—systolic/end diastolic diameter) and ejection fraction (left ventricular end diastolic—systolic/end diastolic volume) is possible with meticulous attention to imaging technique and precise measurements.

### Atrioventricular and Semilunar Valves

The tricuspid and pulmonary valve annuli measure slightly larger than the mitral and aortic valves. Valves should be measured when they are maximally open: in diastole for the atrioventricular valves and systole for the semilunar valves. Significant size discrepancy between the two semilunar and/or atrioventricular valves should prompt careful evaluation for CHD.[13] The mitral valve should be supported by two well-spaced ventricular papillary muscles easily

## Abstract:

Congenital abnormalities of the heart are common, occurring in approximately 8 of every 1000 newborns, and approximately 25% of those in whom an abnormality is identified have critical congenital heart disease (CHD) with risk for significant perinatal compromise or death. With appropriate technique, fetal echocardiography may reveal virtually all in-utero cardiovascular abnormalities, including congenital and acquired fetal heart disease and arrhythmias. Accurate and timely diagnosis affords the opportunity to guide in-utero therapy and planning for the perinatal period. This chapter reviews indications for fetal echocardiography, imaging technique, and several cardiovascular abnormalities.

## Keywords:

prenatal cardiac assessment
fetal echocardiography
fetal heart
fetal arrhythmia
congenital heart disease

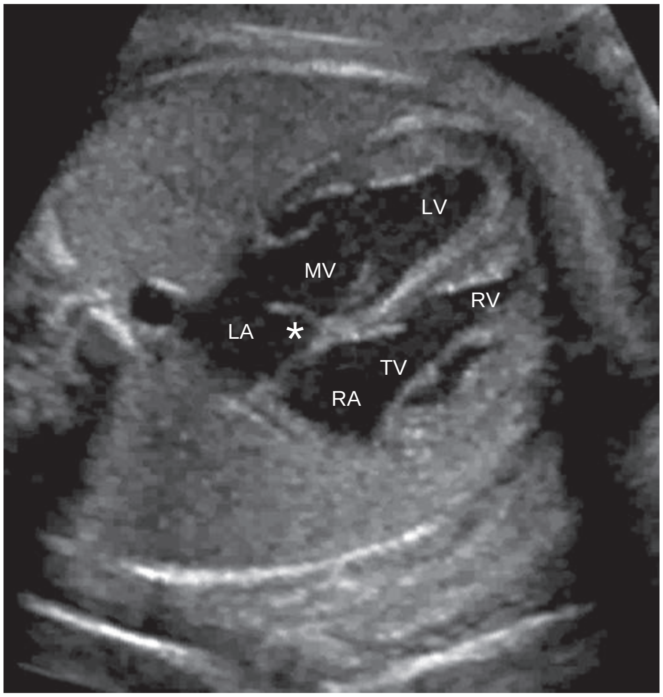

**Figure 70.1. Normal atrial and ventricular morphology on four-chamber view.** *LA,* Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve; * denotes septum primum. The systemic venous connections and atrial appendages are not visible in this projection.

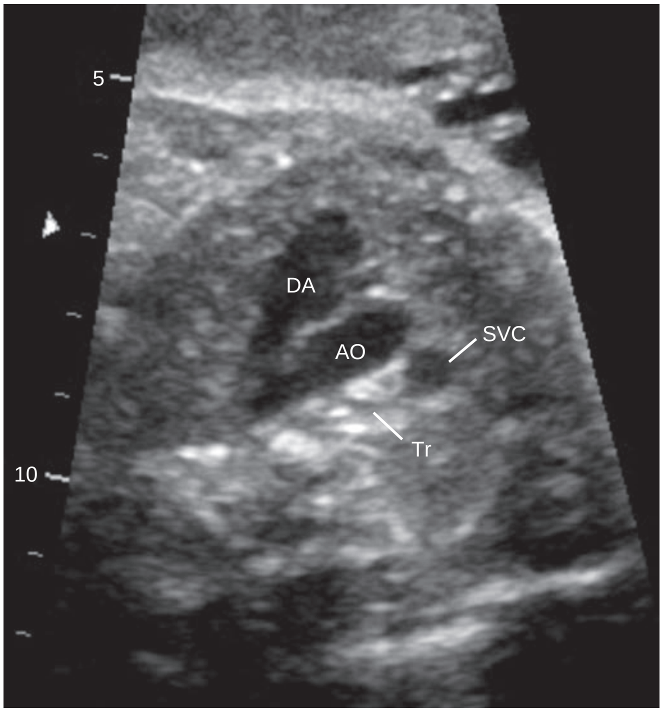

**Figure 70.2. Normal three-vessel trachea view.** The aorta and ductus arteriosus course away from the right-sided superior vena cava and to the left of the trachea. *Ao,* Aorta; *DA,* ductus arteriosus; *SVC,* superior vena cava; *Tr,* trachea.

identifiable on short-axis imaging. Color Doppler should readily identify any atrioventricular or semilunar valve regurgitation. Pulsed-wave Doppler assessment of all valves should be performed. Both atrioventricular valves should have biphasic flow patterns, and both semilunar valves should have a brisk upstroke with a narrow spectrum of normal velocities and no aliasing or increased velocity to suggest stenosis.

## Aorta, Pulmonary Artery, and the Aortic and Ductal Arches

The relationship of the aorta and pulmonary outflow to the ventricles should be determined. The aorta and pulmonary artery arise from the left and right ventricles, respectively, and should cross over one another. Any relationship where the great vessels do not cross should prompt consideration of transposed great arteries and significant CHD.

The aortic arch, main and branch pulmonary arteries, and ductal arch should be assessed in multiple planes. In addition to the sagittal view, where the entirety of the aortic and ductal arches can be assessed, the three-vessel trachea view is particularly useful in assessing location, size, and flow pattern of the aortic and ductal arches.[14] Arch sidedness can be determined from the three-vessel view; the usual arrangement being the aorta and ductus arteriosus coursing to the left as they pass in front of the trachea (Fig. 70.2). Additionally, the three-vessel-trachea view is of particular utility in diagnosing aortic arch hypoplasia and/or ductus arteriosus abnormalities.

# PRENATAL IMAGING: TIMING AND INDICATIONS

The optimal period for transabdominal imaging is 20 to 28 weeks' gestation, although transabdominal imaging at earlier gestations ages has been reported.[15] Transvaginal transducers can be used to image the fetal heart as early as 8 weeks, with successful diagnosis of heart defects possible at 11 weeks.[16,17] Although some particularly nuanced anatomic features are not detectable with early scanning, identification of single ventricle CHD and significant outflow abnormalities is feasible. Third-trimester imaging is frequently limited by less amniotic fluid relative to the size of the fetus, and the diminished likelihood of significant changes in fetal position further restricts available imaging planes.

Indications for fetal echocardiography based on maternal or fetal risk factors are extensive and expanding (Box 70.1).[18] The most common reasons for referral are a family history of CHD, fetal arrhythmia, maternal diabetes, and extracardiac abnormalities. The indication most predictive of cardiac disease is an abnormal four-chamber view on routine obstetric ultrasound, underscoring the importance of high-quality obstetric screening. Fetal arrhythmia, hydrops, and polyhydramnios are also important predictors of CHD. Equally important is an understanding of indications for which fetal echocardiography is not recommended (Box 70.2); fetal echocardiography is a highly specialized examination and should be reserved for appropriate circumstances, as unnecessary fetal cardiac evaluations may generate family anxiety.[19]

# EVALUATION FOR SPECIFIC CARDIAC DEFECTS

## Septation Defects

### Atrial Septal Defects

Atrial septal defects are the second most common form of CHD; however, detection of most atrial septal defects during fetal life is challenging due to the presence of the normal fetal foramen ovale (see Chapter 72). The most common atrial septal defect, the somewhat confusingly named "secundum" type, is actually a deficiency in septum primum, the flap valve of the foramen ovale. As such, secundum defects are in close proximity to a normal and large fetal shunt, making prenatal detection virtually impossible.

### **BOX 70.1** Indications for Fetal Echocardiography

**INDICATIONS WITH HIGHER RISK PROFILE (ESTIMATED >2% ABSOLUTE RISK)**

- Maternal pregestational diabetes mellitus
- Diabetes mellitus diagnosed in the first trimester
- Maternal phenylketonuria (uncontrolled)
- Maternal autoantibodies (SSA/SSB+)
- Maternal medications
- ACE inhibitors
- Retinoic acid
- NSAIDs in third trimester
- Maternal first trimester rubella infection
- Maternal infection with suspicion of fetal myocarditis
- Assisted reproduction technology
- CHD in first degree relative of fetus (maternal, paternal, or sibling with CHD)
- First- or second-degree relative with disorder with Mendelian inheritance with CHD association
- Fetal cardiac abnormality suspected on obstetrical ultrasound
- Fetal extracardiac abnormality suspected on obstetrical ultrasound
- Fetal karyotype abnormality
- Fetal tachycardia or bradycardia, or frequent or persistent irregular heart rhythm
- Fetal increased nuchal thickness >95% (≥3 mm)
- Monochorionic twinning
- Fetal hydrops or effusions

**INDICATIONS WITH LOWER RISK PROFILE (ESTIMATED >1% BUT <2% ABSOLUTE RISK)**

- Maternal medications
    - Anticonvulsants
    - Lithium
    - Vitamin A
    - Selective serotonin reuptake inhibitors (only paroxetine)
    - NSAIDs in first/second trimester
- CHD in second-degree relative of fetus
- Fetal abnormality of the umbilical cord or placenta
- Fetal intraabdominal venous anomaly

### **BOX 70.2** Fetal Echocardiography Not Indicated (≤1% Risk)

- Maternal gestational diabetes mellitus with HbA1c <6%
- Maternal medications
    - Selective serotonin reuptake inhibitors (other than paroxetine)
    - Vitamin K agonists (Coumadin), although fetal survey is recommended
- Maternal infection other than rubella with seroconversion only
- Isolated CHD in a relative other than first or second degree

Similarly, superior and inferior type sinus venosus defects, which represent a deficiency in a wall shared between a pulmonary vein and either the superior or inferior vena cava, are difficult to detect. Coronary sinus septal defect, a deficiency in the wall of the coronary sinus, is also difficult to detect. Primum atrial septal defects, a form of endocardial cushion defect and one that is often associated with Down syndrome, may be more readily detectable (Fig. 70.3).

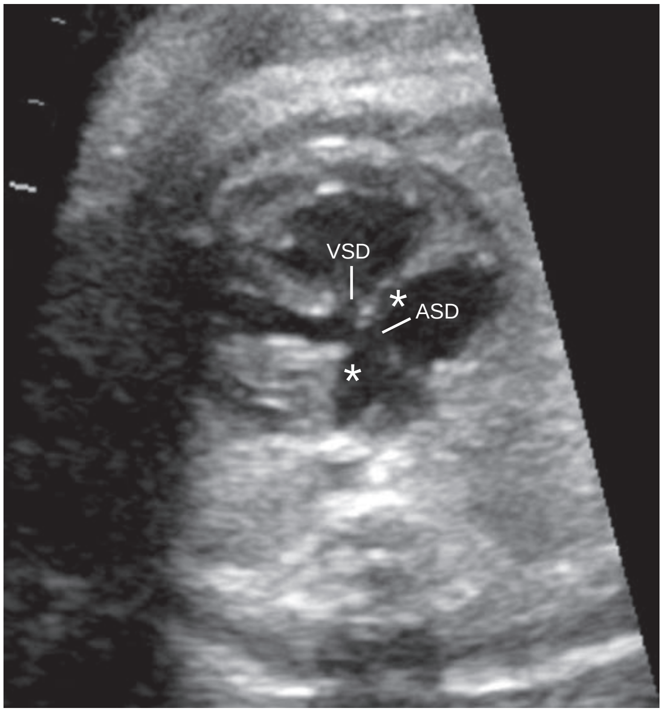

**Figure 70.3.** Balanced atrioventricular canal defect comprising a primum type atrial septal defect, an atrioventricular (inlet) type ventricular septal defect, and a common atrioventricular valve. *ASD,* Atrial septal defect; *VSD,* ventricular septal defect; * denotes common atrioventricular valve.

## Ventricular Septal Defects

Ventricular septal defects are the most common form of CHD. There are several nomenclature systems for describing their location. One relatively simple and effective way of grouping them is (1) perimembranous (or membranous), (2) atrioventricular (AV) canal (or inlet), (3) conoventricular (or outlet), and (4) muscular (see Chapter 72). Perimembranous defects are the most common but, due to the presence of the nearby tricuspid and aortic valves and their often being partially occluded with tricuspid valve tissue, they are relatively difficult to detect. AV canal type defects are posterior and located next to the atrioventricular valves. Conoventricular defects are generally readily visible with close attention to the ventriculoarterial junction and are often associated with other abnormalities (tetralogy of Fallot, truncus arteriosus). Muscular defects can be found anywhere in the muscular septum. Moderate to large defects require surgical intervention in infancy for patients with congestive heart failure, whereas small defects often close on their own. Conoventricular defects with or without other associated lesions frequently require surgical intervention in infancy.

Proper imaging technique for evaluation of the ventricular septum is essential. As some defects are more readily detectable by color Doppler, side-by-side two-dimensional and color Doppler imaging is often helpful. Sweeps through the septum in multiple planes, beginning at the level of the fetal stomach and continuing throughout the outflows are often helpful. Narrowed sector width, a color box over the region of interest, and a scale low enough to detect flow across the pressure-equalized fetal ventricles also facilitate detection (Fig. 70.4).

## Atrioventricular Canal Defects

Atrioventricular canal (endocardial cushion) defects comprise a spectrum of abnormalities. In their complete form, there is a primum type atrial septal defect, an atrioventricular canal type ventricular septal defect, and a common atrioventricular valve (see Chapter 72). Other forms of atrioventricular defects may include virtually any combination of the above noted defects. Repair for the complete form is required in infancy.

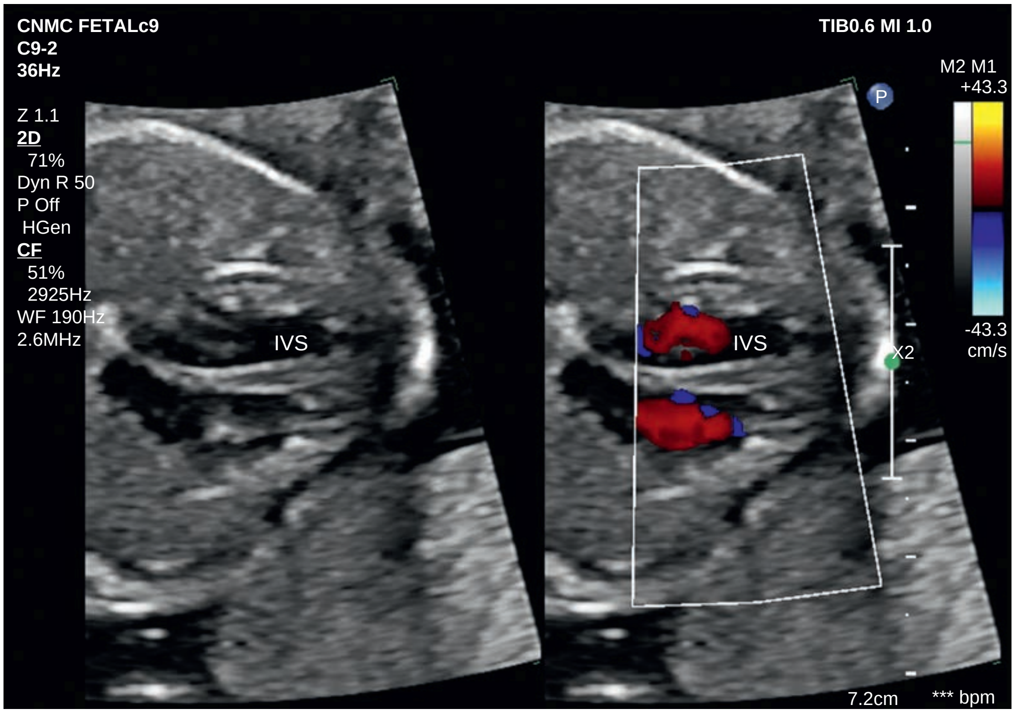

**Figure 70.4. Proper technique for imaging the ventricular septum.** The ventricular septum is perpendicular to the ultrasound beam, the *color scale* is relatively low, the *color box* covers the entire region of interest, and the frame rate is adequate (>30 Hz), all increasing the likelihood that abnormal flow across the ventricular septum will be detected. Imaging should be performed with sweeps in multiple planes. *IVS,* Interventricular septum.

## Inflow/Outflow Abnormalities

### Right-sided Inflow Lesions

Right-sided inflow lesions include abnormalities of the tricuspid valve and right ventricular development. These include Ebstein anomaly, tricuspid valve dysplasia, and tricuspid stenosis or atresia (see Chapter 74). In Ebstein anomaly, there is incomplete delamination of the septal leaflet of the tricuspid valve during development, resulting in poor leaflet coaptation and regurgitation (Fig. 70.5). There is a wide spectrum of outcomes of fetal Ebstein abnormality, ranging from in-utero hydrops and fetal demise to those requiring no intervention.[20] The distinction between tricuspid valve dysplasia and Ebstein anomaly is somewhat academic, but the term tricuspid valve dysplasia typically refers to incomplete delamination but with maintenance of the usual annular level and perhaps more functional myocardium, whereas in Ebstein anomaly, the valve annulus is displaced apically into the ventricle.

Tricuspid atresia or stenosis can be associated with hypoplasia of the right ventricle and pulmonary outflow obstruction. Tricuspid atresia may be associated with ductal-dependent systemic or pulmonary blood flow requiring prostaglandin, depending on whether a ventricular septal defect is present and the relationship of the great arteries. In all cases of tricuspid atresia, single-ventricle palliation is required.

### Right-sided Outflow Lesions

Pulmonary outflow obstruction can be subvalvar, valvar, or supravalvar (see Chapter 74). The disease spectrum ranges from newborns with severe cyanosis and single ventricle CHD to infants with normal oxygen saturation and a near normal pulmonary outflow tract. Isolated pulmonary valve stenosis is diagnosed by

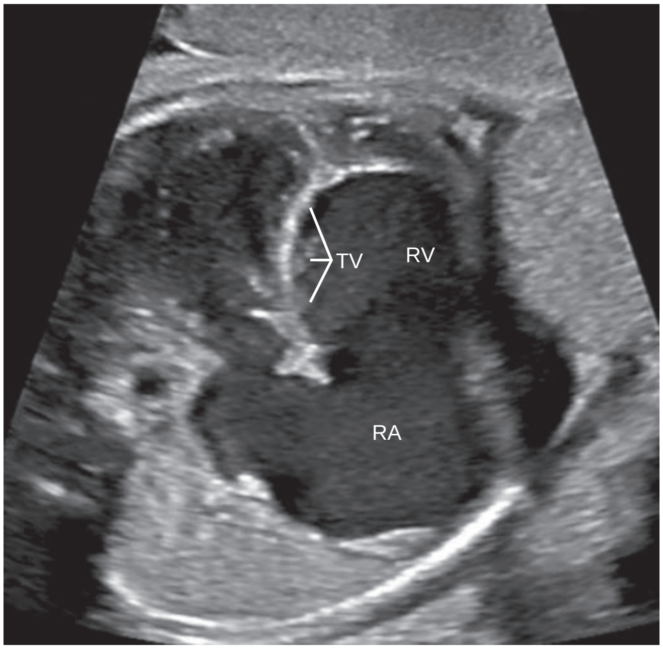

**Figure 70.5. Ebstein anomaly of the tricuspid valve.** The septal leaflet of the tricuspid valve is apically displaced with multiple tethering attachments to the ventricular septum, resulting in tricuspid insufficiency and right atrial and ventricular enlargement. *RA,* Right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

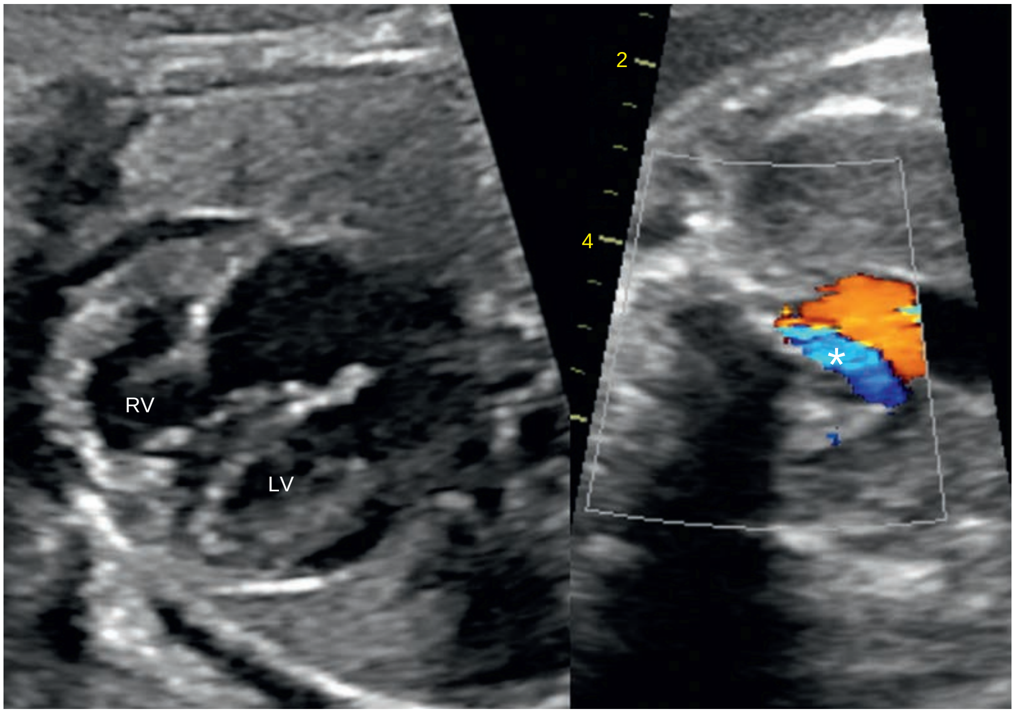

**Figure 70.6. Fetus with coarctation of the aorta.** There is significant ventricular size discrepancy, with the tricuspid valve and right ventricle larger than the mitral valve and left ventricle. Color Doppler imaging in the three-vessel trachea view demonstrates a narrow and retrograde jet of flow in the transverse aortic arch. *LV,* Left ventricle; *RV*, right ventricle, * on color Doppler image denotes retrograde transverse aortic arch flow.

identifying doming and thickened pulmonary valve leaflets, but this lesion can be very difficult to diagnose in utero due to the normally high fetal pulmonary vascular resistance. Supravalvar and branch pulmonary artery stenosis is difficult to detect in utero, but when recognized in the absence of a conotruncal defect, the possibility of Williams syndrome should be entertained. Subvalvar obstruction is usually seen in combination with other defects, such as tetralogy of Fallot, discussed later.

### Left-sided Inflow Lesions

Left ventricular inflow abnormalities include cor triatriatum, congenital mitral stenosis, and congenital mitral insufficiency (see Chapter 73). Cor triatriatum implies incomplete incorporation of the pulmonary veins into the posterior aspect of the left atrium and is rarely detected in utero. Congenital mitral valve anomalies may occur in isolation or in combination with left ventricle, aortic valve, and aortic arch abnormalities, an association sometimes referred to as Shone syndrome.[21] A mitral valve abnormality should be suspected when there is a small mitral valve annulus, an abnormal subvalvar apparatus, or mitral regurgitation.

### Left-sided Outflow Lesions

Left sided outflow tract obstruction can occur at the subvalvar, valvar, or supravalvar level (see Chapter 73). Infants of diabetic mothers, especially mothers with poor glucose control, are at risk for hypertrophic cardiomyopathy, with or without significant obstruction.[22] Even in severe cases, the hypertrophy usually regresses by 3 months of age. Valvar aortic stenosis, identified by a thick and doming aortic valve and increased flow velocity across the valve, can be seen in utero and can be associated with left ventricular dysfunction and progressive hypoplasia.

Coarctation of the aorta can be particularly difficult to diagnosis in utero, as imaging of the fetal aortic arch is often limited. Suspicion for coarctation should be raised in the presence of right-left size discrepancy, including a significantly larger tricuspid or pulmonary valve when compared with the mitral or aortic valves, respectively. Aortic isthmus hypoplasia, antegrade diastolic flow in the transverse aortic arch, or retrograde flow in the transverse aortic arch are also important indicators of fetal coarctation (Fig. 70.6). Importantly, any left-sided obstructive lesions in the presence of a female fetus should prompt consideration of Turner syndrome.[23]

## Conotruncal Defects

Conotruncal defects comprise a wide spectrum of abnormalities involving the connection between the ventricles and great arteries (see Chapter 75). Together these lesions comprise a large percentage of significant CHD, some of which are lethal if not detected promptly after birth and underscore the importance of careful interrogation of the outflow tracts on screening cardiac ultrasound. Lesions in this group include transposition of the great arteries (TGA), tetralogy of Fallot, truncus arteriosus, interrupted aortic arch, and double outlet right ventricle; a common unifying factor is typically a conoventricular (outlet) septal defect. With the exception of TGA, any conotruncal defect should raise suspicion for chromosome 22q11 microdeletion (DiGeorge syndrome), a possibility that should be incorporated into prenatal counseling.[24]

Tetralogy of Fallot is the most common form of cyanotic CHD and represents a failure of the conal septum to align properly with the remainder of the ventricular septum. This single embryologic aberration is responsible for the other typical findings, including an overriding aorta, subpulmonary and valvar pulmonary stenosis, and right ventricular hypertrophy (Fig. 70.7).

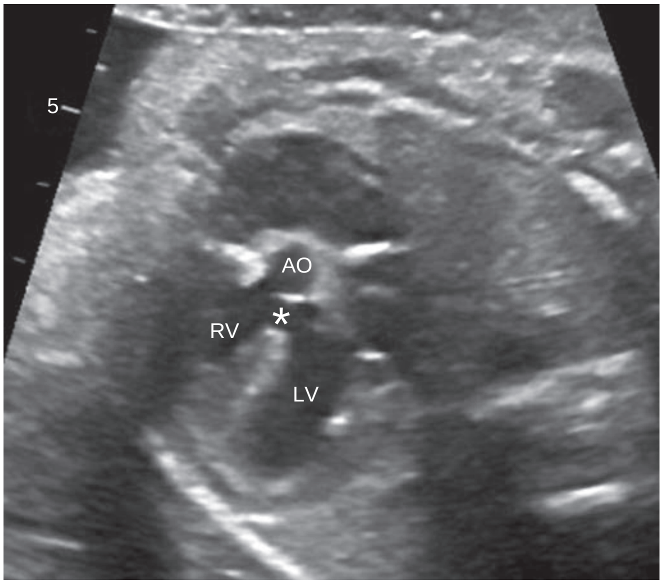

**Figure 70.7. Tetralogy of fallot.** Typical appearance of tetralogy of Fallot and many other conotruncal defects. There is a conoventricular septal defect and an over-riding semilunar valve. *AO,* Aorta; *RV,* right ventricle; *LV,* Left ventricle; * denotes ventricular septal defect.

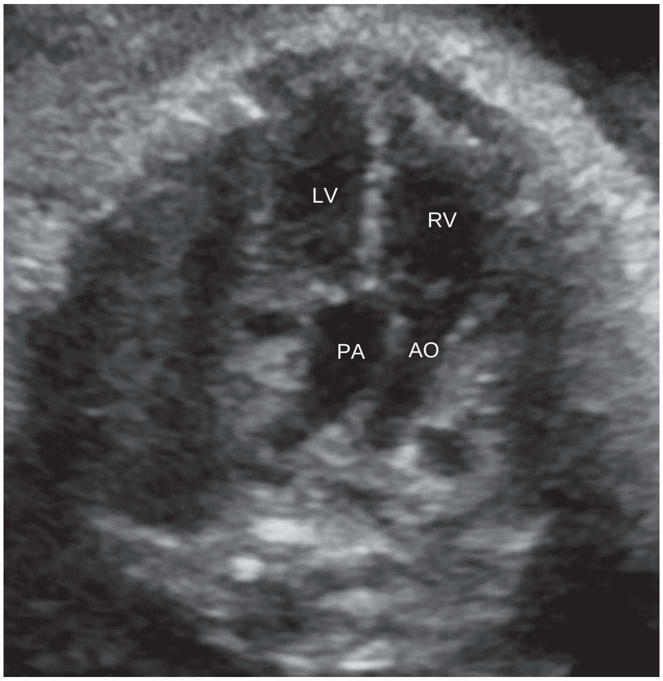

**Figure 70.8. Transposition of the great arteries.** The main pulmonary artery arises from the left ventricle and bifurcates. The aorta arises from the right ventricle. The great vessels appear parallel as they arise from the ventricles. *AO,* Aorta; *LV,* left ventricle; *PA,* pulmonary artery; *RV,* right ventricle.

TGA is the second most common form of cyanotic CHD. In TGA the aorta originates from the right ventricle, and the pulmonary artery arises from the left ventricle. Echocardiography shows parallel great vessels with the aorta located anterior and rightward of the pulmonary artery. The bifurcation of the pulmonary artery can by readily identified as it arises from the left ventricle (Fig. 70.8). Additional abnormalities, such as ventricular septal defects, multilevel pulmonary stenosis, or coarctation of the aorta, may also be identified. It is critically important to recognize that the four-chamber view is normal in TGA, as it is in most conotruncal defects, again underscoring the importance of outflow tract views.

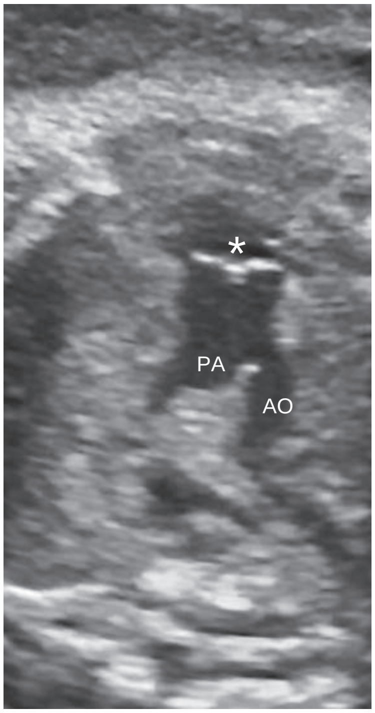

**Figure 70.9. Truncus arteriosus.** This view demonstrates the truncal valve, which gives rise to a vessel that bifurcates into a pulmonary vessel and an aortic vessel. *AO,* Aorta; *PA,* pulmonary artery; * denotes the truncal valve.

In truncus arteriosus, a single outflow tract originates from the heart and bifurcates into aortic and pulmonary branches; there is usually an associated conoventricular septal defect (Fig. 70.9). The truncal (outflow) valve is often abnormal, with significant stenosis or insufficiency possible.

## Ventricular Hypoplasia

Significant underdevelopment of either ventricle can result in single-ventricle CHD, broadly referred to as hypoplastic right or left heart syndromes (HRHS or HLHS) (Fig. 70.10 and Chapter 75). Single-ventricle CHD is usually recognizable on transverse (four-chamber) views of the fetal heart. After birth, patients require staged surgical palliation ultimately resulting in a Fontan-type circulation, wherein the systemic venous blood is rerouted directly into the pulmonary arteries, and the single functional ventricle ejects exclusively into the systemic circulation.

Hypoplastic right heart syndrome can result from tricuspid atresia or pulmonary atresia with an intact ventricular septum (see Chapter 74). Hypoplastic left heart syndrome may have severe aortic and mitral stenosis or atresia and requires complex surgery (Norwood palliation) in the newborn period. While single-ventricle abnormalities represent significant and severe forms of CHD, it is important to recognize that outcomes for infants diagnosed with single-ventricle CHD continue to improve as therapies evolve. Many infants survive well into adulthood with an excellent quality of life.

## Systemic and Pulmonary Venous Abnormalities

Abnormalities of the systemic and pulmonary veins comprise a vast array of entities (see Chapter 71). In isolation, systemic venous

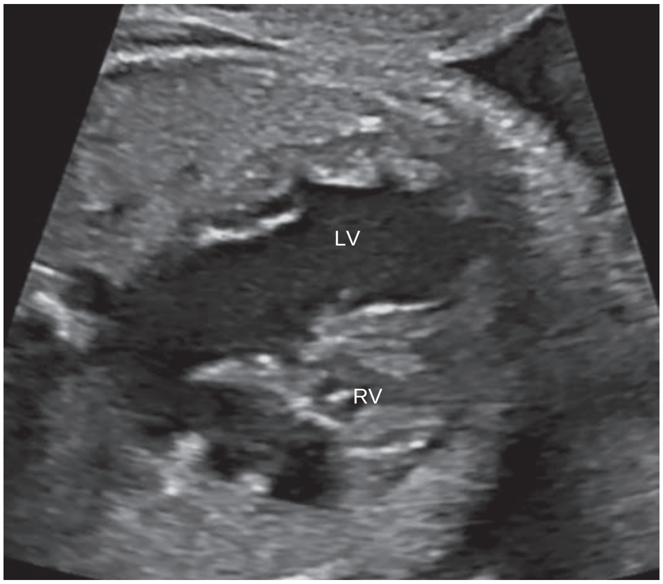

**Figure 70.10. Hypoplastic right heart syndrome (pulmonary atresia with intact ventricular septum).** The right ventricle has severely diminished intracavity volume and is not capable of sustaining the pulmonary circulation. *LV,* Left ventricle; *RV,* right ventricle.

abnormalities often have no clinical consequences, although their presence should prompt a thorough investigation for associated defects. Bilateral superior vena cavae, including persistent left superior vena cava into the coronary sinus is one such common normal variant with no clinical consequence. This should be suspected when there is an abnormal "extra" vessel in the three-vessel trachea view and a dilated coronary sinus. It can also readily be visualized in a short-axis view (e-Fig. 70.11). Postnatal imaging is warranted, however, to evaluate for any subtle abnormalities such as coronary sinus septal defect or bicuspid aortic valve.

Abnormalities of pulmonary veins are often difficult to detect prenatally due to the relatively small amount of flow, approximately 10% of the cardiac output, coursing to the lungs in utero. Usually, two left and two right pulmonary veins connect to the left atrium. Fetal echocardiographic imaging is considered sufficient when one right and one left pulmonary vein is visualized connecting normally to the left atrium with a normal pulsed-wave Doppler pattern (Fig. 70.12). Some or all of the pulmonary veins can drain anomalously to the systemic circulation, called partial or total anomalous pulmonary venous connection (PAPVC or TAPVC), respectively. While PAPVC is difficult to diagnose prenatally, TAPVC should be identifiable with proper technique. Multiple sonographic signs have been identified suggesting TAPVC including a "bald" left atrium, a "twig" sign, and increased left atrium to descending aorta distance (e-Fig. 70.13). In addition, abnormalities in pulmonary venous Doppler have been shown to be diagnostic for abnormal pulmonary venous connection.[25] Although most forms of TAPVC are not associated with perinatal compromise, the infradiaphragmatic form is associated with obstruction to pulmonary venous egress, low cardiac output, and severe perinatal compromise.

## AORTIC ARCH ANOMALIES

Abnormalities of the aortic arch (apart from coarctation of the aorta, discussed earlier) include the relatively benign and normal variant of right aortic arch with mirror image branching but also include vascular rings, including double aortic arch, which can cause aerodigestive difficulties in infancy and childhood (see Chapter 76). Detection of these abnormalities is most readily achieved by utilizing the three-vessel trachea view (Fig. 70.14).

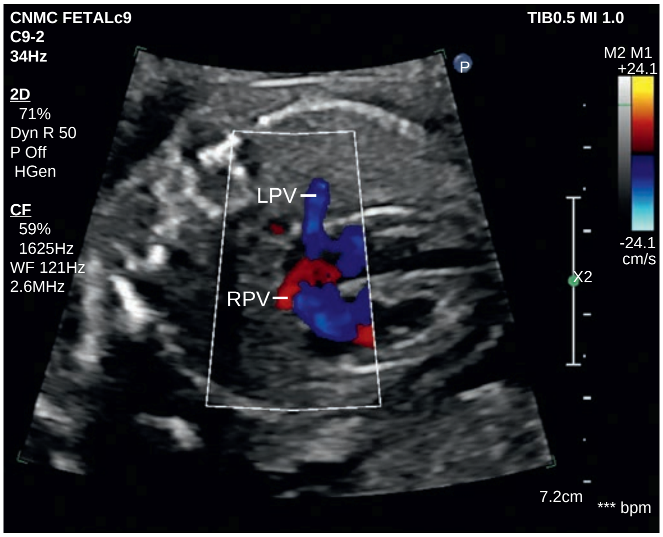

**Figure 70.12. Proper technique for imaging the pulmonary veins.** The pulmonary veins are most easily imaged in a transverse (four-chamber) view of the heart. A relatively narrow color box is placed over the left atrium, and the color scale is decreased. One right and one left pulmonary vein are clearly identified connecting to the left atrium. Pulsed-wave Doppler interrogation should follow. *LPV,* Left pulmonary vein; *RPV,* right pulmonary vein.

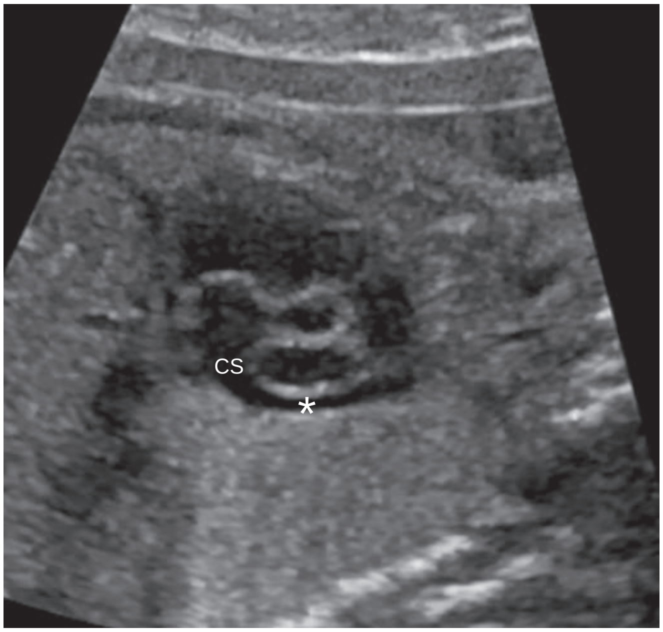
Delineation between right aortic arch and double aortic arch in utero, while possible, may be difficult due to the presence of the fetal ductus arteriosus. Nevertheless, detection of a right aortic arch should raise suspicion for a vascular ring and should prompt evaluation with postnatal echocardiogram and possibly cardiovascular magnetic resonance imaging or computed tomography to accurately assess the aortic arch and related structures. Perhaps most importantly, abnormalities of arch sidedness, including when found in isolation, can be associated with chromosome 22q11 microdeletion syndrome (DiGeorge syndrome).[26] Therefore family counseling as well as prenatal and/or postnatal genetic testing should strongly be considered when such an abnormality is detected.

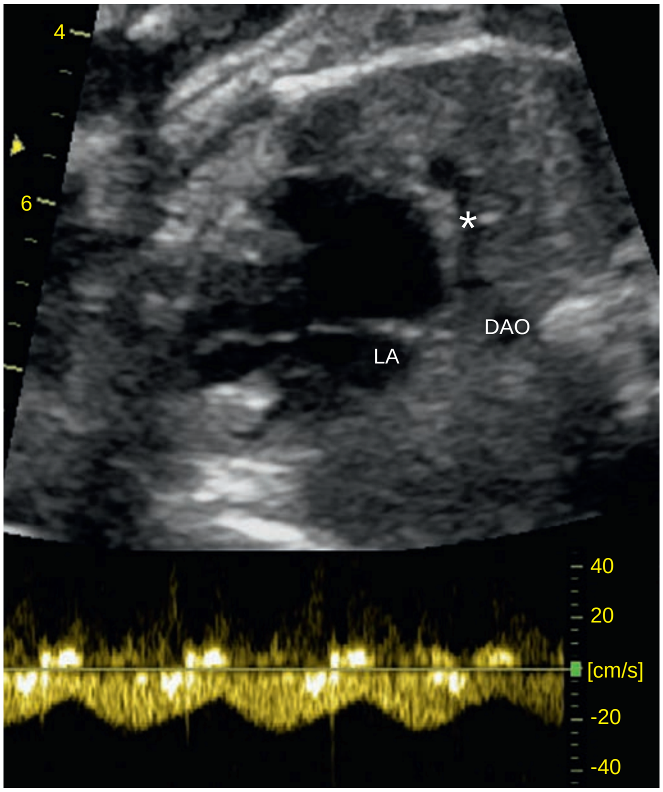
The patent ductus arteriosus is a normal fetal structure; its premature closure can lead to right-sided heart failure in utero. Indomethacin and other nonsteroidal anti-inflammatory drugs predispose to this condition. Another rare abnormality is aneurysm of the ductus arteriosus in utero. In both cases, the heart typically normalizes at delivery, although postnatal evaluation is warranted.[27,28]

### Heterotaxy Syndrome

Heterotaxy syndrome comprises a broad spectrum of abnormalities, the underlying abnormality of which is derangement of the usual laterality of thoracic and abdominal organs.[29] Although often quite complex, the CHD in heterotaxy syndrome is readily delineated with the usual structured fetal echocardiographic examination with meticulous attention to systemic and pulmonary venous abnormalities, atrial and ventricular morphology, and outflow tracts. While often classified into asplenia (bilateral "right-sidedness") or polysplenia (bilateral "left-sidedness") subtypes to accompany the presence or absence of an identifiable spleen, this designation is of limited clinical utility as both subtypes may have splenic dysfunction. More important is the correct identification of the CHD and appropriate subspecialty consultations before and after birth (Fig. 70.15). Of note, polysplenia subtypes may be associated with heart block, which can affect prenatal and perinatal outcomes.[30]



**e-Figure 70.11.** Left superior vena cava to coronary sinus. *CS,* Coronary sinus; * denotes left superior vena cava.



**e-Figure 70.13. Sonographic signs consistent with total anomalous pulmonary venous connection.** The left atrium is "bald" (no pulmonary venous connection), there is increased left atrium-to-descending aorta distance, and there is a "twig" sign, indicating the presence of a pulmonary venous confluence posterior to the left atrium. There is an abnormal pulmonary venous spectral Doppler pattern with a monophasic pulsatile pattern. *DAO,* Descending aorta; *LA,* left atrium; * denotes "twig" sign (pulmonary venous confluence).

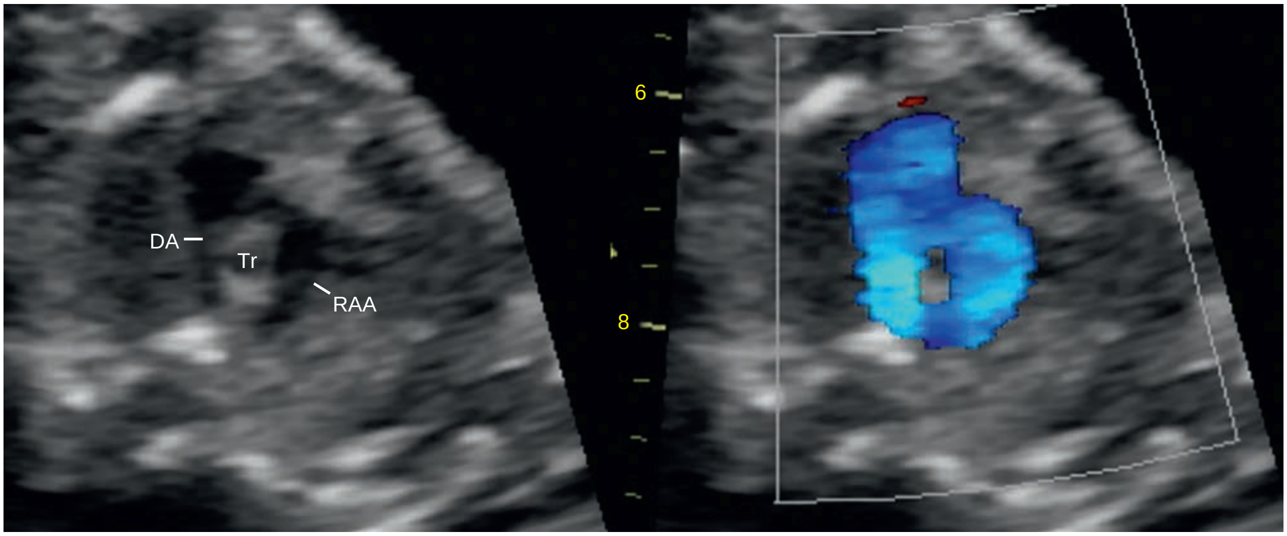


**Figure 70.14. Right aortic arch.** The right aortic arch courses to the right of the trachea, whereas the ductus arteriosus courses to the left of the trachea. Similar findings are likely in the presence of a double aortic arch. *DA,* Ductus arteriosus; *RAA,* right aortic arch; *Tr,* trachea.

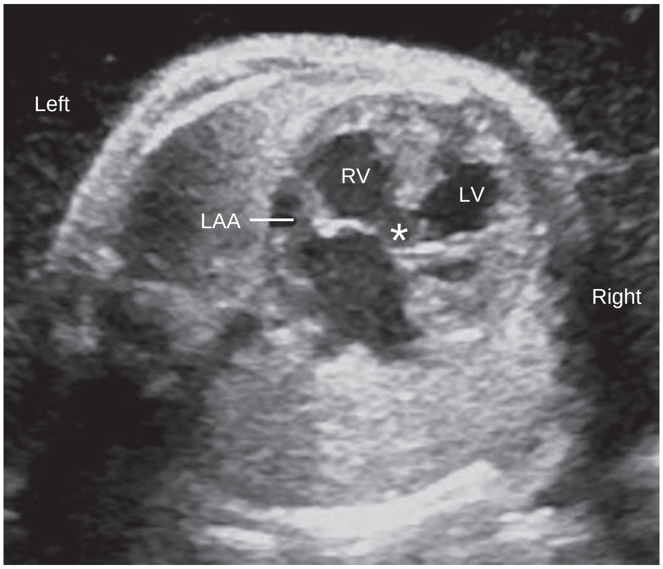

**Figure 70.15. Heterotaxy.** Fetal left and right are labeled. Ventricular inversion is present. There is a balanced atrioventricular canal defect. Bilateral left atrial appendages are present, consistent with polysplenia. *LAA,* Left atrial appendage, *LV*, left ventricle; *RV,* right ventricle; * denotes atrioventricular canal defect.

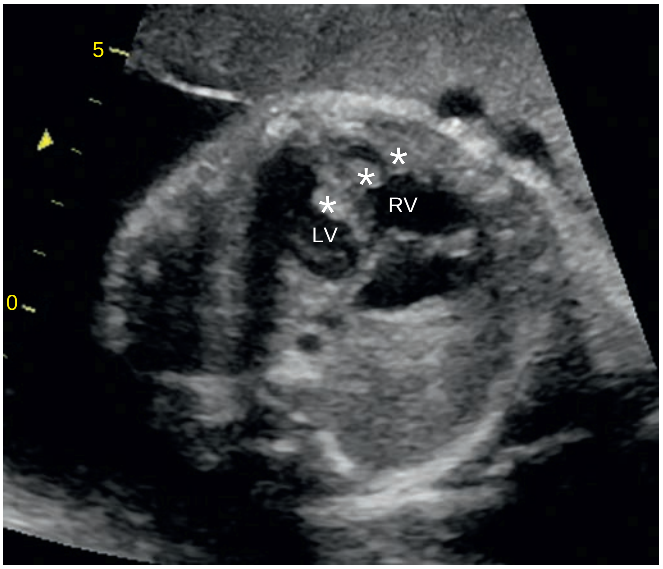

**Figure 70.16. Rhabdomyoma.** Multiple cardiac masses (*) are seen within the right and left ventricular myocardium consistent with rhabdomyomas. Genetic testing revealed the presence of tuberous sclerosis. *LV,* Left ventricle; *RV,* right ventricle.

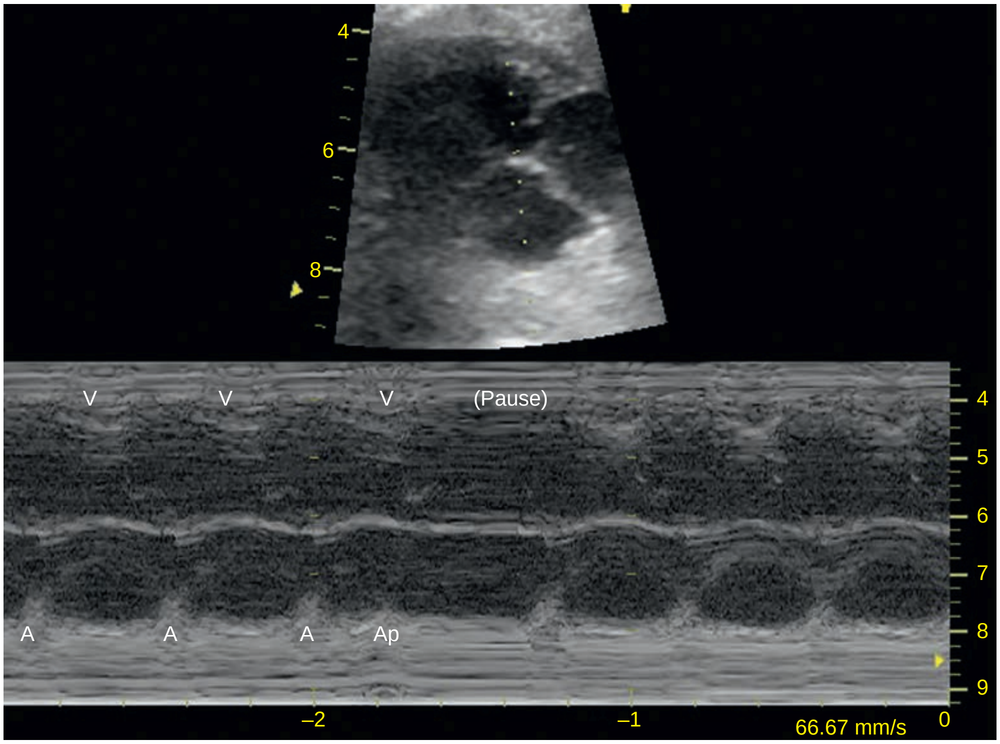
## Cardiac Masses

Echogenic foci associated with the mitral valve chordae and papillary muscles are frequently noted on fetal heart imaging and are of no clinical consequence. Their presence is benign and does not require additional follow-up.[31] Larger or more numerous masses, particularly those found adherent to the atrial wall or embedded in the ventricular myocardium, suggest the presence of cardiac tumors. The most common prenatally identified cardiac tumors are rhabdomyomas (Fig. 70.16 and Chapter 80). These tumors are typically benign and regress in childhood, although they can rarely cause obstruction to inflow or outflow. While the tumors regress, it is important to note that rhabdomyomas have a strong association with tuberous sclerosis.[32,33]

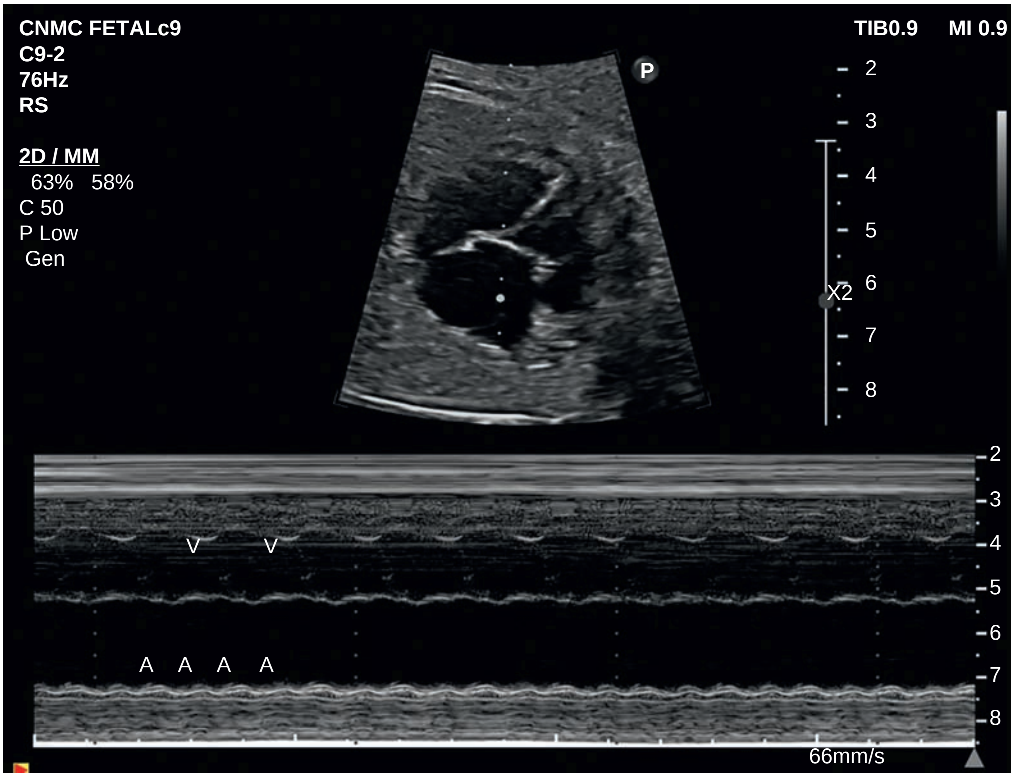
## FETAL ARRHYTHMIAS

Echocardiography can provide accurate diagnosis of fetal arrhythmias.[34,35] Premature atrial contractions (e-Fig. 70.17) are common and usually benign. Supraventricular tachycardia comprises a spectrum of heart rhythm abnormalities, including inappropriate sinus tachycardia, reentrant accessory pathway-mediated tachycardias, atrial flutter and fibrillation, or ectopic atrial tachycardia. M-mode and pulsed-wave Doppler imaging is particularly useful in identifying these arrhythmias (e-Fig. 70.18). Ventricular tachycardia, while less common, can be a sign of fetal compromise or inherited arrhythmia, such as long QT syndrome.

Fetal bradycardia may be benign and is often caused by blocked premature atrial contractions. Complete heart block, a rare



**e-Figure 70.17. Premature atrial contractions as detected by M-mode interrogation.** Three sinus beats are followed by a premature atrial contraction, which is not conducted to the ventricles, resulting in a compensatory pause. *A,* Atrial contractions; *Ap,* premature atrial contraction; *V,* ventricular contraction.



**e-Figure 70.18. Atrial flutter with 2 : 1 atrial to ventricular conduction.** For every two atrial contractions, there is one ventricular contraction. The atrial rate is approximately 440 beats per minute, and the ventricular rate is approximately 220 beats per minute. *A,* Atrial contractions; *V,* ventricular contractions.

complication of fetal exposure to maternal SSA autoantibodies,[36] can be diagnosed by M-mode or pulsed-wave Doppler (e-Fig. 70.19). Serial Doppler assessment of the time between atrial and ventricular contraction is used in maternal SSA antibody carriers to follow the fetal conduction system (e-Fig. 70.20).[37] Sinus bradycardia is also important and may be associated with maternal medication administration (beta-blocker) or possibly an inherited or de-novo genetic predisposition to arrhythmia (long QT syndrome).

## MANAGEMENT OF FETAL CARDIAC DISEASE

### Delivery Planning for Fetuses With Heart Disease

Fetal echocardiography is an exceptionally useful tool for informing families and planning for the delivery of a fetus with a cardiovascular abnormality. Somewhat reassuringly, most forms of structural CHD do not progress in utero and, with thoughtful management, the fetus with heart disease may deliver safely at term in a controlled fashion, even in the presence of ductal-dependent CHD. Some lesions, such as TGA or HLHS with restrictive or intact atrial septum, TAPVC with obstruction, or complete heart block, may merit additional resources in the delivery room and/or highly specialized delivery planning involving multiple subspecialists. Many centers utilize an acuity-level-based system for assessing and planning for the delivery of infants with congenital abnormalities, an approach that has been shown to be both accurate and effective (e-Table 70.1).[18,38]

### Treatment of Fetal Arrhythmias

Fetal arrhythmias in which there is potential for or evidence of compromise are amenable to in utero treatment. Persistent arrhythmias can result in cardiac dysfunction and hydrops if left untreated. Maternal administration of digoxin or flecainide is often successful as a first-line drug in fetuses with many forms of supraventricular tachycardia, although some reports suggest sotalol may be preferable in the treatment of atrial flutter.[39,40] Multidrug therapy or other agents such as amiodarone can be used in refractory cases. Close monitoring of the mother for drug toxicity and the fetus for arrhythmia control is mandatory, and initiation of drug therapy may necessitate hospitalization. Complete heart block is difficult to manage if the rate is low or if there is associated cardiac dysfunction. Screening of a mother with SSA antibodies beginning at approximately 16 weeks is recommended, and if heart block is identified, prompt maternal steroid administration and in some instances intravenous immune globin have been used with some success; however, early delivery if feasible and pacemaker placement may be required if hydrops and fetal compromise is present.

## FETAL INTERVENTIONS FOR STRUCTURAL HEART DISEASE

As previously noted, most CHD changes little throughout gestation. Rarely, however, some lesions progress throughout gestation and may be amenable to percutaneous in-utero intervention. Specifically, fetuses with aortic or pulmonary valve stenosis identified early in the second trimester may have progressive right- or left-heart hypoplasia, ultimately resulting in single-ventricle CHD. For a highly select group of patients, fetal catheter-based intervention to relieve aortic stenosis or pulmonary atresia/stenosis can be considered (Fig. 70.21).[41] The most robust experience with percutaneous fetal cardiac intervention has been for aortic stenosis with evolving HLHS. There is evidence to suggest that progression of left ventricular hypoplasia can be interrupted with appropriately timed intervention in well-selected patients. Among the first 100 patients undergoing fetal aortic valvuloplasty for evolving HLHS, 38 were able to achieve a biventricular circulation, although virtually all patients required multiple catheter-based and/or surgical interventions for left-sided heart disease.[42] Results have also been reported for intervention on HLHS with intact or restrictive atrial septum, pulmonary atresia with intact ventricular septum with evolving HRHS, and dysplastic mitral valve complex.[43,44] Fetal cardiac intervention requires a highly specialized center with multiple care providers for the fetus and mother as well as a thorough understanding of the risks and benefits of such procedures.

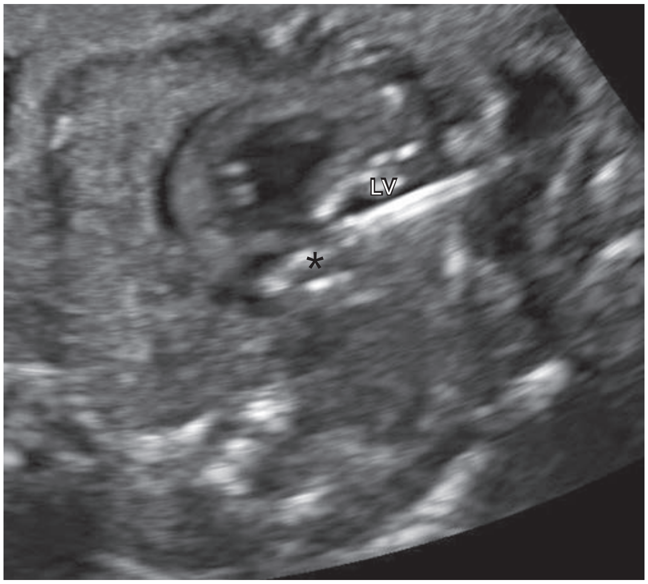


**Figure 70.21. Fetal cardiac intervention for aortic stenosis with evolving hypoplastic left heart syndrome.** Under sonographic guidance, a coronary angioplasty balloon is guided through the maternal abdomen, fetal thoracic wall, and left ventricular myocardium and advanced into the stenotic aortic valve and inflated, relieving aortic stenosis. *LV,* Left ventricle; * denotes coronary angioplasty balloon.

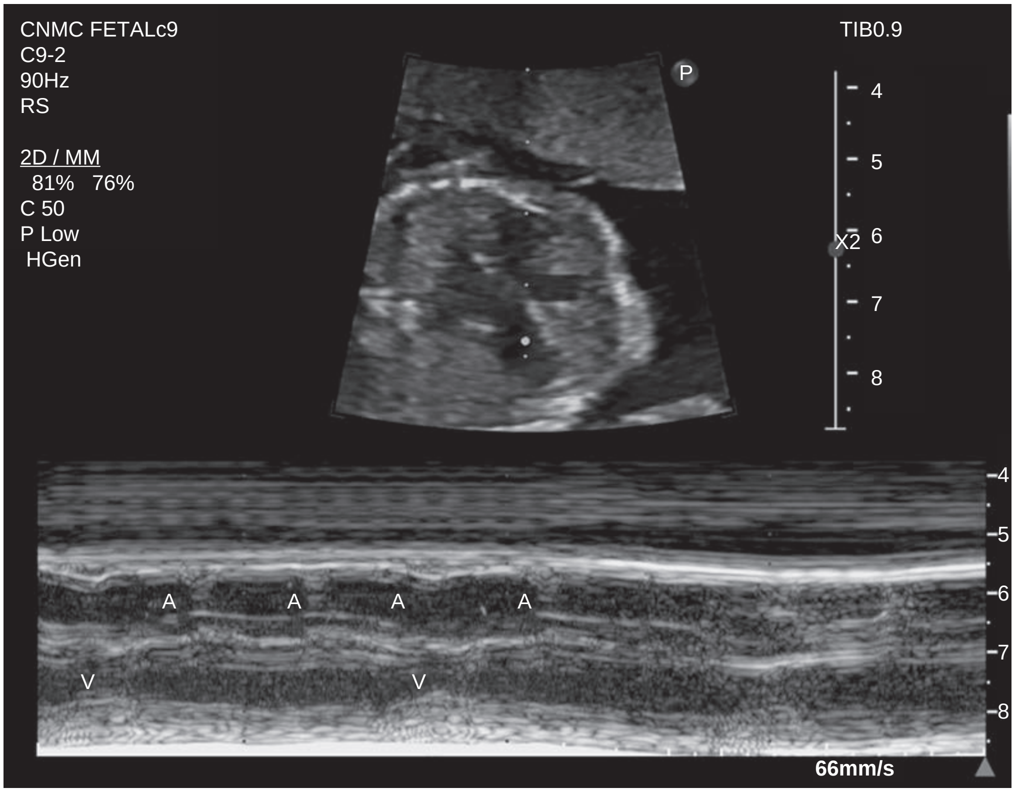
## LIMITATIONS OF FETAL ECHOCARDIOGRAPHY

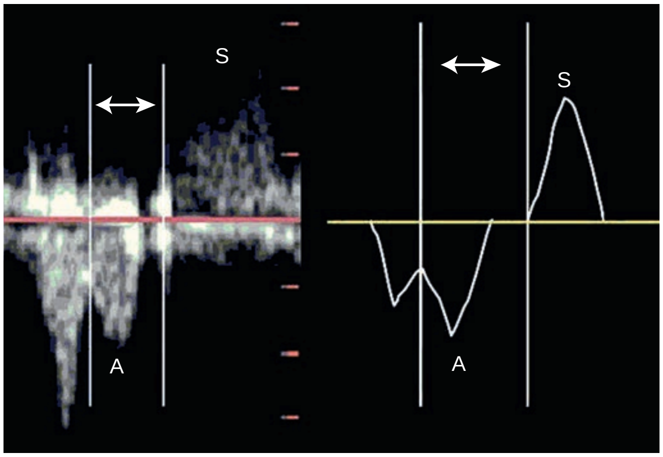
Fetal echocardiography is a highly sensitive and specific diagnostic test; nevertheless, it is important for providers and families that its limitations be well understood. Due to the presence of the foramen ovale, most atrial septal defects are virtually undetectable in the fetal heart. Similarly, subtle abnormalities of pulmonary venous connections, such as PAPVC, are extremely difficult to detect in the fetus. While large ventricular septal defects, particularly in the conotruncal region, should be readily detectable, more subtle perimembranous and muscular ventricular septal defects are difficult or impossible to detect. Similarly, isolated coarctation of the aorta can be difficult to detect given the presence of the fetal ductus arteriosus. Despite these limitations, prenatal detection of significant or critical CHD likely to affect the newborn or young infant is virtually always possible. This realistic framing of the capabilities and limitations of fetal echocardiography will help families understand the results of their diagnostic testing.

## CONCLUSION

Fetal echocardiography is used as an adjunct to other prenatal evaluations, including radiology, genetics, high-risk perinatology, and subspecialty services, to provide a multidisciplinary treatment and counseling approach for fetuses with cardiovascular disease. Detection of most forms of CHD is possible, allowing delivery planning to optimize outcomes. Therapies are available for many arrhythmias, and prenatal intervention is possible for a select group of structural abnormalities.



**e-Figure 70.19. Complete heart block.** There is complete dissociation between atrial and ventricular activity. The atrial rate is approximately 130 beats per minute, and the ventricular rate is approximately 50 beats per minute. *A,* Atrial contractions; *V,* ventricular contractions.



**e-Figure 70.20. Mechanical atrioventricular ("PR") interval.** The interval is calculated by determining the time between atrial systole (the mitral a wave) and ventricular systole, typically delineated by the aortic outflow Doppler. *A,* Atrial systole; *S,* ventricular systole.

**e-TABLE 70.1** Level of Care Assignment and Coordinating Action Plan

| Loc | Definition | Example CHD | Delivery Recommendations | DR Recommendations |
|---|---|---|---|---|
| P | CHD in which palliative care is planned | CHD with severe/fatal chromosome abnormality or multisystem disease | Arrange for family support/ palliative care services<br>Normal delivery at local hospital | |
| 1 | CHD without predicted risk of hemodynamic instability in the DR or first days of life | VSD, AVSD, mild TOF | Arrange cardiology consultation or outpatient evaluation<br>Normal delivery at local hospital | Routine DR care<br>Neonatal evaluation |
| 2 | CHD with minimal risk of hemodynamic instability in DR but requiring postnatal catheterization/surgery | Ductal-dependent lesions, including HLHS, critical coarctation, severe AS, IAA, PA/IVS, severe TOF | Consider planned induction usually near term<br>Delivery at hospital with neonatologist and accessible cardiology consultation | Neonatalogist in DR<br>Routine DR care, initiate PGE if indicated<br>Transport for catheterization/ surgery |
| 3 | CHD with likely hemodynamic instability in DR requiring immediate specialty care for stabilization | d-TGA with concerning atrial septum primum (note: it is reasonable to consider all d-TGA fetuses without an ASD at risk)<br>Uncontrolled arrhythmias<br>CHB with heart failure | Planned induction at 38–39 wk; consider C/S if necessary to coordinate services<br>Delivery at hospital that can execute rapid care, including necessary stabilizing/lifesaving procedures | Neonatologist and cardiac specialist in DR, including all necessary equipment<br>Plan for intervention as indicated by diagnosis<br>Plan for urgent transport if indicated |
| 4 | CHD with expected hemodynamic instability with placental separation requiring immediate catheterization/surgery in DR to improve chance of survival | HLHS/severely RFO or IAS<br>d-TGA/severely RFO or IAS and abnormal DA<br>Obstructed TAPVR<br>Ebstein anomaly with hydrops<br>TOF with APV and severe airway obstruction<br>Uncontrolled arrhythmias with hydrops<br>CHB with low ventricular rate, EFE, and/or hydrops | C/S in cardiac facility with necessary specialists in the DR usually at 38–39 wk | Specialized cardiac care team in DR<br>Plan for intervention as indicated by diagnosis; may include catheterization, surgery, or ECMO |

*APV,* Absent pulmonary valve; *AS,* aortic stenosis; *ASD,* atrial septal defect; *AVSD,* atrioventricular septal defect; *CHB,* complete heart block; *CHD,* congenital heart disease; *C/S,* cesarean section*; d-TGA,* transposition of the great arteries, *DA,* ductus arteriosus; *DR,* delivery room; *ECMO,* extracorporeal membrane oxygenation; *EFE,* endocardial fibroelastosis; *HLHS,* hypoplastic left heart syndrome; *IAA,* interrupted aortic arch; *IAS,* intact atrial septum; *LOC,* level of care; *PA/IVS,* pulmonary atresia/intact ventricular septum; *PGE,* prostaglandin; *RFO,* restrictive foramen ovale; *TAPVR,* total anomalous pulmonary venous return; *TOF,* tetralogy of Fallot; *VSD,* ventricular septal defect.

## KEY POINTS

- Congenital abnormalities of the heart are the most common birth defects, occurring in approximately 8 of every 1,000 newborns. Approximately 25% of those in whom a cardiac abnormality is identified have critical CHD, with risk for serious morbidity or mortality in the perinatal period.
- A structured examination of the fetal cardiac anatomy and physiology allows identification of most forms of CHD, providing the opportunity to plan proper perinatal cardiac care to optimize outcomes.
- The optimal timing for imaging the fetal heart is 20 to 28 weeks' gestation, although imaging before and after this window is possible.
- Therapies are available for many fetal arrhythmias, and prenatal intervention is possible for a select group of structural abnormalities. With proper medical and surgical care, outcomes for the overwhelming majority infants and children with heart defects, including those with single-ventricle CHD, are excellent.

## PART 3 Congenital and Cardiovascular Abnormalities

# 71

# Abnormal Pulmonary and Systemic Venous Connections

*Joyce T. Johnson, Angira Patel, Brian Reilly, and Cynthia K. Rigsby*

## PARTIAL ANOMALOUS PULMONARY VENOUS CONNECTION AND SCIMITAR SYNDROME

***Overview.*** Partial anomalous pulmonary venous connection (PAPVC) is present when one or more pulmonary veins drain into a systemic vein. Because a single anomalous connection may be unrecognized, the incidence is difficult to establish, but it has been reported to be present in 1 in 200 postmortem examinations.[1,2]

***Etiology, Pathophysiology, and Clinical Presentation.*** All pulmonary veins from one lung may have anomalous drainage or parts of the lung may have anomalous drainage to the same or different systemic veins. Anomalous drainage of the left pulmonary veins is most often to the brachiocephalic vein or coronary sinus.[3] On the right, anomalous drainage is most often to the superior vena cava (SVC), right atrium, or inferior vena cava (IVC).[4] When there is anomalous pulmonary venous drainage of all the right pulmonary veins or just the middle and lower lobe veins to the IVC, scimitar syndrome is present. Other anomalies associated with scimitar syndrome include hypoplasia of the right lung and bronchial system, hypoplasia of the right pulmonary artery, systemic arterial supply to the right lower lung, and pulmonary sequestration.[5–8]

Approximately 67% of patients with partial anomalous pulmonary venous return also have atrial-level defects, most commonly a sinus venosus defect (see Chapter 72).[9] Sinus venosus defects are not true atrial septal defects (ASDs) but occur as a result of deficiency of the wall between the SVC and the right upper pulmonary veins or of the wall between the right atrium and the right upper or lower pulmonary veins. Thus a superior sinus venosus defect is associated with anomalous drainage of the right pulmonary veins to the SVC or to the right atrium.

Anomalous connection of one pulmonary vein usually is not clinically apparent in childhood, but these patients may present in the third and fourth decades with cyanosis resulting from increased pulmonary vascular resistance.[10] If all but one of the pulmonary veins drains anomalously, the clinical manifestations may be similar to total anomalous pulmonary venous connection. If an anomalous pulmonary venous connection is associated with a sinus venosus defect, signs and symptoms usually are related to the amount of shunting through the defect. Patients with scimitar syndrome may present in infancy with pulmonary hypertension from the arterial supply to the right lower lung, stenosis of the anomalous pulmonary veins, or pulmonary infections. Otherwise, this syndrome may be detected in adulthood in patients who do not have significant symptoms.[11]

***Imaging.*** With anomalous drainage of multiple veins, cardiomegaly with right heart enlargement and increased pulmonary flow are seen on chest radiography. Findings with scimitar syndrome include a crescent-shaped anomalous pulmonary vein (resembling a Turkish sword or scimitar) paralleling the lower right heart border (Fig. 71.1). Patients generally have associated hypoplasia of the right lung, a small right pulmonary artery, and varying degrees of cardiac dextroposition.

Cross-sectional imaging goals include identifying the anomalous pulmonary to systemic venous connection, locating each pulmonary vein and its drainage relative to the left atrium, and determining the location of venous obstruction, if present (e-Fig. 71.2). Evaluation for the presence and size of either an ASD or sinus venosus defect is necessary (e-Figs. 71.3 and 71.4). The heart and great vessels are evaluated for other abnormalities, and when scimitar syndrome is present, the upper abdomen should be assessed for anomalous venous drainage and systemic arterial supply to the lung (Fig. 71.5). Both computed tomography (CT) and magnetic resonance imaging (MRI) are highly sensitive and specific for evaluation of anomalous pulmonary venous drainage, and three-dimensional CT or magnetic resonance angiography (MRA) is very useful for identifying the relationship between the anomalous pulmonary veins and the left atrium.[12,13] MRI also is useful for ASD evaluation and for quantification of systemic to pulmonary shunting. CT and MRI are accurate in assessing for postoperative pulmonary vein obstruction or narrowing (e-Fig. 71.6).[13–15]

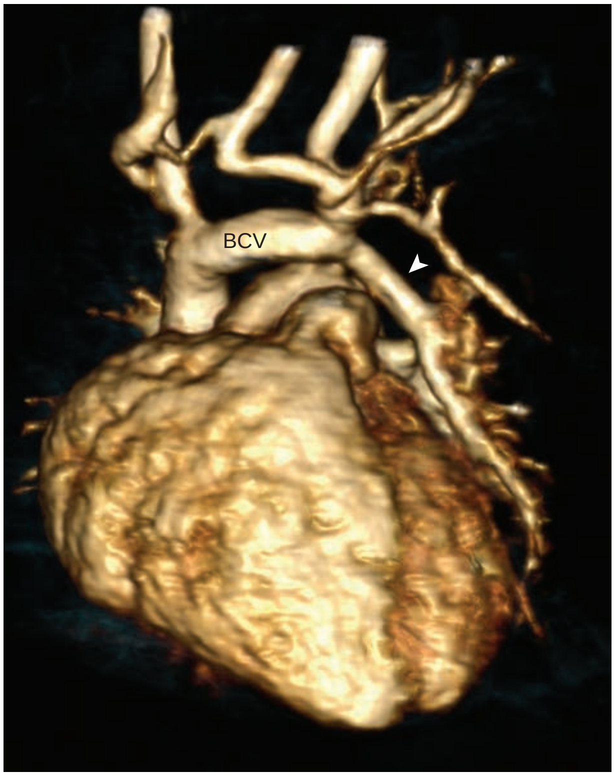
***Treatment.*** Surgical correction is indicated when the ratio of pulmonary to systemic arterial flow is greater than 1.5 : 1; outcomes generally are excellent.[4] In patients with scimitar syndrome, pulmonary resection or catheter occlusion of the anomalous arterial blood supply may be necessary. The anomalous vein in patients with scimitar syndrome may be anastomosed directly to the left atrium.

Superior sinus venosus defects may be closed with a patch at the junction of the SVC and right atrium, with baffling of the pulmonary venous return to the left atrium. Alternatively, the SVC is divided above the pulmonary veins, with implantation of the SVC to the right atrial appendage and baffling of the SVC orifice with the right pulmonary venous return to the left atrium. The incidence of postoperative SVC or pulmonary vein stenosis is less than 10%.[16]

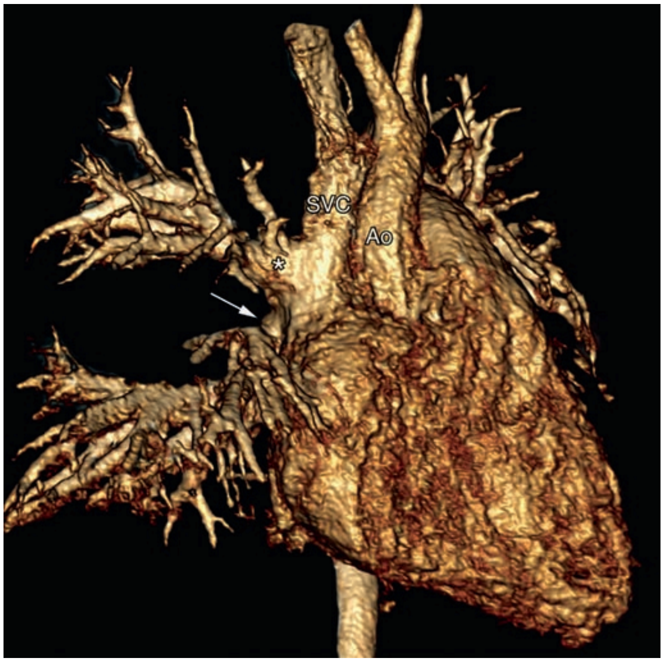
## TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

***Overview.*** Total anomalous pulmonary venous connection (TAPVC) is a congenital anomaly in which all of the pulmonary veins connect to the systemic venous circulation rather than to the left atrium. TAPVC accounts for approximately 1% to 5% of all congenital heart disease.[17,18] TAPVC often is present in patients with visceral heterotaxy and asplenia and single-ventricle physiology.[18]

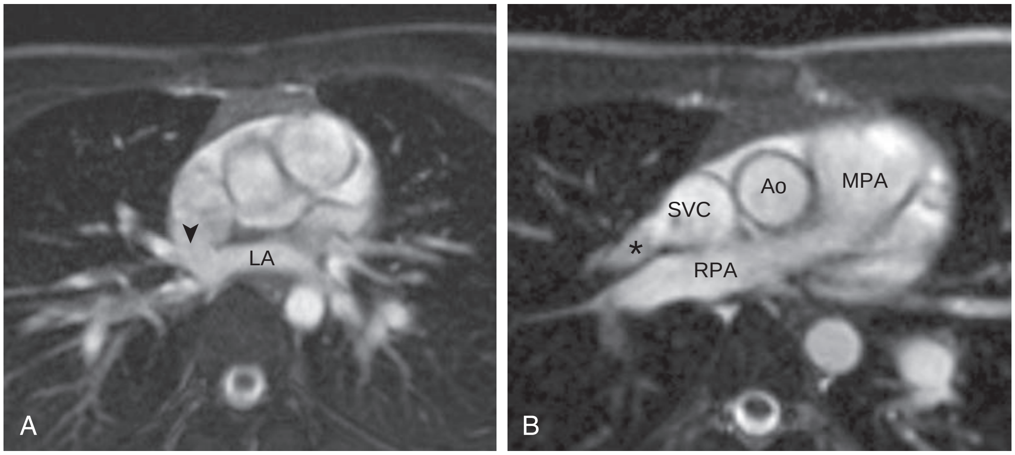
***Etiology, Pathophysiology, and Clinical Presentation.*** The cause of TAPVC is thought to be lack of incorporation of the common pulmonary vein into the left atrium. In type I or supracardiac TAPVC (49% of cases), all four pulmonary veins join to form a confluence posterior to the left atrium and then most commonly connect to a persistent left vertical vein, which drains to the left brachiocephalic vein and to the right SVC or via the right vertical vein to the right SVC. In type II or cardiac TAPVC (16% of cases), the pulmonary veins form a confluence that drains either



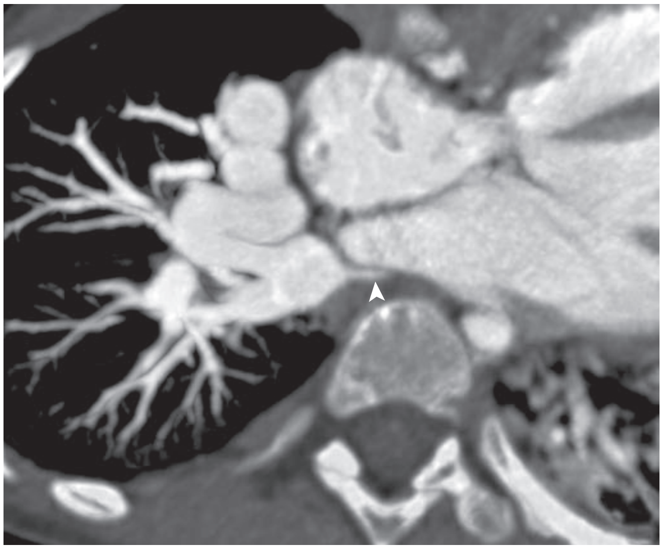
**e-Figure 71.2. Partial anomalous pulmonary venous connection (PAPVC).** A three-dimensional magnetic resonance angiogram viewed from the left anterior oblique projection shows the PAPVC *(arrowhead)* from the left upper lobe with drainage to the left brachiocephalic vein *(BCV)*.



**e-Figure 71.3. Partial anomalous pulmonary venous return in the setting of a superior sinus venosus defect.** A right anterior oblique three-dimensional magnetic resonance angiogram shows the right upper pulmonary veins *(asterisk)* draining to the SVC and the right middle lobe pulmonary veins *(arrow)* draining to the SVC at the level of the sinus venosus defect. *Ao,* Aorta; *SVC,* superior vena cava.



**e-Figure 71.4. Sinus venosus defect with partial anomalous pulmonary venous return.** (A) An axial cine steady-state free-precession (SSFP) image shows the sinus venosus defect *(arrowhead)* located superior to the expected location of the oval fossa, consistent with a superior sinus venosus defect. (B) Oblique axial SSFP located superior to (A) showing the right upper pulmonary vein *(asterisk)* draining to the superior vena cava. *Ao,* Aorta; *LA,* left atrium; *MPA,* main pulmonary artery; *RPA,* right pulmonary artery; *SVC,* superior vena cava.



**e-Figure 71.6. Severe right pulmonary vein stenosis.** A computed tomography axial oblique reformat performed 5 years after repair of obstructed supracardiac total anomalous pulmonary venous connection with separate anastomoses of the right and left pulmonary veins to the left atrium. Severe right pulmonary vein stenosis *(arrowhead)* is present at the anastomotic site.

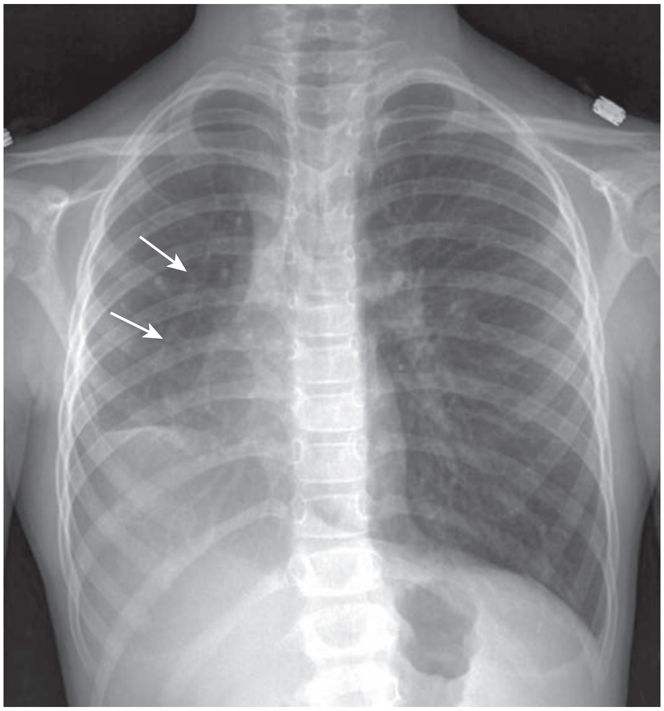


**Figure 71.1. Scimitar syndrome.** A frontal chest radiograph shows the rightward shift of the mediastinum as a result of right lung hypoplasia. In the right side of the chest, a linear density indicative of the anomalous draining "scimitar" vein is seen *(arrows)*.

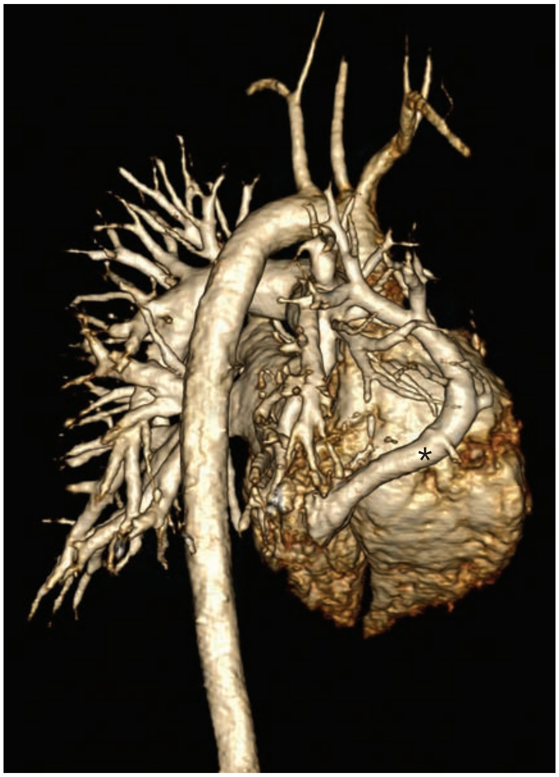

**Figure 71.5. Scimitar syndrome.** A three-dimensional magnetic resonance angiogram viewed from right posterior oblique shows the anomalously draining right pulmonary "scimitar" vein *(asterisk)* draining to the inferior vena cava.

directly into the right atrium or to the coronary sinus, which then drains normally into the right atrium. In type III or infracardiac TAPVC (26% of cases), the pulmonary veins converge as a common pulmonary vein that extends below the diaphragm and drains to the portal vein, ductus venosus, hepatic vein, or IVC. Type IV TAPVC (9% of cases) is a mixed type in which the pulmonary veins drain separately to at least two different systemic sites, most commonly supracardiac and cardiac sites (e-Fig. 71.7 and Fig. 71.8).[20]

Obstruction occurs in 46% of patients with supracardiac TAPVC as the left vertical vein passes between the left pulmonary artery and left mainstem bronchus or as the right vertical vein crosses between the right pulmonary artery and right mainstem bronchus or at its entrance into the right SVC.[17,20] With cardiac TAPVC, obstruction is not nearly as frequent (20%).[20] With infracardiac TAPVC, obstruction is common (87%) and can occur at the level of the diaphragm and/or at the site of anomalous systemic venous insertion, including the ductus venosus or the hepatic sinusoids.[17,20]

Pulmonary venous obstruction dictates the clinical presentation and physiology.[17] Patients without pulmonary venous obstruction generally present with symptoms later in the newborn period or in infancy or childhood.[18,20] Symptoms can be nonspecific and include tachypnea, feeding difficulties, repeated respiratory infections, and failure to thrive.[10] The anomalous venous connection acts as a large left-to-right shunt with a marked increase in pulmonary blood flow, especially after the pulmonary vascular resistance drops normally after birth. All patients with TAPVC have either a patent foramen ovale or an ASD. The atrial connection can be small and can contribute to venous obstruction. When pulmonary venous flow is obstructed, pulmonary blood flow is limited, leading to pulmonary venous hypertension and congestion. Because the amount of blood flowing through the pulmonary circuit is not increased, inadequate oxygenation occurs. Patients with this disorder typically present in the neonatal period, often shortly after birth, with marked cyanosis and cardiorespiratory failure.

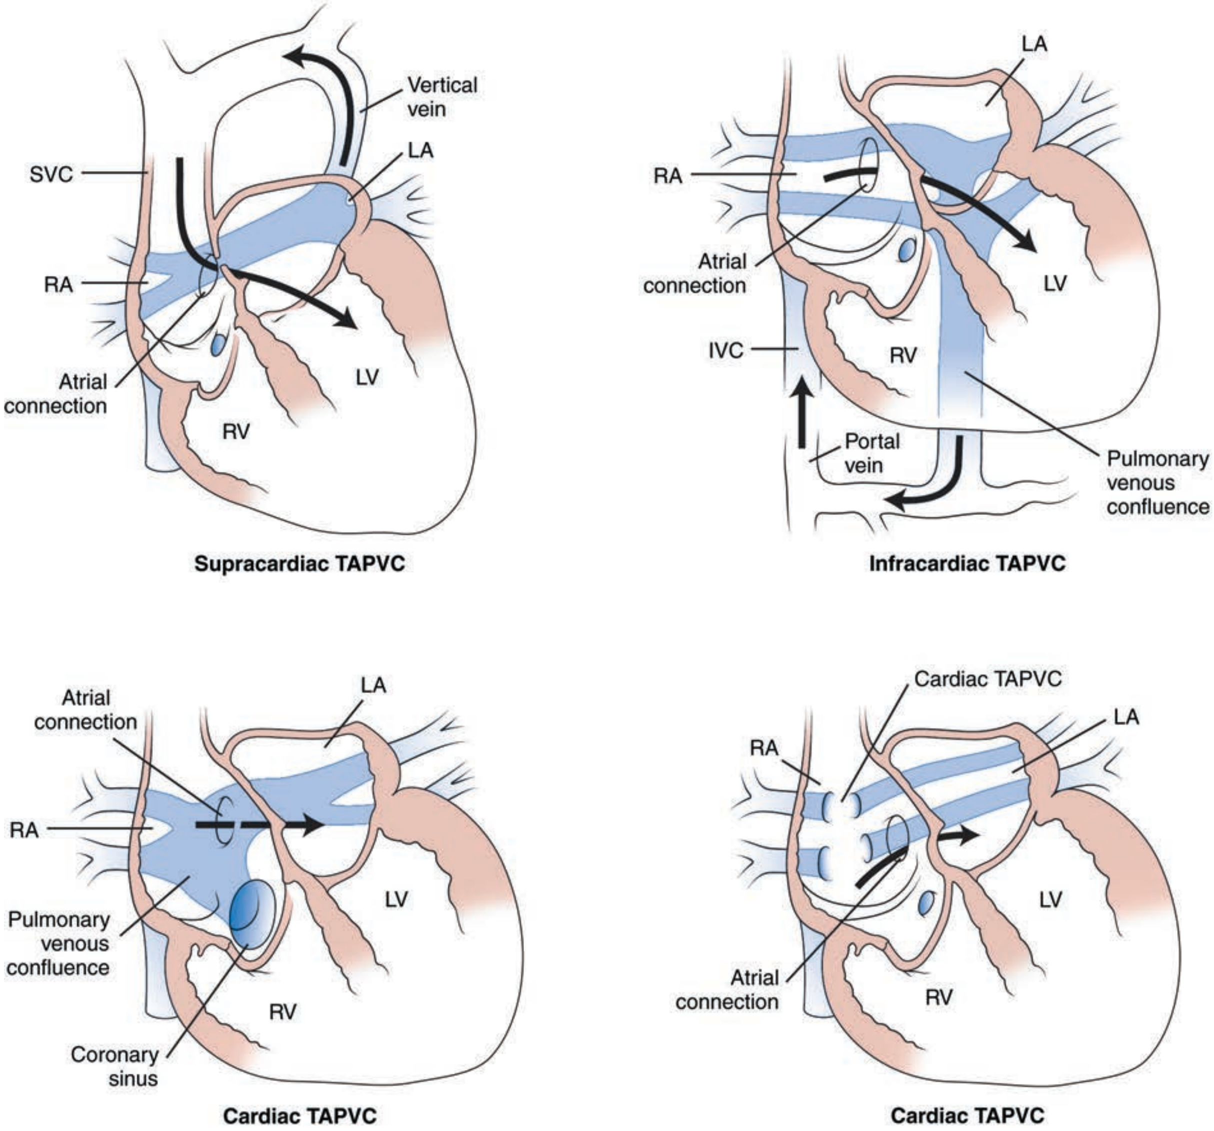
***Imaging.*** Chest radiographic findings in TAPVC without obstruction include increased pulmonary vascularity because of the marked left-to-right shunt, along with main pulmonary artery and right heart enlargement. Occasionally, the anomalous course of a pulmonary vein or the vertical course of a dilated left vertical vein may be seen (Fig. 71.9). In patients with obstructed pulmonary venous flow, the chest radiograph shows pulmonary venous congestion, and because of the decreased inflow to the left heart, the heart often is not enlarged (Fig. 71.10). Cross-sectional imaging goals are as listed in the PAPVC imaging section.

***Treatment.*** Patients with obstructed TAPVC and unstable hemodynamics must undergo urgent repair because no effective medical management options are available. Timing of repair for patients without venous obstruction can be more elective. The surgical objective is to redirect pulmonary venous flow to the left atrium, remove the anomalous connection or connections, and close the ASD. Long-term outcome is excellent after repair, with 5-year survival rates of up to 97%.[21] The major postoperative complication is persistent or progressive pulmonary venous obstruction in 15% to 19% of patients.[18,20]

## COR TRIATRIATUM AND OTHER ANOMALIES OF THE PULMONARY VEINS

***Overview.*** Cor triatriatum sinister is rare, representing only 0.1% to 0.4% of congenital heart disease cases.[22,23] It is associated with other cardiac anomalies in 12% to 50% of cases.[24]

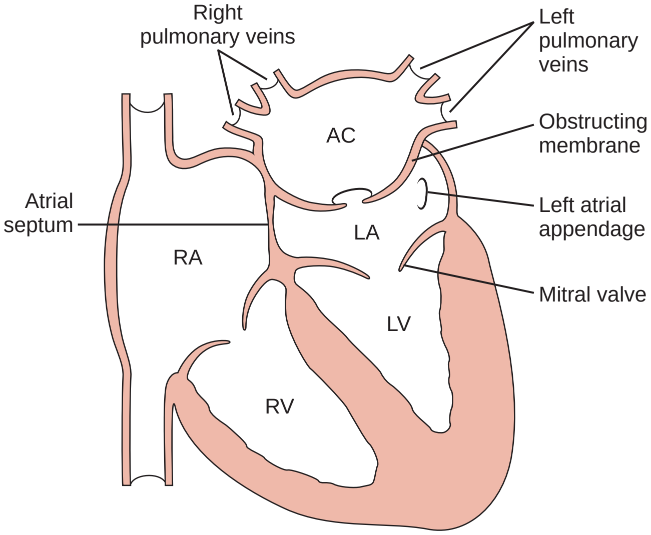
***Etiology, Pathophysiology, and Clinical Presentation.*** In cor triatriatum, the pulmonary veins connect to an accessory left atrial chamber, which is separated from the true left atrium by a fibromuscular membrane with a typically small, obstructed opening (e-Fig. 71.11).[23] An ASD may be present. The embryology is



**Supracardiac TAPVC** **Infracardiac TAPVC**

**Cardiac TAPVC** **Cardiac TAPVC**

**e-Figure 71.7. Darling classification of total anomalous pulmonary venous connection (TAPVC).** With supracardiac TAPVC, pulmonary venous connection is to a vertical vein, draining to the left brachiocephalic vein and superior vena cava *(SVC)*. With infracardiac TAPVC, the pulmonary veins connect to a systemic venous vessel below the diaphragm (the portal vein in this diagram). With cardiac TAPVC, the pulmonary veins connect either to the coronary sinus or directly to the right atrium *(RA)*. The direction of systemic blood flow *(dark arrows)* is shown. Note that blood must flow through an atrial connection to reach the left side of the heart. *IVC,* Inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle. *(From Wilson A. Total anomalous pulmonary venous connection,* E-Medicine, *March 28, 2006.)*



**e-Figure 71.11. Diagram of cor triatriatum.** An accessory chamber *(AC)* of the left atrium *(LA)* is present, with an obstructing membrane in between. Note that the mitral valve and the left atrial appendage are part of the true LA. *LV,* Left ventricle; *RA,* right atrium; *RV,* right ventricle.

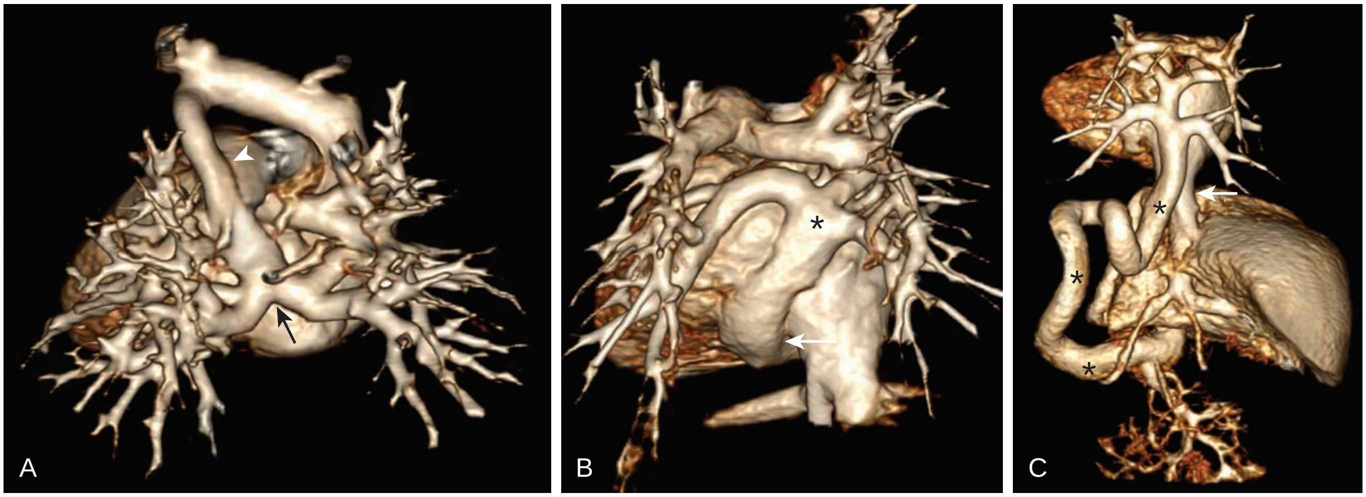


**Figure 71.8. Three-dimensional computed tomography angiogram posterior views of different types of total anomalous pulmonary venous connection (TAPVC).** (A) Supracardiac TAPVC. The pulmonary venous confluence *(arrow)* connects to the ascending vertical vein, the enlarged left brachiocephalic vein, and the enlarged superior vena cava. (B) Cardiac TAPVC. The pulmonary venous confluence *(asterisk)* connects to the coronary sinus *(arrow)*. (C) Infracardiac TAPVC. The pulmonary venous confluence extends below the diaphragm via a tortuous descending vertical vein *(asterisks)* to drain to the portal vein and inferior vena cava *(arrow)*.

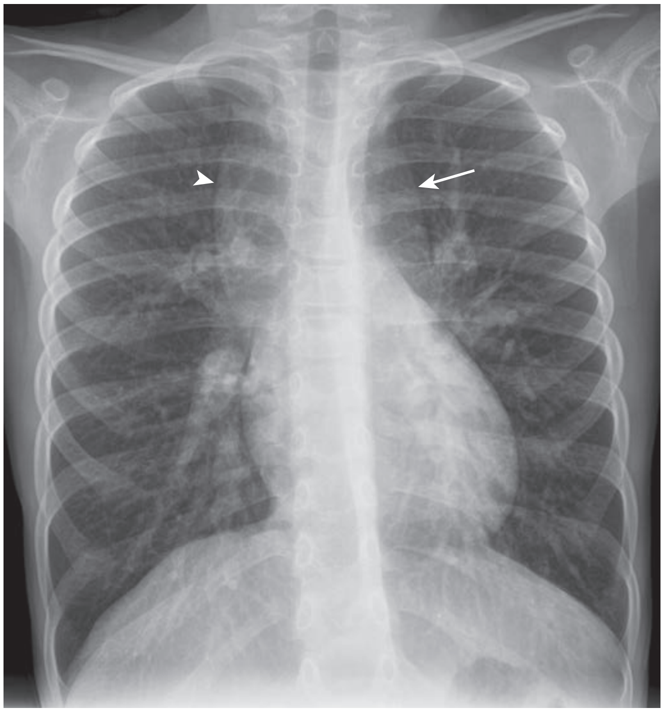

**Figure 71.9. Total anomalous pulmonary venous connection (TAPVC).** A chest radiograph in a 12-year-old with nonobstructed supracardiac TAPVC shows a "snowman" heart as a result of an enlarged left vertical vein *(arrow)* and superior vena cava *(arrowhead)*.

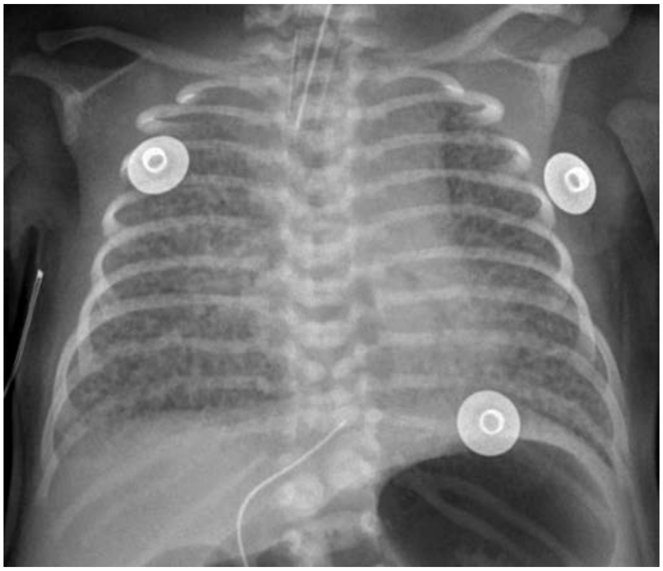

**Figure 71.10. Obstructed total anomalous pulmonary venous connection (TAPVC).** A chest radiograph in a newborn with obstructed TAPVC shows a normal heart size and pulmonary edema pattern as a result of venous obstruction.

thought to result from incomplete incorporation of the common pulmonary vein into the left atrium, and the accessory chamber represents the embryologic common pulmonary vein.[25] Localized stenosis, hypoplasia, or atresia of individual or all pulmonary veins also can occur, with abnormal absorption of the common pulmonary vein into the left atrium.[26] With these variants, an accessory left atrial chamber does not exist, but there is either focal stenosis of pulmonary veins near the left atrial junction, diffuse long-segment hypoplasia or narrowing of individual pulmonary veins, or unilateral or bilateral atresia of the common pulmonary vein or of individual pulmonary veins in extreme cases.[27]

Because of the typically obstructed opening between the accessory left atrium and the true left atrium, the predominant physiology is that of pulmonary venous obstruction. With small openings and more severe obstruction, patients tend to present in the neonatal period with low cardiac output and right heart failure.[28] With larger, less obstructed openings, patients may not present with symptoms until older childhood or even adulthood. Complete atresia of all the individual pulmonary veins is not compatible with life unless significant bronchopulmonary venous collaterals are present (e-Fig. 71.12).[29]

***Imaging.*** The chest radiograph may show evidence of right ventricular enlargement and pulmonary edema related to the pulmonary venous obstruction. Enlargement of the left atrial region, representing both left atrial chambers, also may be present.

Cross-sectional imaging goals include evaluation of the two left atrial chambers and the intervening membrane and complete evaluation of the pulmonary veins and the relationship of the veins to the membrane (Fig. 71.13). CT is ideal for evaluation of pulmonary vein stenosis and for evaluation of the lung.[30,31]

***Treatment.*** Surgery for cor triatriatum is generally performed as soon as the diagnosis is made. The intervening septum of the left atrium is resected and, if an ASD is present, it is closed. The prognosis is good for patients who survive the perioperative period and who have no associated cardiac anomalies.[28] Operative management of individual pulmonary vein hypoplasia, stenosis, or atresia is variable, and balloon angioplasty has led to disappointing results.[32,33] Atresia of the common pulmonary vein with a sizable pulmonary venous confluence may be repaired, similar to TAPVC.[34,35]

## ANOMALIES OF SYSTEMIC VENOUS CONNECTIONS

Abnormal systemic venous connections represent a heterogeneous group of malformations with clinical manifestations that can range from none to severe desaturation.

### Anomalies of the Superior Vena Cava

Persistence of the left SVC results from failure of the left anterior and left common cardinal veins to involute.[36] In patients with congenital heart disease, the incidence varies from 11% to 34%.[37,38] Bilateral SVCs usually have normal drainage, with the right SVC into the right atrium and the left SVC to the coronary sinus and the right atrium (92%); however, abnormal drainage to the left atrium via an unroofed coronary sinus occurs in 8% of cases (e-Fig. 71.14).[39] Although bilateral SVCs with normal drainage have no hemodynamic consequences, they can have technical implications for cardiac catheterization or surgery. Abnormal SVC drainage into the left atrium can result in cyanosis. A left SVC may be suspected based on a shadow in the left upper border of the mediastinum on a chest radiograph. Imaging will show an associated dilated coronary sinus, and the caliber of the brachiocephalic vein is inversely proportional to the size of the left SVC (Fig. 71.15). In some cases, the brachiocephalic vein is absent when a left SVC is present.

### Anomalies of the Inferior Vena Cava and Hepatic Veins

IVC anomalies include interrupted IVC, which is defined by the absence of the hepatic or suprahepatic segment of the IVC with azygous or hemiazygous continuation into the right or left SVC (e-Fig. 71.16)[40] and is seen in up to 86% of patients with visceral heterotaxy and polysplenia.[41] Patients with asplenia usually have a normal IVC but can have a prominent azygous vein and separate drainage of the hepatic veins into the right atrium (e-Fig. 71.17).[42,43]

### Anomalies of the Brachiocephalic Veins

The normal course of the left brachiocephalic vein is obliquely downward to the right, passing anterior to the aortic arch. A retroaortic brachiocephalic vein is characterized by an abnormal position behind the ascending aorta (e-Fig. 71.18).[44] An anomalous retroesophageal brachiocephalic vein is characterized by an abnormal course posterior to the trachea and esophagus, and joining the azygous vein before draining to the SVC (e-Fig. 71.19).[45]

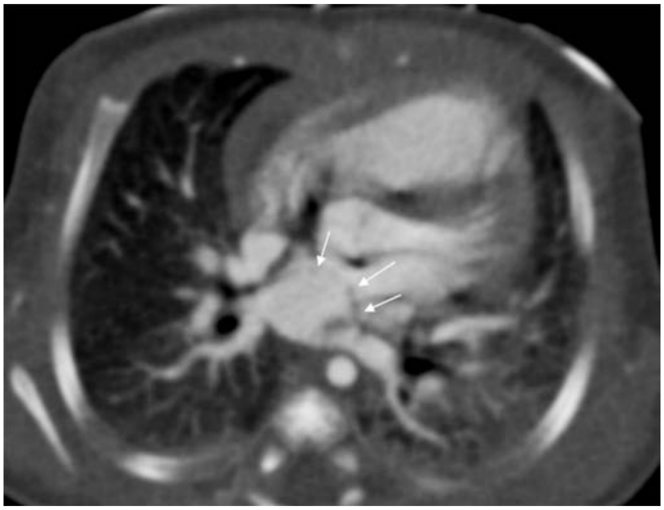

**Figure 71.13. Cor triatriatum.** Axial contrast-enhanced computed tomography (CT) image showing a linear membrane in the left atrium upstream from the mitral valve *(arrows)*. The pulmonary veins enter the left atrium proximal to the membrane are separated from the true left atrium by the membrane.

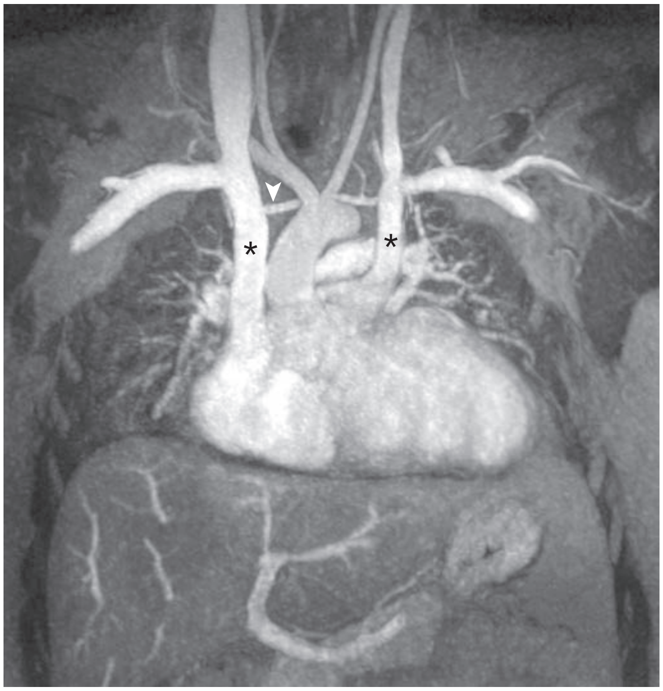

**Figure 71.15. Left superior vena cava.** A coronal thick maximum intensity projection MRA showing bilateral superior vena cavae (SVCs) *(asterisks)*. A small bridging vein is present *(arrowhead)*.

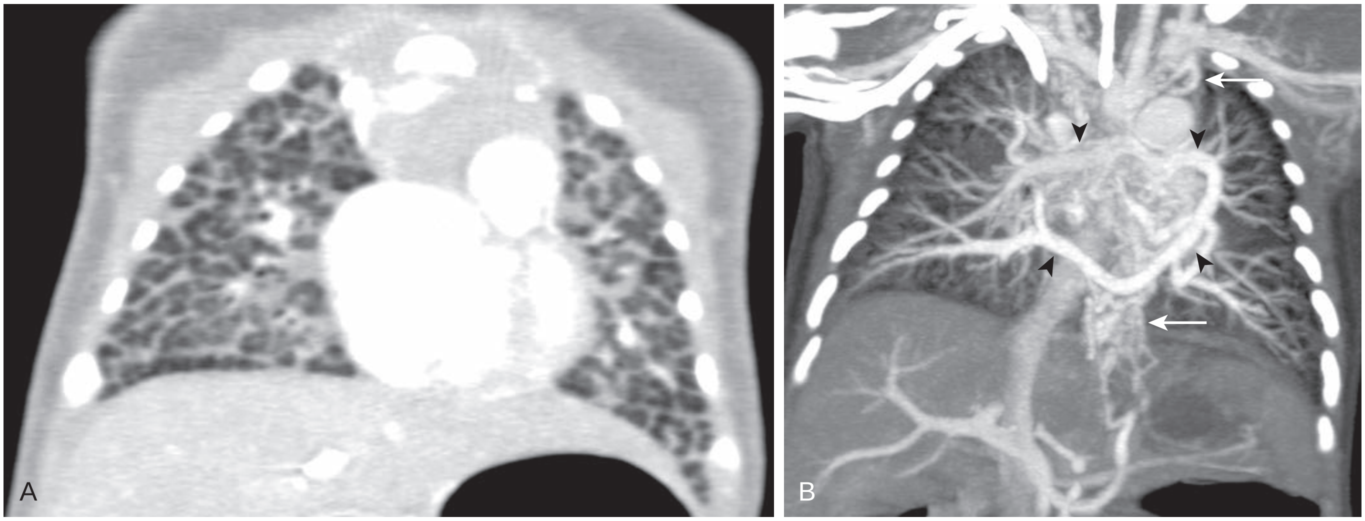
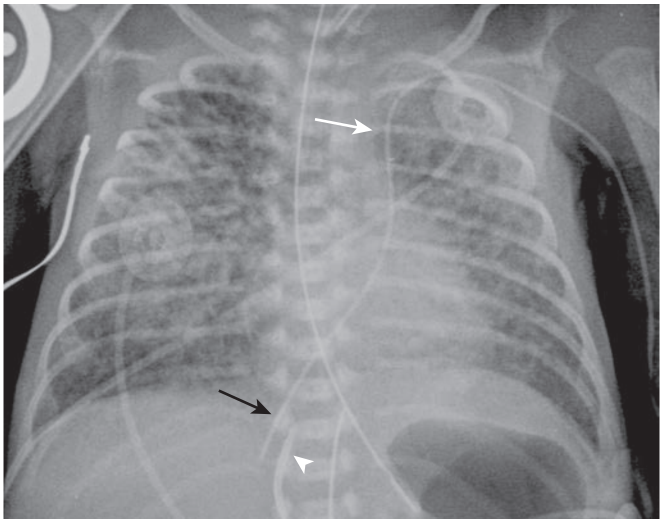
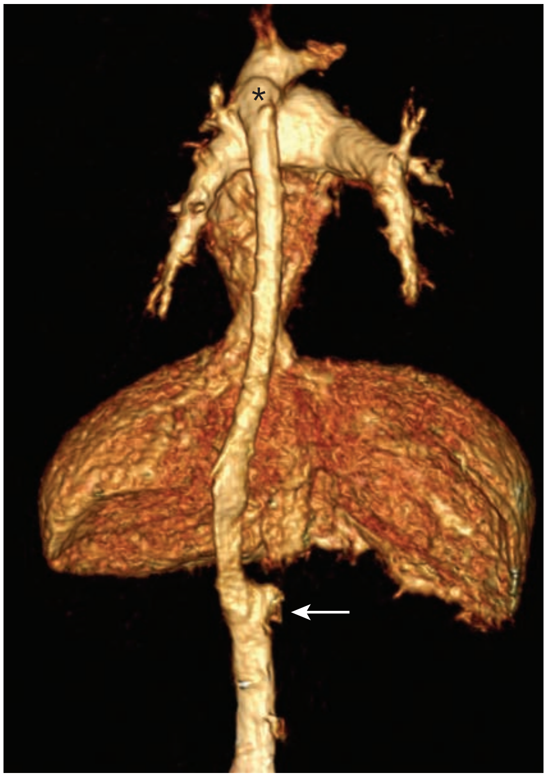


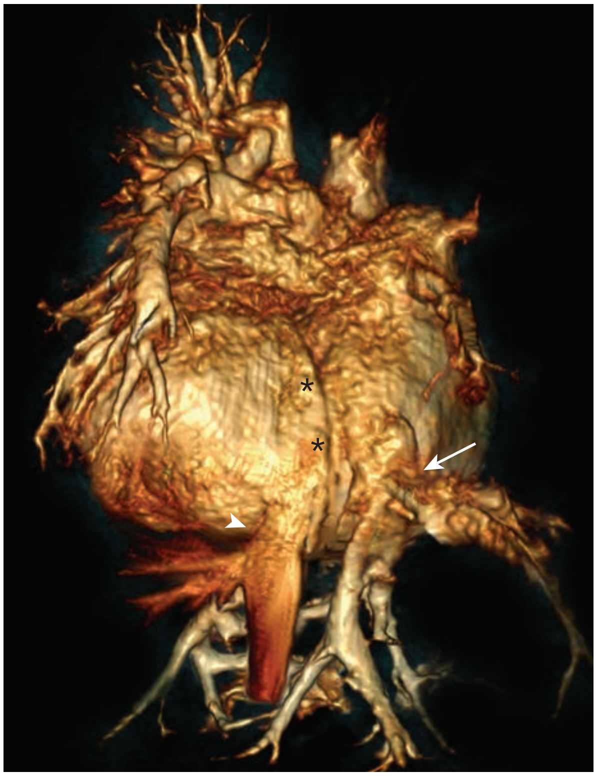
**e-Figure 71.12. Newborn with total anomalous pulmonary venous connection and pulmonary vein atresia.** (A) Coronal computed tomography (CT) lung window shows severe interstitial edema and septal thickening. (B) Coronal CT maximum intensity projection image shows that the anomalous pulmonary veins *(arrowheads)* join but the common pulmonary vein is atretic, and thus the venous drainage is via multiple small collateral vessels to the systemic system *(arrows)*.



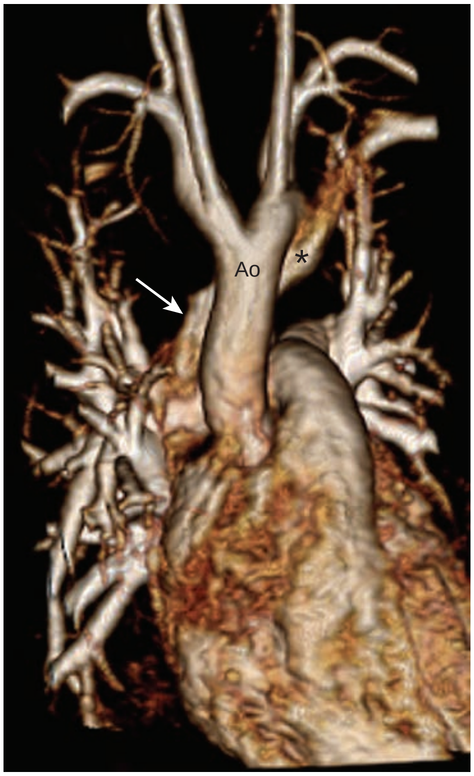
**e-Figure 71.14. Chest radiograph with left superior vena cava.** A frontal chest radiograph in a newborn showing a left-sided central venous catheter extending into the left SVC *(white arrow)*, the coronary sinus, and through the right atrium with its tip in the inferior vena cava, hepatic vein, or ductus venosus *(black arrow)*. An umbilical venous catheter also is shown *(arrowhead)*.



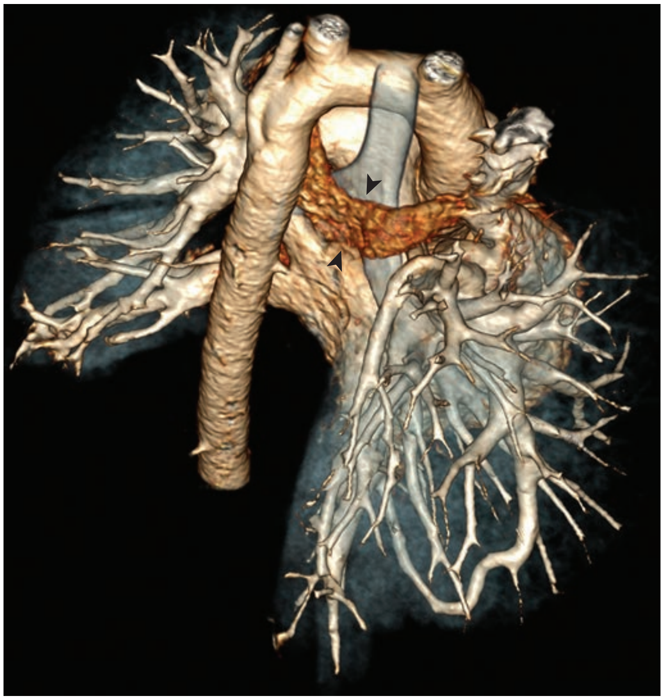
**e-Figure 71.16. Interrupted inferior vena cava with azygous continuation.** Posterior view three-dimensional magnetic resonance angiogram showing interrupted IVC *(arrow)* with azygous continuation coursing posterior to the liver, draining into the left superior vena cava *(asterisk)*.



**e-Figure 71.17. Systemic venous abnormality in heterotaxy.** A three-dimensional magnetic resonance angiogram posterior view showing abnormal hepatic venous drainage with the right-sided hepatic veins *(arrow)* draining directly to the right-sided atrium and the left-sided hepatic veins *(arrowhead)* draining to the left-sided atrium. *Asterisks* mark the atrial septum.



**e-Figure 71.18. Retroaortic left brachiocephalic vein.** A three-dimensional magnetic resonance angiogram showing the left brachiocephalic vein *(asterisk)* coursing posterior and inferior to the aortic arch *(Ao)* draining to the superior vena cava *(arrow)*. *(Courtesy Rajesh Krishnamurthy, Nationwide Children's Hospital, Columbus, Ohio.)*



**e-Figure 71.19. Retrotracheal and retroesophageal left brachiocephalic vein.** A three-dimensional computed tomography angiography posterior oblique view showing the retroaortic and retrotracheal left brachiocephalic vein *(arrowheads)*. The esophagus is collapsed and not seen. An anomalous right pulmonary arterial to venous communication is present.

## KEY POINTS

- PAPVC and partial anomalous pulmonary venous return present with right side volume overload similar to an ASD. Assessment of the degree of left-to-right shunting and associated cardiovascular defects is important.
- TAPVC presents in early infancy with variable cyanosis and pulmonary edema on a chest radiograph. The ascending or descending vein course must be accurately described, with assessment for any obstruction to the pulmonary venous drainage.
- Anomalous systemic venous connections can present with no clinical manifestations or cyanosis depending on the route of drainage. Diagnosis can be important for surgical planning such as placement of central lines and/or cannulation for cardiopulmonary bypass.

## ATRIAL SEPTAL DEFECT

***Overview.*** An atrial septal defect (ASD) is a defect in the atrial septum that allows communication between the right atrium (RA) and left atrium (LA). Isolated ASDs account for 6% to 10% of all congenital heart disease.

***Etiology.*** Two primary types of ASDs occur and are classified by their relationship to the fossa ovalis (Fig. 72.1). Secundum-type defects (80%–90% of all ASDs) occur in the region of the fossa ovalis. Although a patent foramen ovale is similar in location, it usually is not considered a true defect as it is a persistence of the normal interatrial communication from fetal life and is present in 27% to 34% of the general population (Fig. 72.2).[1,2] Ostium primum defects occur anterior to the fossa ovalis at the base of the atrial septum, are usually larger defects, and are almost always associated with other structural heart defects. Additionally, two defects—sinus venosus defects and unroofed coronary sinus—do not involve the atrial septum but are physiologically equivalent to an ASD as they allow blood to shunt from the LA to RA.[3,4] Sinus venosus defects are typically located posterior and superior to the fossa ovalis but may sometimes be posterior and inferior. These occur as a result of abnormal resorption of the right horn of the sinus venosus during embryologic development leading to a defect in the wall that separates the right pulmonary veins from the superior vena cava and the RA, typically resulting in anomalous drainage of the right upper, middle, or lower pulmonary veins to either the RA or superior vena cava (see Chapter 71).[5] An unroofed coronary sinus is rare and occurs as a result of a partial or complete absence of the wall between the inferior LA and the roof of the coronary sinus. An unroofed coronary sinus generally is associated with drainage of a left superior vena cava to the coronary sinus or LA.[6]

***Pathophysiology and Clinical Presentation.*** Small secundum ASDs may close spontaneously[7]; however, primum ASDs, sinus venosus defects, and coronary sinus defects generally do not decrease in size. Shunt volume is related to the size of the defect, right and left heart compliance, and pulmonary vascular resistance. Larger shunt volumes lead to right atrial, right ventricular, and pulmonary artery enlargement. Over time, pulmonary hypertension may develop.

Most infants and young children with ASDs are asymptomatic. ASDs usually are detected at about 6 months of age,[8] often during evaluation for a murmur or as an incidental finding on a chest radiograph. Older children with moderate to large ASDs may have symptoms of fatigue and dyspnea. In addition to pulmonary hypertension, older children and adults with ASDs may have atrial tachyarrhythmias or paradoxical strokes, a risk that increases with age.[9–12]

***Imaging.*** Chest radiography in the neonate usually shows that the heart is normal in size and pulmonary flow is normal. Findings in infancy and childhood include mild cardiomegaly related to right atrial and ventricular enlargement (Fig. 72.3). The LA is not enlarged, which distinguishes an ASD from other left-to-right shunt lesions. Usually main pulmonary artery enlargement and increased pulmonary vascularity is found if the pulmonary to systemic flow ratio is greater than two to one. If the patient has significant pulmonary hypertension, enlarged central pulmonary arteries and peripheral pulmonary arterial vessel tapering may be seen (e-Fig. 72.4).

Echocardiography is the imaging modality of choice to evaluate the location, size, direction of flow across the defect, atrial and ventricular chamber size, ventricular function, right ventricular systolic pressure, and to assess for associated cardiovascular abnormalities. Magnetic resonance imaging (MRI) or computed tomography (CT) may also be used for evaluation of the atrial septum in cases of poor acoustic windows[13] or to evaluate the pulmonary veins in patients with suspected sinus venosus defects (Videos 72.1 to 72.3).[14] Left and right ventricular size and quantitative systolic function can be assessed. Right ventricular volume overload is detected as diastolic septal flattening or diastolic bowing of the septum from right to left with severe volume overload. Comparison of right and left ventricular stroke volumes can be used to calculate the ratio of pulmonary to systemic arterial flow (Qp:Qs). Right ventricular pressure is assessed by evaluating the degree of tricuspid regurgitation and septal systolic position. Systolic septal flattening is indicative of elevated right ventricular pressure. Phase contrast MRI can be used to estimate the size of the ASD and to determine the direction and amount of atrial shunting by calculation of Qp:Qs (e-Fig. 72.5).[15]

***Treatment.*** Closure should be performed in childhood to avoid complications of arrhythmia, right ventricular dysfunction, pulmonary hypertension, and paradoxical embolus.[16] ASD closure can be performed surgically or via transcatheter closure; the latter procedure has become the primary therapy for anatomically favorable secundum defects. After closure, children with ASDs have an excellent prognosis.

## ATRIOVENTRICULAR SEPTAL DEFECT

***Overview.*** Atrioventricular septal defects (AVSDs) account for 4% of all cases of congenital heart disease.[17] Most patients with complete AVSD have Down syndrome.[18] AVSD is also associated with visceral heterotaxy syndromes.[19,20]

***Etiology.*** AVSD results from abnormal development of the embryologic endocardial cushions and produces a spectrum of disease (Fig. 72.6). In its mild form, partial AVSD, a crescent-shaped primum ASD is found in the inferior portion of the atrial septum immediately adjacent to the atrioventricular (AV) valves, along with an associated "cleft" mitral valve with separate mitral and tricuspid valve orifices. Persons with the complete form have an ostium primum defect, an inlet ventricular septal defect (VSD) beneath the plane of the AV valves, and a single or common AV valve, with variable leaflet size, location, and morphology. Most importantly, the common valve has two components that "bridge" the ventricular septum and may form attachments to the septal surface and/or both the right and left sides of the heart.[21] In most cases, the common AV valve is shared equally between the right and left ventricles, but the valve orifice may be unequally shared favoring either the right or left ventricle.[20] Components of common AV valves are referred to as left- or right-sided valves rather than mitral or tricuspid as there is a single valve annulus.

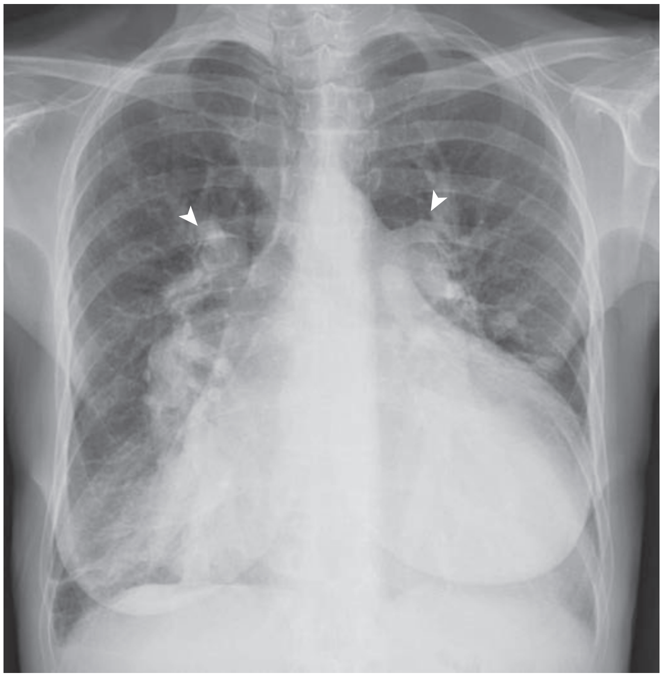
***Pathophysiology and Clinical Presentation.*** In complete AVSD, the amount of left-to-right shunting is generally large and related to the size of the ASD and VSD, right and left heart compliance, and pulmonary vascular resistance. The shunting may be interatrial, interventricular, or typically both. Significant left AV valve insufficiency can exacerbate congestive heart failure.

## Abstract:

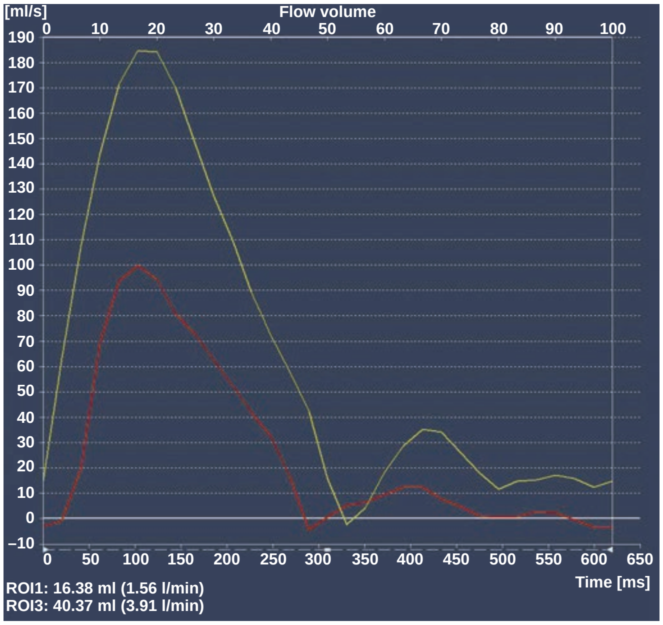
Systemic to pulmonary arterial shunts refers to any physiologic shunting in which fully oxygenated blood intended for systemic circulation is diverted to the pulmonary circulation after return of systemic venous blood to the heart. This results in the mixing of fully oxygenated blood with deoxygenated blood. The result of this shunting leads to increased pulmonary blood flow and is not associated with clinical cyanosis. The clinical presentations, pathologic features and characteristic imaging findings are dependent on the location of such a shunt as well as the degree of shunting that occurs. These shunts include atrial septal defects, atrioventricular septal defects, ventricular septal defects, patent ductus arteriosus and aortopulmonary windows. This chapter is a concise review of the etiologies, pathophysiology, clinical presentations, imaging findings and treatment of these defects.

## Keywords:

atrial septal defect
ventricular septal defect
patent ductus arteriosus
AP window
atrioventricular septal defect



**e-Figure 72.4. Atrial septal defect and pulmonary hypertension.** Frontal chest radiograph of an adult with an atrial septal defect and Eisenmenger syndrome shows moderate to severe cardiomegaly with enlarged central pulmonary arteries *(arrowheads)* and peripheral tapering of pulmonary vessels.



**e-Figure 72.5.** Curves representing blood flow in the aorta *(red)* and pulmonary artery *(yellow)* obtained by phase contrast magnetic resonance imaging in a child with an atrial septal defect. The pulmonary flow is 3.9 L/min, the systemic flow is 1.6 L/min, and the pulmonary-to-systemic flow ratio is 2.5 : 1, indicating a significant left-to-right shunt.

Infants with complete AVSD present with tachypnea, tachycardia, and signs of congestive heart failure as pulmonary resistance falls during the newborn period. Patients with partial AVSD may be asymptomatic as infants and young children, although symptoms may develop early in life if significant associated mitral valve regurgitation is present.[22]

***Imaging.*** The amount of left-to-right shunting is reflected on the chest radiograph and may reflect the physiology of either the ASD, VSD, or both. In complete AVSD, findings include moderate to marked cardiomegaly with right atrial and right ventricular enlargement and increased pulmonary vascularity (Fig. 72.7). Left atrial enlargement may be seen in large VSDs or, if significant, associated left AV valve insufficiency is present. Children with large left-to-right shunts commonly have lung hyperinflation, which may be related to an increase in airway resistance from enlarged pulmonary arteries and veins or to an increase in lung volume related to the increase in blood volume.

Echocardiography is the primary modality for evaluation of AVSD, but MRI can be used as an adjunct in complex cases, especially when an accurate assessment of right and left ventricular size is needed.[23,24] Components to evaluate include the ostium primum portion of the atrial septum and the inlet portion of the ventricular septum, the AV valve leaflet morphology and attachments, the papillary muscle architecture, the level and direction of shunting, ventricle size and systolic function, and the presence of outflow tract obstruction or other cardiovascular anomalies (Fig. 72.8).

***Treatment.*** Patients with partial AVSD generally undergo complete surgical repair between 1 and 4 years of age. For patients with complete AVSD, early repair between 2 and 4 months of life is recommended to avoid the development of significant pulmonary hypertension.[20] Surgical goals include ASD and VSD closure with creation of two patent and competent AV valves, and preservation of the conduction system. Long-term survival after repair for partial and complete AVSD is excellent.[18,25–27]

## VENTRICULAR SEPTAL DEFECT

***Overview.*** Isolated VSD accounts for approximately 20% of all cases of congenital heart disease, with an incidence of approximately 2 per 1000 live births.[28] Isolated VSDs are slightly more common in girls than in boys.[29,30] VSD may be isolated or part of a complex congenital heart malformation.[31–33]

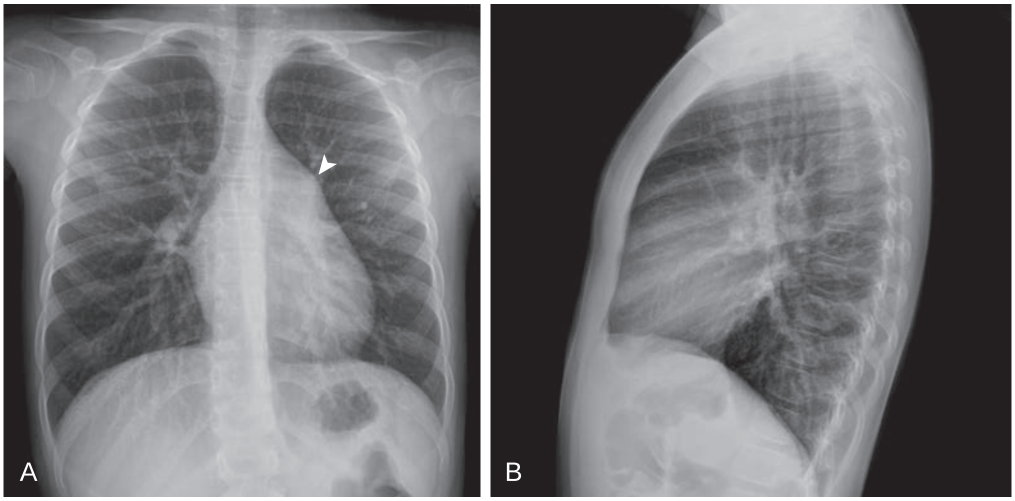

**Figure 72.3. Atrial septal defect, secundum type, in a 7-year-old.** Frontal (A) and lateral (B) views of the chest show mild cardiomegaly, a prominent pulmonary artery *(arrowhead)*, and increased pulmonary vascularity without left atrial dilation.

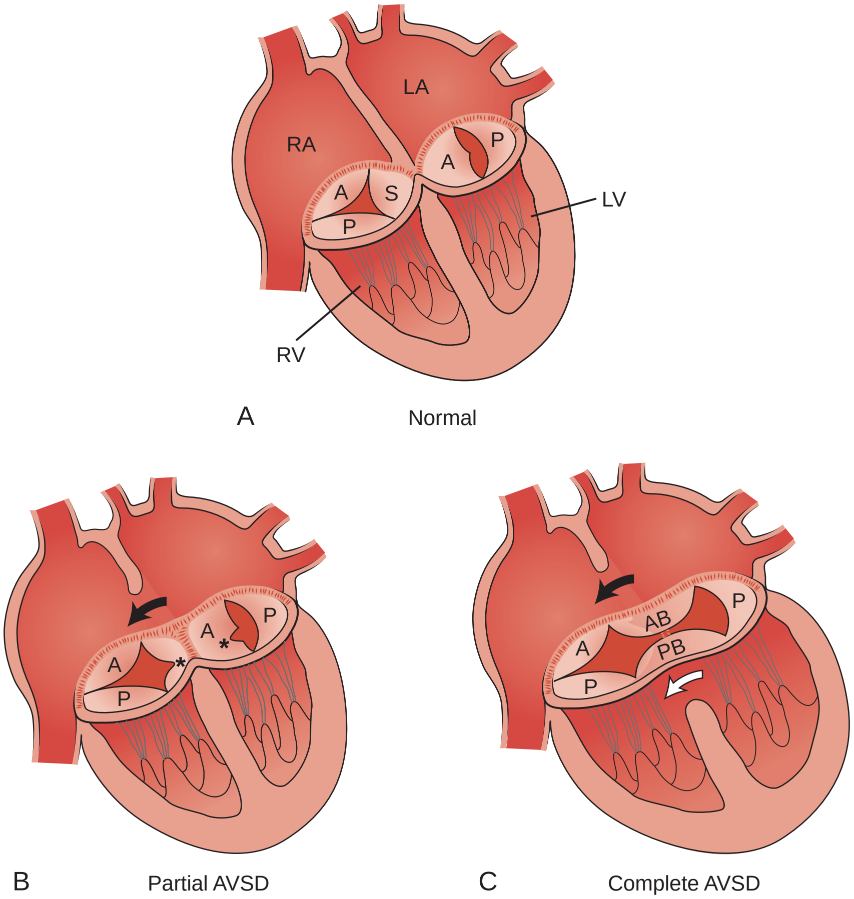

**Figure 72.6. Diagrams illustrating the spectrum of atrioventricular septal defect (AVSD).** (A) The normal tricuspid valve has three leaflets, anterior *(A)*, posterior *(P)*, and septal *(S)*, and the normal mitral valve has two leaflets, anterior *(A)* and posterior *(P)*. (B) Partial AVSD showing the clefts *(asterisks)* in the septal leaflet of the tricuspid valve, the anterior leaflet of the mitral valve, and the ostium primum atrial septal defect (ASD) *(arrow)*. (C) Complete AVSD showing the common atrioventricular valve with the anterior bridging *(AB)* and posterior bridging *(PB)* leaflets, the ostium primum ASD *(black arrow)*, and the inlet ventricular septal defect *(white arrow)*. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. *(Modified from Park MK. Left-to-right shunt lesions. In Park MK, ed.* Pediatric Cardiology for Practitioners, *St Louis: Mosby Elsevier; 2002.)*

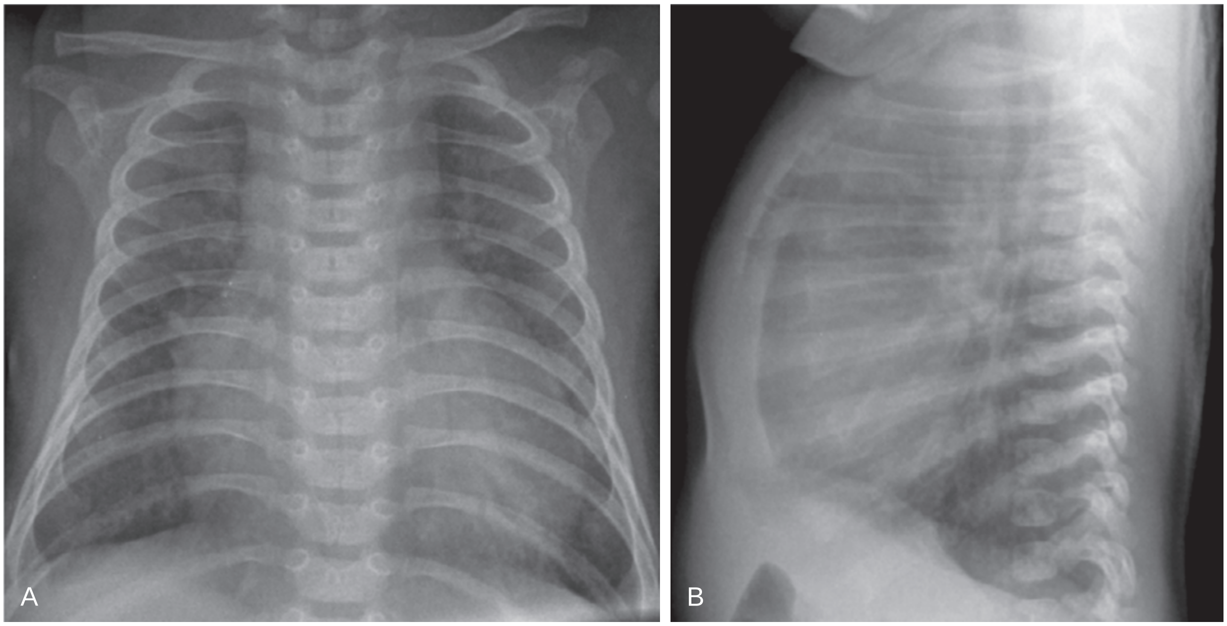

**Figure 72.7. Atrioventricular septal defect in a 6-week-old.** Frontal (A) and lateral (B) views of the chest show moderate cardiomegaly with enlargement of the right atrium and ventricle, increased pulmonary vascularity, and lung hyperinflation.

***Etiology.*** The ventricular septum can be divided into four components, and VSDs may involve one or more of these components (Table 72.1). The inlet septum extends from the tricuspid annulus to the septal attachments of the tensor apparatus of the tricuspid valve. AVSD is associated with a defect in this portion of the septum. The muscular septum involves the trabeculated portion of the right ventricle and extends from the tricuspid valve attachments to the apex of the ventricle and up to the septal band. Single or multiple muscular defects can be present in this portion of the septum. The outlet or conal portion of the ventricular septum separates the ventricular outflow tracts and, when viewed from the right ventricle, extends from the septal band to the pulmonary valve. The thin, membranous septum lies adjacent to the anteroseptal commissure of the tricuspid valve on the right side of the heart and to the right and noncoronary cusps of the aortic valve on the left side. Approximately 80% of VSDs involve the area around the membranous septum (Fig. 72.9).[34,35]

***Pathophysiology and Clinical Presentation.*** The physiologic effect of a VSD is determined by its size, right and left heart compliance, and pulmonary vascular resistance. Small defects offer high resistance to flow, and large defects offer low resistance to flow. Large defects subject the pulmonary vasculature to high flow and high pressure, which frequently results in pulmonary hypertension.

Symptoms vary depending on the size of the VSD and the degree of left-to-right shunting. At birth, pulmonary resistance is high, limiting left-to-right shunting. As pulmonary resistance falls during early infancy, left-to-right shunting increases. When shunting becomes significant, failure to thrive, dyspnea, and congestive heart failure may be seen. Irreversible pulmonary hypertension can develop within 2 to 3 years and frequently is seen in young adults.[32]

***Imaging.*** Chest radiograph findings vary depending on the size of the VSD and are normal in a person with a small VSD. Findings

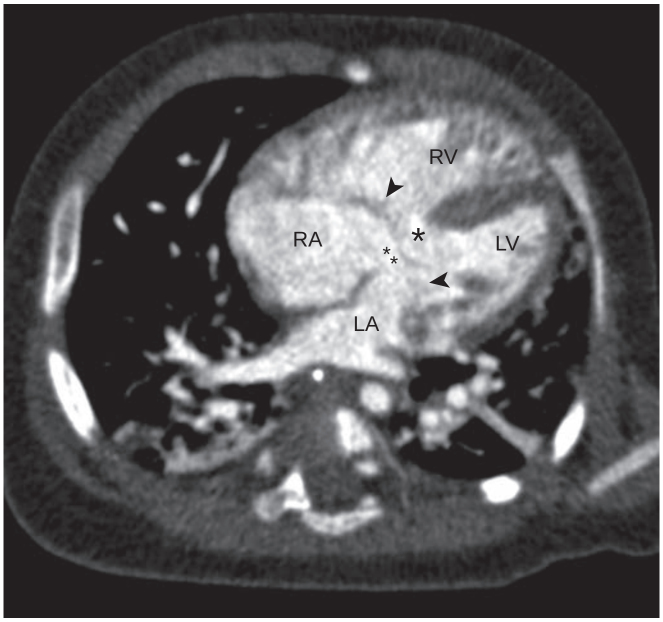

**Figure 72.8. Complete atrioventricular septal defect (AVSD).** Four-chamber view from a contrast enhanced CT angiography study in an infant with a balanced AVSD shows the ostium primum defect *(double asterisks)*, inlet ventricular septal defect *(single asterisk)*, and common atrioventricular valve *(arrowheads)* that bridges the right and left sides of the heart. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

| Type | Synonym | Frequency | Associated Features |
|---|---|---|---|
| Membranous | Perimembranous<br>Paramembranous<br>Conoventricular<br>Infracristal | 80% | Adherence of tricuspid valve tissue to defect with left ventricle–right atrial shunt<br>Extension to muscular, inlet, or outlet septum<br>Anterior malalignment of the infundibular septum causing aortic override<br>Posterior malalignment of the ventricular septum causing subaortic stenosis<br>Small defects may spontaneously close |
| Inlet | Atrioventricular septal defect<br>Atrioventricular canal type | 5%-8% | — |
| Outlet | Conal<br>Subpulmonary<br>Doubly committed juxtaarterial<br>Supracristal<br>Infundibular | 5%-7% | Right coronary leaflet prolapse through defect<br>Aortic regurgitation<br>Dilation of the right sinus of Valsalva |
| Muscular | Trabecular<br>Marginal | 5%-20% | Small defects may spontaneously close<br>Defects may be multiple |

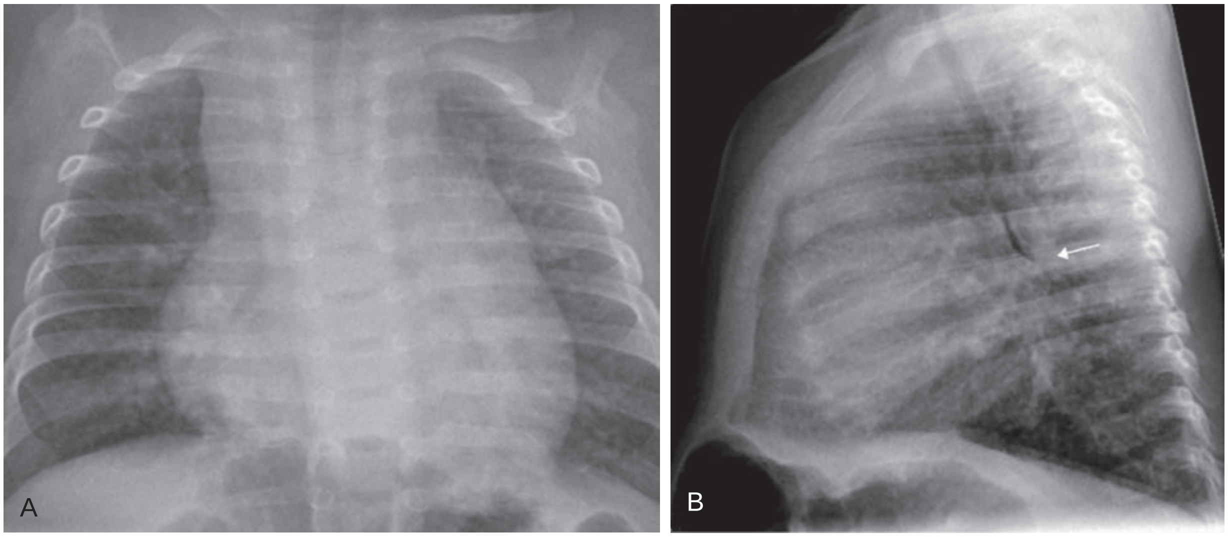

**Figure 72.10. Ventricular septal defect in a 3-month-old.** Frontal (A) and lateral (B) views of the chest show right atrial, right ventricular, and left atrial enlargement with posterior displacement of the left main stem bronchus (*arrow* in B) and increased pulmonary vascularity.

with moderate to large VSDs include cardiomegaly with enlargement of the LA, left ventricle, and pulmonary arteries and increased pulmonary blood flow (Fig. 72.10). Congestive heart failure occurs frequently in infants with a moderate or large defect. Pulmonary hypertension may be evident in older children or young adults.

Echocardiography is the imaging method of choice for evaluation of VSDs. Imaging goals include addressing the size, number, and location of VSDs and the degree of left-to-right or right-to-left shunting. Estimates of right ventricular and pulmonary artery pressures and right and left heart volumes are obtained. The tricuspid and aortic valves are evaluated for possible tethering of valve tissue into the borders of the defect. MRI and CT are useful for noninvasive evaluation of VSDs and hemodynamic consequences, with a reported 90% accuracy in detection (Fig. 72.11).[36,37] Phase contrast MRI measurements in the aorta and pulmonary artery or a comparison of right and left ventricular stroke volumes can be used to evaluate Qp:Qs, and qualitative assessment of the septal position can be used as a measure of ventricular volume and/or pressure overload.

***Treatment.*** During the first year of life, 80% to 90% of small (<0.5 cm) VSDs become smaller or completely close.[30] Operative correction is preferable before 6 months of age in patients with large VSDs to decrease the risk of developing irreversible pulmonary hypertension. Consideration for early closure of outlet defects is recommended to prevent development of aortic sinus prolapse and progressive valve regurgitation. The results of operative closure are excellent, with a very low risk of morbidity or mortality. VSDs are closed most frequently via a right atrial approach, but transpulmonary artery and transaortic approaches also are used. Transcatheter device closure is an alternative to surgery for selected single or multiple VSDs, usually in the muscular septum, and also has been used intraoperatively (e-Fig. 72.12).

## PATENT DUCTUS ARTERIOSUS

***Overview.*** Patent ductus arteriosus (PDA) accounts for approximately 10% of all congenital heart disease.[38] Approximately 20% to 30% of premature infants have a PDA, and the incidence increases with increased prematurity.[39] Complex congenital heart disease may include PDA with ductal dependent pulmonary or systemic blood flow.

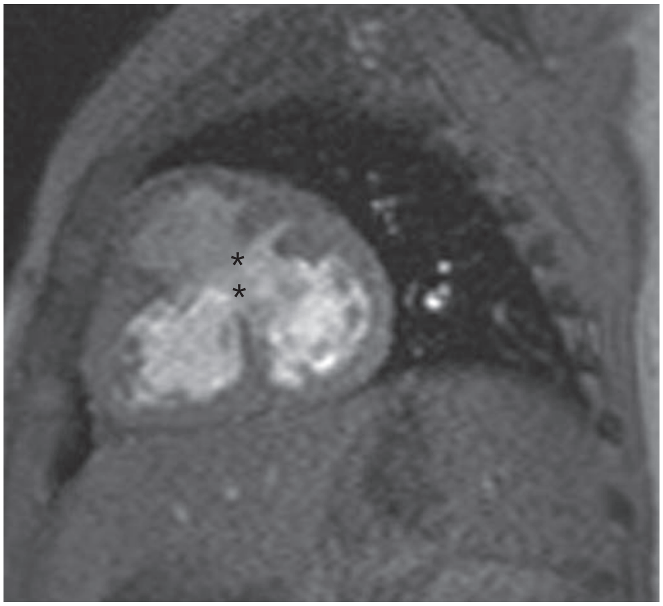

**Figure 72.11. A ventricular septal defect in a 2-year-old.** A short-axis steady-state free-precession magnetic resonance (MR) image shows a large muscular ventricular septal defect *(asterisks)*.

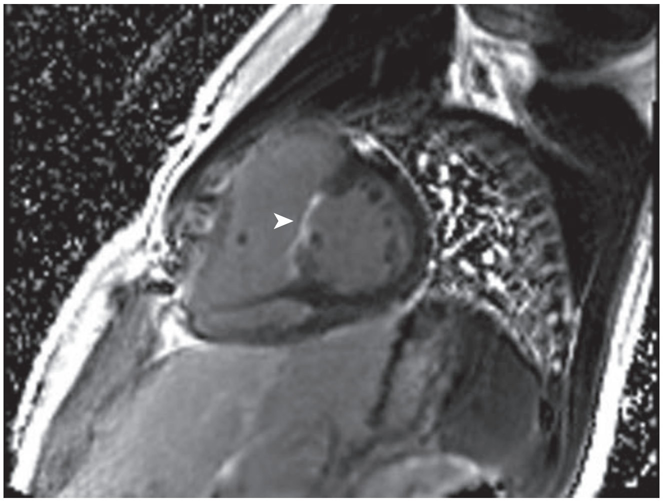
***Etiology and Pathophysiology.*** PDA represents the persistence of the embryologic sixth aortic arch, which most commonly connects the left pulmonary artery with the descending aorta just beyond the origin of the left subclavian artery (see Chapter 62). With a right arch, the ductus arteriosus may be on the right. Prostaglandins maintain ductal patency during fetal life. At birth, increased blood oxygen concentration causes constriction of the duct, usually within hours after birth. Ductal closure is delayed in premature infants with respiratory distress and hypoxia because the immature ductal tissue is less sensitive to oxygen-mediated constriction. In a majority of cases of PDA in term infants, the etiology is unknown.[40–42]



**e-Figure 72.12. Patch repair of a ventricular septal defect.** A short-axis delayed-enhancement MR image shows late enhancement corresponding to the location of the ventricular septal defect patch *(arrowhead)*. The patch is significantly thinner than the adjacent normal myocardium.

***Clinical Presentation.*** The amount of left-to-right shunting depends on the length and diameter of the duct and the degree of pulmonary hypertension. Pulmonary hypertension may develop if a large PDA is left untreated. In premature infants without significant lung disease, a PDA may become clinically apparent 24 to 72 hours after birth. Congestive heart failure occurs if the shunt is large. In premature infants with significant lung disease, the prevalence of PDA is greater than 80%. Screening echocardiography may detect a PDA in these infants before clinical manifestations occur. A term infant with a small PDA is generally asymptomatic, and the PDA often is detected because of the presence of a murmur. Term infants with moderate to large PDAs may display poor feeding, irritability, and failure to thrive and may have congestive heart failure.[43]

***Imaging.*** Pulmonary edema and cardiomegaly may be seen as signs of a PDA on a chest radiograph. In premature infants who exhibit lung infiltrates after the first few days of life, particularly with an increase in heart size, PDA should be considered. Chest radiographs of term infants with significant shunting show increased pulmonary blood flow and cardiomegaly (e-Fig. 72.13).

Echocardiography is the standard imaging technique for evaluating a PDA. Goals of imaging are to measure the PDA size and diameter, assess the amount of left-to-right or right-to-left shunting and the degree of pulmonary hypertension, and identify possible complicating factors such as a ductal aneurysm. CT or MRI may be used in conjunction with echocardiography to define anatomy in complicated cases and to determine Qp:Qs (Fig. 72.14).[44,45]

***Treatment.*** Indomethacin or ibuprofen therapy often are successful in achieving PDA closure in premature infants, followed by surgical ligation if medical therapy fails. Nonsurgical transcatheter closure is the method of choice for small to moderate PDAs in most term infants.[46,47] Larger PDAs in term infants generally are managed surgically. Patient prognosis is excellent if ductal closure is performed between 6 and 24 months of age.[48]

## AORTOPULMONARY WINDOW

Aortopulmonary (AP) window is rare and accounts for 0.2% cases of congenital heart disease.[49–52] AP window is the result of incomplete aortopulmonary septation resulting in communication between the ascending aorta and pulmonary artery. This defect creates a large, high-pressure, left-to-right shunt that usually is apparent clinically in the first weeks of life and is similar to a large PDA in pathophysiology.

***Imaging.*** Chest radiographic findings include cardiomegaly with left atrial and left ventricular enlargement, increased pulmonary blood flow, and prominence of the ascending aorta and pulmonary artery related to the left-to-right shunt at the level of the great vessels. Imaging is performed to evaluate the anatomy of the aortopulmonary window and its relationship to the aortic and pulmonary valves, to define the coronary anatomy, to estimate pulmonary pressure and ventricular function, to assess Qp:Qs, and to evaluate for other cardiovascular defects. Differentiation from truncus arteriosus is critical and is accomplished by the identification of two separate semilunar valves (Fig. 72.15).

***Treatment.*** Early surgical patch repair for large defects or suture repair for small defects to separate the great vessels should be performed before the development of pulmonary hypertension. The outcome following surgery generally is excellent.

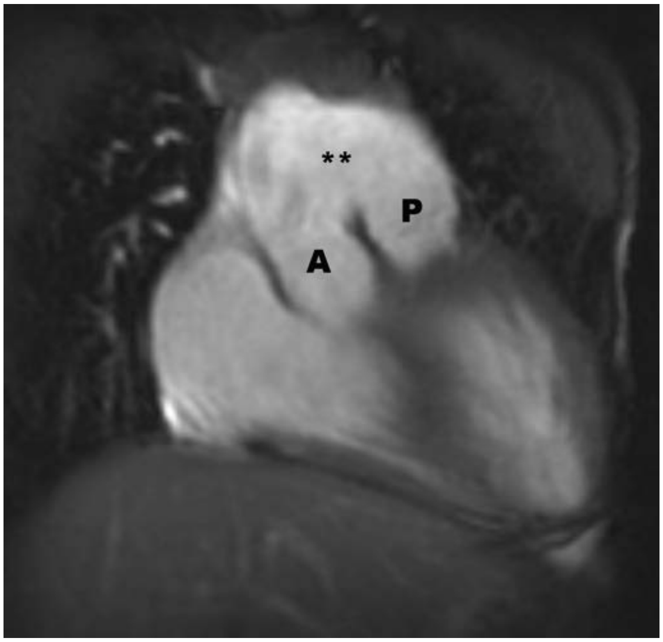

**Figure 72.15. Aortopulmonary window.** A coronal steady-state free-precession MR image shows separate origins of the aortic root *(A)* and pulmonary trunk *(P)* with a large communication *(asterisks)* between the ascending aorta and the pulmonary trunk. *(Courtesy Deborah L. Thompson, MD, Dalhousie University.)*

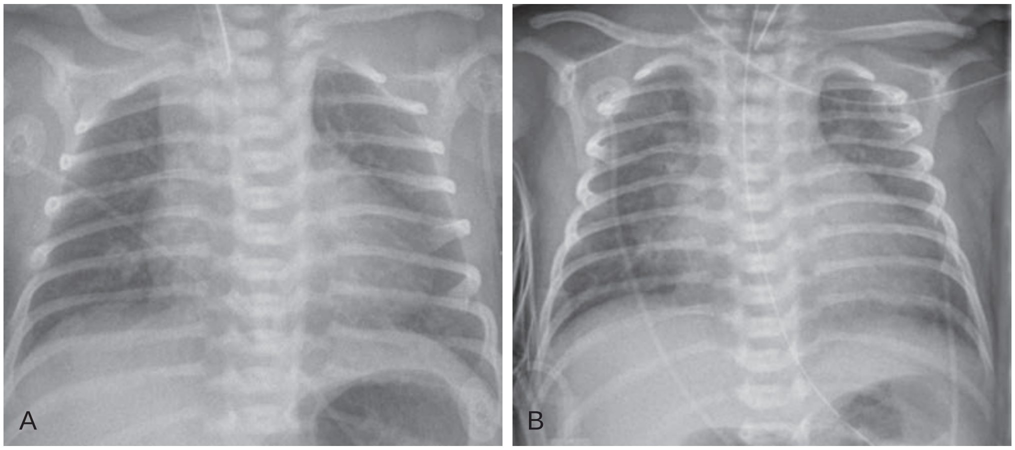

**e-Figure 72.13. Sequential chest radiographs in a newborn with a patent ductus arteriosus (PDA).** (A) Frontal chest radiograph on day 2 of life shows top normal heart size and normal pulmonary vascularity. (B) A chest radiograph on day 8 of life shows an increase in heart size and increased pulmonary vascularity consistent with a PDA diagnosed by echocardiography.

## KEY POINTS

- The most common cause of cardiomegaly in an acyanotic patient with increased pulmonary vascularity is VSD. Differential diagnosis includes ASD, AVSD, PDA, and aortopulmonary window.
- ASD does not cause left atrial enlargement, which distinguishes ASD from other left-to-right shunts.
- Phase contrast MRI can be used to assess the direction of flow and to determine the amount of shunting by calculation of the ratio of pulmonary to systemic flow (Qp:Qs).

## HYPOPLASTIC LEFT HEART SYNDROME

***Overview.*** Hypoplastic left heart syndrome (HLHS) is a spectrum of disease characterized by underdevelopment of the left ventricle with obstruction or atresia of ventricular inflow and outflow. HLHS accounts for approximately 2% to 3% of all cases of congenital heart disease, with a slight male predominance.[1,2] HLHS is most commonly isolated, but extracardiac anomalies occur in up to 30%[3] and a variety of genes and syndromes may be associated.

***Etiology and Pathophysiology.*** The structural defects of HLHS include varying degrees of hypoplasia of left heart structures: hypoplastic ascending aorta and arch (often with discrete coarctation), aortic valve atresia or stenosis, hypoplastic left ventricle, and mitral atresia or stenosis (Fig. 73.1). Patent ductus arteriosus (PDA) and patent foramen ovale or atrial septal defect (ASD) are essential for survival. The ventricular septum is intact, and endocardial fibroelastosis or thickening of the left ventricular endocardium may be present.[4] Right heart structures are typically enlarged,[5] and the tricuspid valve may be abnormal and regurgitant.[6]

Both the pulmonary and systemic circulations depend on the right ventricle. Oxygenated pulmonary venous blood returns to the left atrium, and because of the significant left ventricular inflow obstruction and decreased compliance, an obligatory left-to-right shunt is present at the atrial level through a patent foramen ovale or ASD. In the right atrium, the oxygenated pulmonary venous blood mixes with deoxygenated systemic venous blood and flows into the right ventricle. Blood is pumped to the pulmonary artery, with systemic blood then flowing from right to left through the PDA. The brachiocephalic vessels and coronary arteries are perfused through retrograde flow from the PDA into the arch and ascending aorta. The descending aorta is perfused from antegrade flow through the PDA.

***Clinical Presentation.*** Cyanosis and tachypnea generally are apparent within hours to 2 days after birth.[7] With the normal postnatal drop in pulmonary vascular resistance, pulmonary blood flow increases and systemic blood flow decreases, leading to respiratory distress and poor systemic perfusion. As the PDA constricts, perfusion of the ductal-dependent systemic and coronary circulations further declines, with resulting myocardial ischemia, shock, and death. In the setting of poor arteriovenous mixing as a result of inadequate interatrial communication, shock and death may occur almost immediately after birth without intervention.

***Imaging.*** HLHS is readily identified in utero by the obstetric ultrasound four-chamber cardiac view, with approximately 60% of cases diagnosed prenatally.[8,9] Chest radiographic findings are variable. If the interatrial communication is unrestrictive, there is progressively increasing pulmonary overcirculation with increased vascularity and cardiomegaly after the first hours of life (e-Fig. 73.2). With a restrictive atrial septum, the heart size may be normal with pulmonary venous congestion that may be misinterpreted as primary lung disease.

Echocardiography is the imaging method of choice and generally delineates all relevant presurgical anatomy. Cross-sectional imaging can be performed as an adjunct to echocardiography in complex cases.[10] Magnetic resonance imaging (MRI) may be especially useful when the left ventricle is marginally hypoplastic and the possibility exists of a two-ventricle surgical repair, whether in the neonatal period or after initial single-ventricle palliation (Fig. 73.3 and Video 73.1).[4,11] In these cases, MRI quantifies left ventricular volume, left versus right ventricular stroke volumes, and mitral versus tricuspid valve inflows to help plan the most appropriate surgical repair. MRI is also increasingly being used after the first stage of the palliative single ventricle surgery to quantify systemic right ventricular systolic function and tricuspid regurgitation and to evaluate for residual or recurrent coarctation and pulmonary artery stenosis or hypoplasia before the second-stage bidirectional cavopulmonary anastomosis.[12–14] Less frequently, cardiac computed tomography angiography (CTA) may be used for preoperative vascular evaluation.[15] After the third-stage Fontan completion procedure, MRI (Fig. 73.4) is complementary to echocardiography, particularly in older patients with poor acoustic windows, and can improve risk stratification for transplant-free survival in this population.[16,17]

***Treatment.*** Initial medical management includes intravenous prostaglandin $E_1$ (PGE$_1$) to maintain ductal patency. Ventilatory strategies and medications may be required to maintain adequate systemic perfusion and minimize pulmonary edema by optimizing the ratio of pulmonary to systemic blood flow.[18]

Surgical treatment consists of a three-stage reconstruction procedure (Fig. 73.5). The goal is to create in-series pulmonary and systemic circulations, with right ventricular support of the systemic circulation and passive flow through the pulmonary circulation. This allows for normal arterial oxygen saturation and decreases the volume load on the systemic right ventricle, but the reconstruction must be staged to account for the high neonatal pulmonary vascular resistance and subsequent decrease over the first year of life.

Stage I of the reconstruction—the Norwood procedure—often is performed in the first week of life.[19] The goals of this procedure are to relieve any obstruction to atrial mixing, provide unobstructed systemic and coronary blood flow, and create a stable but restrictive source of pulmonary blood flow. A complete atrial septectomy is performed. The PDA is ligated, and the neo-aortic outflow is created by transecting the main pulmonary artery and anastomosing it to the hypoplastic ascending aorta (Damus-Kaye-Stansel anastomosis), with use of a homograft patch to augment the hypoplastic ascending aorta and aortic arch. Blood flow to the lungs is reestablished either via a right ventricle to pulmonary artery (RV-PA) conduit (Sano shunt)[20] or via a modified Blalock-Taussig shunt (BT shunt) from the subclavian or brachiocephalic artery to the branch pulmonary arteries (Fig. 73.6). If a BT shunt is used, there is diastolic runoff through the shunt that may lead to excessive pulmonary blood flow and "steal" from the coronary and systemic circulation. Conversely, the RV-PA conduit is associated with pulmonary regurgitation and potential right ventricular volume overload, a need for ventriculotomy and potential right ventricular dysfunction, and potential aneurysm formation or pulmonary artery distortion at the site of the conduit insertion.[1,20]

By approximately 3 to 6 months of age, pulmonary vascular resistance has physiologically dropped, and stage II of the reconstruction—the bidirectional cavopulmonary anastomosis (Glenn) or hemi-Fontan procedure—is performed to redirect the upper body systemic venous return directly to the lungs. The superior vena cava (SVC) is anastomosed to the right pulmonary artery, and the SVC is either transected from the right atrium

## Abstract:

This chapter addresses obstructive left heart lesions, including hypoplastic left heart syndrome (HLHS), sub-valvar, valvar, and supravalvar aortic stenosis, and coarctation of the aorta. All have the physiologic similarity of obstruction to systemic outflow, and they often coexist. On the other hand, they vary widely in their prevalence, associations, presentation, and management. Aortic stenosis is most common, accounting for 10% of congenital heart disease cases, and is most often (95%) associated with bicuspid aortic valve, which is found in 1–2% of the general population. HLHS is most rare, accounting for 2–3% of congenital heart disease cases. While HLHS is associated with extracardiac anomalies in up to 30%, valvar aortic stenosis is most commonly isolated, and supravalvar aortic stenosis and coarctation are sometimes associated with typical genetic syndromes. The initial presentation of left heart obstructive lesions ranges from in utero or the first days of life for HLHS, to as late as adulthood for the mildest forms of aortic stenosis. Management varies from staged surgical palliation starting in the neonatal period for HLHS, to the possibility for prolonged medical management in cases of aortic stenosis.

## Keywords:

aortic stenosis
hypoplastic left heart syndrome
coarctation
bicuspid aortic valve

Ductus arteriosus
Hypoplastic aortic and mitral valves
Hypoplastic left ventricle

Hypoplastic left heart syndrome

**Figure 73.1. Diagram of hypoplastic left heart syndrome.** Compared with the normal heart, the mitral and aortic valves are severely hypoplastic or atretic, the left ventricular cavity and aorta are hypoplastic, and systemic blood flow is supplied by the patent ductus arteriosus. *(From American Heart Association. Hypoplastic left heart syndrome. www.americanheart.org. © 2006, American Heart Association, Inc.)*

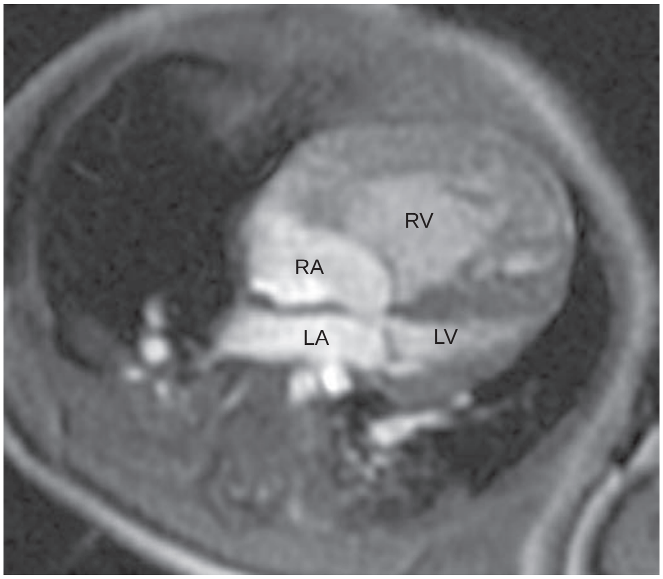

**Figure 73.3. Hypoplastic left heart syndrome.** Four-chamber steady-state free-precession (SSFP) magnetic resonance (MR) image of a 12-week-old with a marginally hypoplastic left ventricle to evaluate for a two-ventricle versus single-ventricle repair. The left atrium *(LA)* and left ventricle *(LV)* are small, with the left ventricular volume calculated at 24.2 mL/m$^2$. The study also showed adequate mitral and aortic valve dimensions. Based on the MRI measurements, the patient underwent a successful two-ventricle repair. See Video 73.1 for a four-chamber cine SSFP MRI of the same patient. *RA,* Right atrium; *RV,* right ventricle.

(Glenn procedure) or isolated from the right atrium with a patch (hemi-Fontan procedure). The BT shunt is divided or the RV-PA conduit is obliterated, and, if necessary, tricuspid valve repair and pulmonary artery angioplasty are performed.

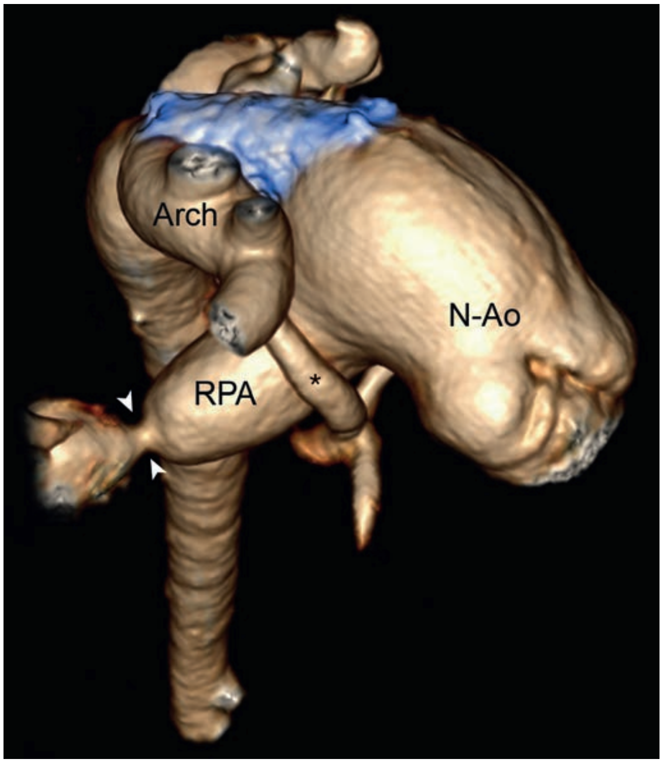
As an alternative to the typical stage I and II procedures previously described, a "hybrid" approach may be undertaken to avoid cardiopulmonary bypass in the fragile neonatal period, particularly when mortality risk is high (e.g., low birth weight or cerebrovascular accident).[1,21] The hybrid stage I procedure combines transcatheter ductus arteriosus stenting to provide systemic flow and surgical branch pulmonary artery banding to limit pulmonary blood flow (e-Fig. 73.7). The comprehensive stage II procedure then must involve creation of the Damus-Kaye-Stansel anastomosis and reconstruction of the aortic arch, removal of the PDA stent and pulmonary artery bands, repair of the pulmonary arteries, atrial septectomy, and the Glenn or hemi-Fontan procedure.[1,21]

Stage III of the reconstruction—the Fontan completion procedure—is generally performed at 18 to 36 months of age (see Fig. 73.4). Inferior vena cava blood flow is directed to the pulmonary arteries either via an extracardiac conduit or an intracardiac right atrial baffle (lateral tunnel). If the stage II procedure was a hemi-Fontan, the lateral tunnel is created and the SVC patch is removed. The Fontan procedure achieves complete separation of the systemic and pulmonary circulations. A fenestration may be left in the Fontan circuit as a "pop-off" into the heart if Fontan pressures are high, and this may lead to a more stable postoperative course.[22,23] Many fenestrations close spontaneously, or they can be closed with a device at later cardiac catheterization.

Survival after the three-stage palliative procedure has improved steadily and now approaches 70%.[9] The stage I Norwood procedure carries the highest mortality, ranging from 7% to 19%.[20] Cardiac transplantation had been considered an alternative to staged Norwood palliation in the past, but because of limited donor availability and the recent improvement in survival after Norwood palliation, transplantation now generally is reserved for patients in whom staged palliation has failed.[1,24]

## AORTIC STENOSIS

***Overview.*** Left ventricular outflow tract (LVOT) obstruction can occur at the level of the aortic valve or in the subvalvar or supravalvar regions. This spectrum of disease represents approximately 10% of cases of congenital heart disease.[25] Valvar aortic stenosis (AS) is by far the most common form of LVOT obstruction and has a male predominance of nearly 80%.[26] Supravalvar AS accounts for 1% to 2% of AS in childhood and is a manifestation of elastin-related arteriopathy; it may occur spontaneously, via autosomal dominant transmission, or in up to 50% as part of Williams syndrome.[27] Subvalvar AS is more common than supravalvar AS[28]; it also has a male predominance and may be associated with more complex disease such as double-outlet right ventricle and transposition of the great arteries.



**e-Figure 73.7. A 5-month-old with hypoplastic left heart syndrome after the hybrid procedure.** Anterior oblique volume-rendered computed tomographic angiography shows the hypoplastic native aorta *(asterisk)*. A stent *(blue)* has been placed to keep the large patent ductus arteriosus open and bilateral branch pulmonary artery bands have been placed to limit pulmonary blood flow (*arrowheads* denote the right pulmonary artery band). *Arch,* Transverse aortic arch; *N-Ao,* neo-aorta; *RPA,* right pulmonary artery.

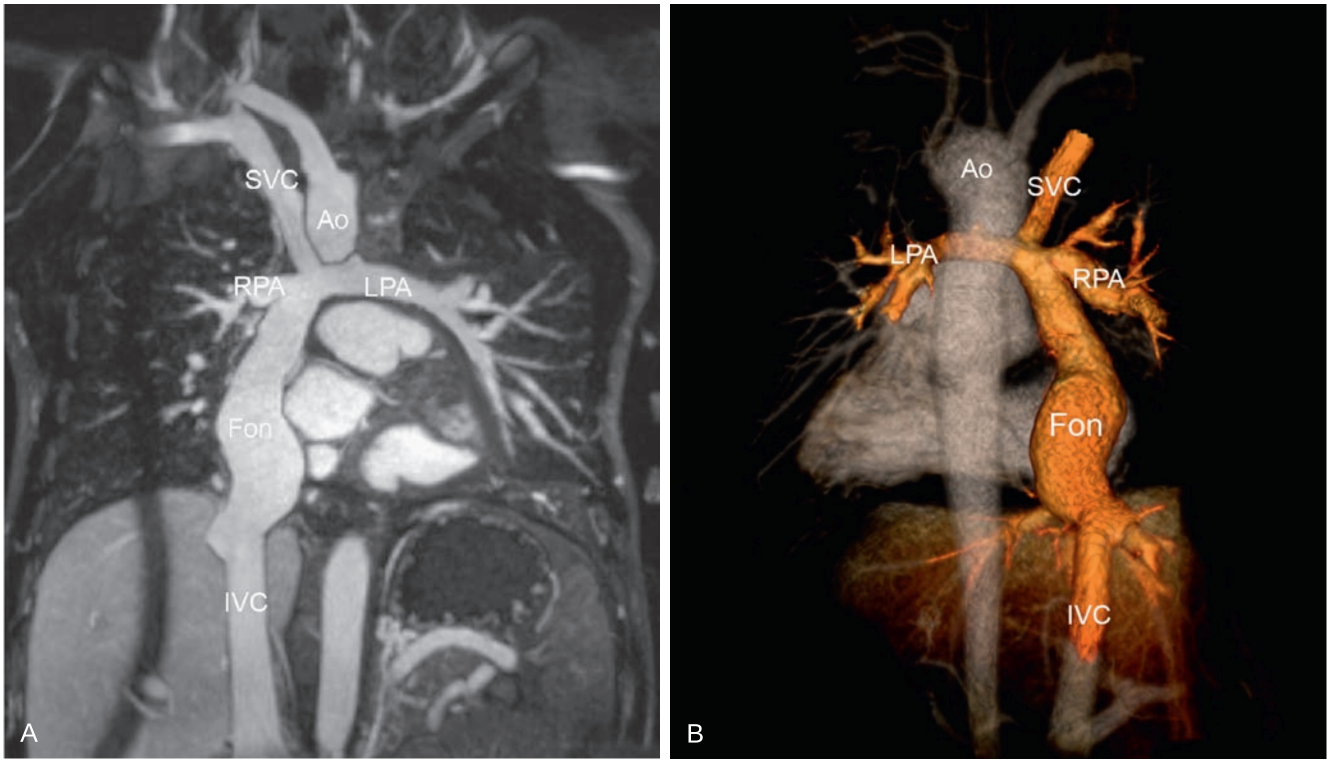


**Figure 73.4. Completed Fontan palliation.** (A) Oblique coronal MR angiography image demonstrating the Fontan connections. (B) Posterior projection of a three-dimensional MR angiography reconstruction demonstrating the Fontan connections. *Ao,* Aorta; *Fon,* Fontan conduit; *IVC,* inferior vena cava; *LPA,* left pulmonary artery; *RPA,* right pulmonary artery; *SVC,* superior vena cava.

***Etiology and Pathophysiology.*** Congenital aortic valve stenosis results from abnormal valve development rather than the degenerative disease commonly seen in adults. The stenotic valve has variable anatomy, with annular hypoplasia, thickened or tethered leaflets, and/or incompletely developed commissures. Valve morphology may predict clinical severity or associated disease.[29,30] Whereas neonatal critical AS often is associated with a unicuspid valve and a small eccentric orifice, bicuspid morphology accounts for up to 95% of cases of congenital valvar AS and is present in up to 85% of patients with coarctation.[31–33] Bicuspid aortic valve is associated with abnormal aortic tissue histologically similar to the medial disease of Marfan syndrome, and aortic dilation can occur even in the absence of significant valvar dysfunction.[34,35]

The narrowing in supravalvar AS most commonly is hourglass in shape and occurs immediately above the sinuses of Valsalva at the sinotubular junction. It may be associated with poststenotic dilatation of the aorta, diffuse aortic arch hypoplasia, aortic valve abnormalities, or coronary artery ostial stenosis.[36,37] Supravalvar AS often is part of a widespread elastin-related arteriopathy.

Subvalvar AS can be discrete or diffuse. The discrete form, which represents the majority of cases, consists of a circumferential thin fibrous membrane just below the valve or less commonly a fibromuscular ridge. In the more severe diffuse form, muscular hypertrophy produces tunnel-like narrowing along the length of the LVOT; this form is usually associated with other cardiac lesions, including multiple left-sided obstructions (Shone complex: supramitral ring, parachute mitral valve with stenosis, coarctation of the aorta),[38] double outlet right ventricle, or interrupted aortic arch.

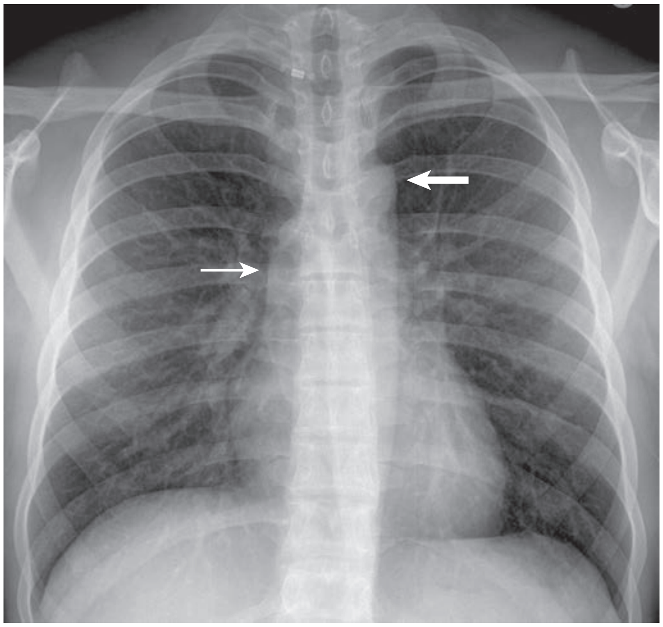
***Clinical Presentation.*** Critical or severe AS may be diagnosed prenatally or present early in infancy with severe left heart obstruction, congestive heart failure, dyspnea, and poor peripheral circulation. In critical AS, systemic flow is ductal dependent. In severe AS, the left ventricle may be dilated, dysfunctional, or hypoplastic. The clinical manifestations of AS in infancy depend on the degree of valvar obstruction and left ventricular dysfunction, as well as other associated left-sided obstructive lesions and the amount of shunted atrial and ductal flow.

AS in children usually is the result of a bicuspid aortic valve, and the obstruction generally is not severe but progresses gradually with age. Children with mild to moderate AS generally are asymptomatic and present with a characteristic systolic ejection murmur. With more severe AS, symptoms include chest pain, dyspnea, decreased exercise tolerance, and syncope, and sudden death may occur.

Patients with supravalvar AS may also experience left heart failure, dyspnea, angina, and syncope related to the degree of LVOT obstruction. Sudden death is a particular risk and may be related to associated coronary ostial obstruction and/or peripheral pulmonary arterial stenosis with biventricular hypertrophy. Patients may also present with systemic hypertension related to diffuse arteriopathy with reduced vascular elasticity.

Subvalvar AS is rarely detected in infancy but may be detected in childhood and is generally progressive. Children may have an asymptomatic systolic ejection murmur. A diastolic murmur of aortic insufficiency may be found in older children, as the turbulent subaortic jet damages the aortic valve over time.[39] In older patients with moderate to severe obstruction, signs of left ventricular failure with dyspnea, chest pain, syncope, and tachypnea may occur.

***Imaging.*** The chest radiograph in infants with critical AS shows cardiomegaly and pulmonary venous congestion. In older children with mild stenosis, the radiograph generally is normal. With more severe stenosis, left atrial enlargement and left ventricular hypertrophy, indicated by depression of the cardiac apex inferiorly toward the diaphragm and posteriorly to the inferior vena cava, may be seen. Poststenotic dilation of the ascending aorta is rare in young children (e-Fig. 73.8).



**e-Figure 73.8. Aortic valve stenosis.** A frontal view of the chest in an 18-year-old shows poststenotic dilation of the ascending aorta *(thin arrow)* and aortic arch *(thick arrow)*.

(B) Stage I Norwood reconstruction using the Sano modification. (C) Hybrid procedure. (D) Stage II or bidirectional Glenn anastomosis. (E) Stage II or bidirectional Glenn anastomosis after the Sano modification. (F) Stage III or Fontan procedure. *Asterisk,* Native ascending aorta; *LA,* left atrium; *LPA,* left pulmonary artery; *LV,* left ventricle; *RA,* right atrium; *RPA,* right pulmonary artery; *RV,* right ventricle; *SVC,* superior vena cava.

Echocardiography is the imaging procedure of choice for the evaluation of valvar AS, but cardiac MRI can complement echocardiography if acoustic windows are poor or larger field of view is needed. Goals of imaging include demonstration of the degree and location of obstruction, valve morphology, leaflet mobility, and effective valve orifice area. The valve typically appears thickened and doming, with asymmetric or restricted leaflet excursion (e-Fig. 73.9 and Video 73.2). Systolic valve area calculated by MRI planimetry correlates well with transesophageal echocardiography and cardiac catheterization measurements (Fig. 73.10 and Video 73.3).[40] Phase-contrast MRI is used to measure transvalvar velocity and regurgitant fraction (e-Fig. 73.11), and the gradient across the aortic valve in millimeters of mercury is calculated using the modified Bernoulli equation ($4V^2$, where $V$ is peak velocity beyond the aortic valve in meters per second). Left ventricular size and function are assessed, and delayed enhancement imaging may demonstrate endocardial fibroelastosis in severe cases (e-Fig. 73.12). Assessment of aortic root, ascending aorta, and arch size is crucial in infants with critical AS, and ongoing surveillance of the thoracic aorta for dilation is indicated in all patients with aortic valve disease.[35]

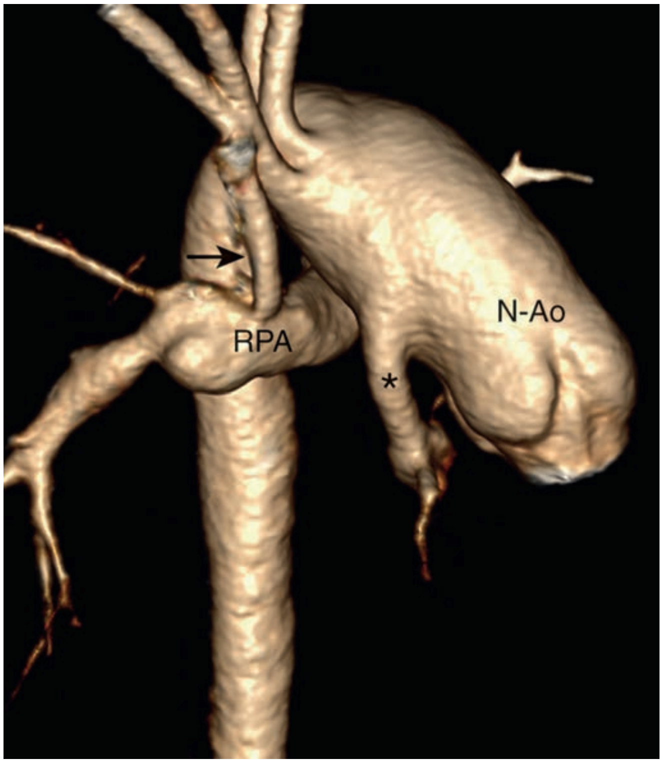


**Figure 73.6. A 6-month-old with hypoplastic left heart syndrome after Stage I Norwood procedure.** Anterior oblique volume-rendered CT angiography shows the hypoplastic native aorta *(asterisk)* anastomosed with the native pulmonary artery (now neo-aorta) and a Blalock-Taussig shunt *(arrow)* extending from the right brachiocephalic artery to the right pulmonary artery. *N-Ao,* Neo-aorta; *RPA,* right pulmonary artery.

In supravalvar AS, cardiac MRI or CTA may complement echocardiography to evaluate the type of stenosis (discrete or diffuse), the coronary ostia, ventricular mass and function, and other sites of vasculopathy (e.g., supravalvar pulmonary stenosis) (Fig. 73.13). In subvalvar AS, echocardiography and sometimes MRI are used to define the discrete subaortic membrane or ridge (Fig. 73.14) or the extent of the tunnel-type subaortic lesion and to quantify effects on ventricular mass and function.

***Treatment.*** Infants with severe or critical AS need urgent treatment. Patients are supported with $PGE_1$ infusion to maintain ductal patency, mechanical ventilation, and inotropic medications. Urgent percutaneous balloon valvuloplasty is the treatment of choice. During the era of aggressive transcatheter intervention, early mortality for infants with severe or critical AS has fallen from as high as 43% to 4% to 13%.[41,42] A neonatal Ross procedure (i.e., transplant of the pulmonary valve to the aortic position with coronary reimplantation and replacement of the pulmonary valve with a homograft conduit) may be considered for dysplastic valves or small aortic annuli[43,44] but is limited by higher rates of autograft deterioration in children compared with adults.[45,46]

Balloon valvotomy is considered in older children with a peak gradient of 50 mm Hg or greater at catheterization, for patients with angina, syncope, or ischemia, and for persons who want to play competitive sports or become pregnant.[47–49] Routine follow-up is necessary to evaluate for aortic insufficiency and recurrent stenosis. Late surgical valve repair or replacement is necessary in approximately 25% to 35% of patients.[42,50] For patients who require valve replacement, a bioprosthetic or mechanical valve may be placed or a Ross procedure may be performed.

Indications for interventions related to supravalvar AS are less clear, and outcomes are less favorable.[51,52] Aortoplasty is performed to enlarge the aortic sinuses, and additional patching of the ascending aorta and transverse aorta may be necessary. Associated coronary ostial stenoses are addressed. Complications include aortic aneurysms and aortic valve dysfunction.[51] Given the recurrent

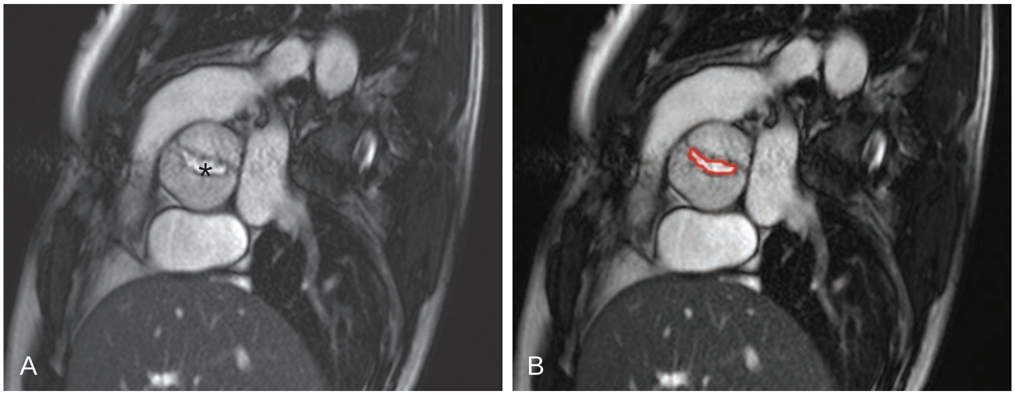

**Figure 73.10. Bicuspid aortic valve in a 25-year-old with history of aortic coarctation.** (A) A cross-sectional steady-state free-precession (SSFP) systolic MR image of a severely stenotic bicuspid aortic valve *(asterisk)* with fusion of the right and noncoronary commissures, giving a "fish-mouth" appearance. See Video 73.3 for a cine SSFP image of the same. (B) The aortic valve area (outlined in red) as measured by planimetry is 1.18 $cm^2$.

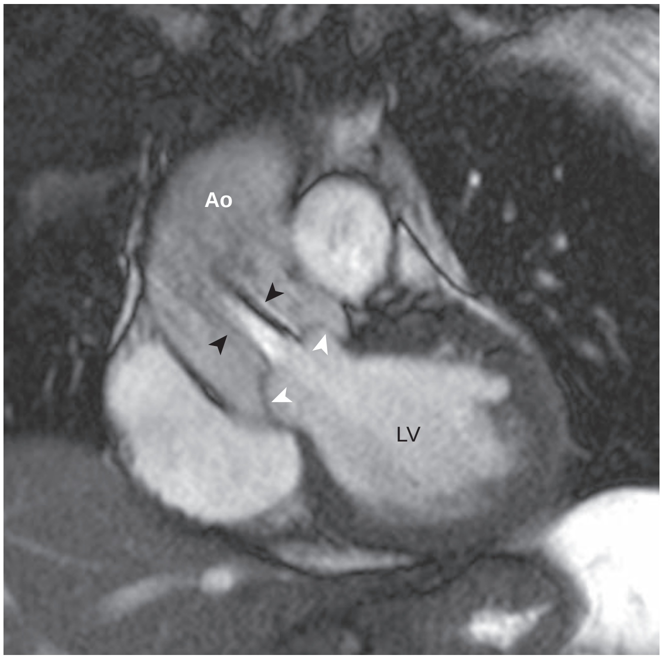
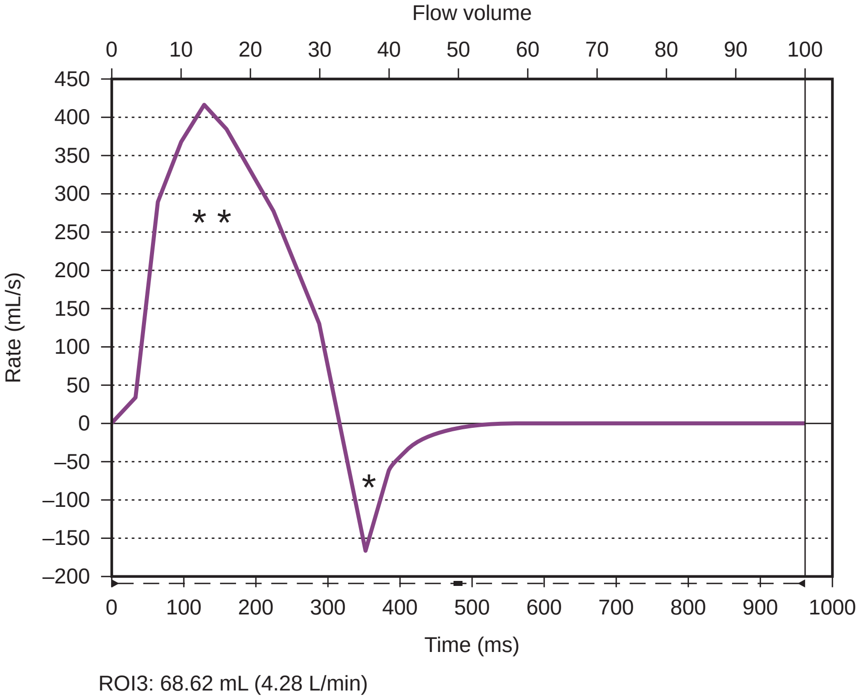
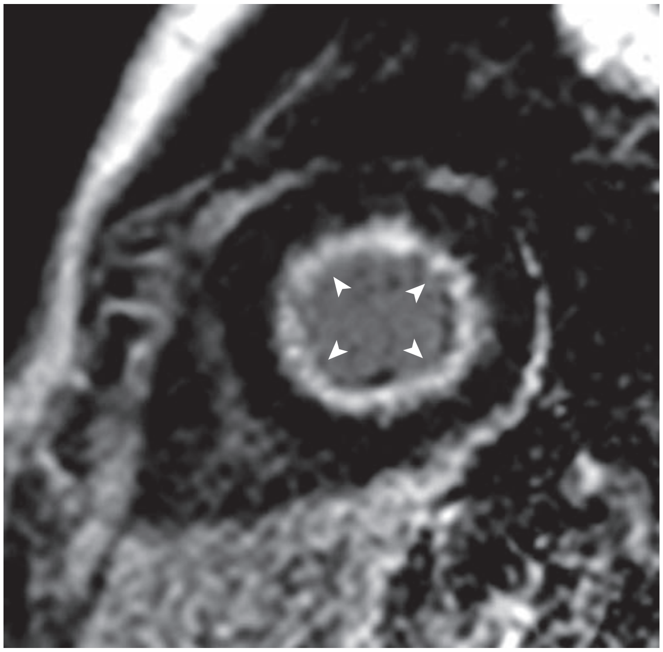


**e-Figure 73.9. Bicuspid aortic valve in a 25-year-old with history of aortic coarctation.** Steady-state free-precession (SSFP) MR image perpendicular to the plane of the bicuspid aortic valve shows upward ballooning of the aortic valve leaflets *(white arrowheads)* and a turbulent poststenotic jet *(black arrowheads)* into the dilated ascending aorta *(Ao)*. See Video 73.2 for cine SSFP MRI of the same case with a regurgitant jet visible. *LV,* Left ventricle.



**e-Figure 73.11. Aortic valve flow curve.** A flow curve obtained by MR phase-contrast imaging acquired just above the aortic valve shows forward *(two asterisks)* and regurgitant *(single asterisk)* flow. The regurgitant fraction (regurgitant flow volume/forward flow volume) was calculated to be 18%.



**e-Figure 73.12. Endocardial fibroelastosis.** Short-axis MRI delayed enhancement image in a 14-year-old with bicuspid aortic valve after multiple balloon aortic valvuloplasty procedures who, in his teenage years, experienced progressive heart failure symptoms, including dyspnea on exertion, increasing fatigue, and decreased exercise tolerance in the setting of normal systolic function. Delayed enhancement inversion recovery images show diffuse subendocardial late enhancement *(arrowheads)*. He underwent a high-risk, but ultimately successful, cardiac transplantation approximately 1 year after he became symptomatic. Pathology of the explanted heart revealed a bicommissural aortic valve, biventricular hypertrophy, hypertrophic subendocardial thebesian veins with prominent intimal thickening, and diffuse endocardial fibroelastosis. *(Modified from Robinson JD, Del Nido PJ, Geggel RL, et al. Left ventricular diastolic heart failure in teenagers who underwent balloon aortic valvuloplasty in early infancy.* Am J Cardiol. *2010;106[3]:426–429.)*

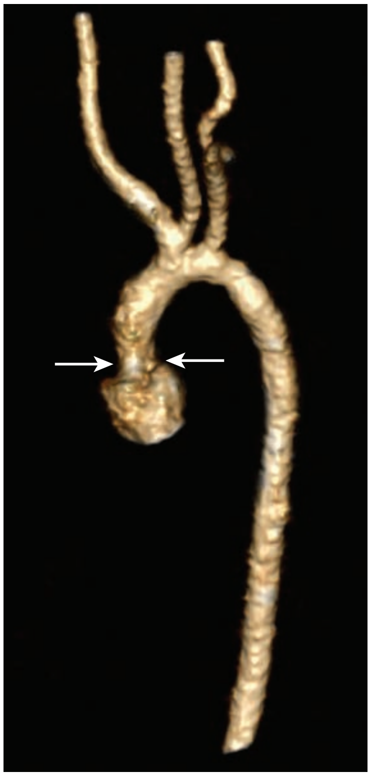


**Figure 73.13. Supravalvar aortic stenosis (AS).** An oblique volume-rendered three-dimensional CT angiographic image shows supravalvar AS with an abrupt caliber change in the proximal ascending aorta *(arrows)*.

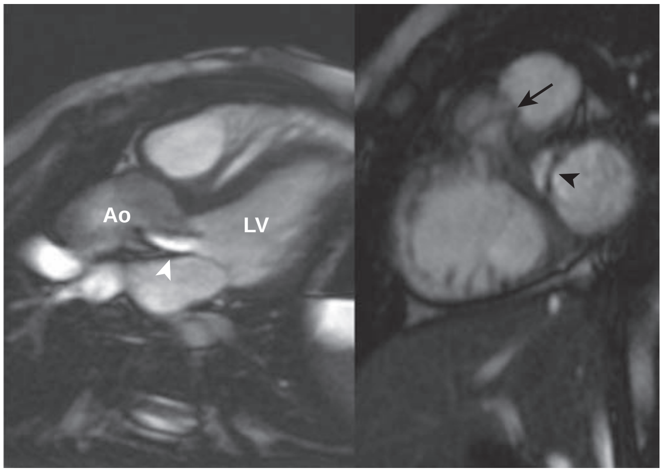

**Figure 73.14. Subaortic stenosis.** Steady-state free-precession MRI long-axis *(left)* and short-axis *(right)* images of the left ventricular outflow tract (LVOT) show a subaortic membrane *(black arrowhead)* causing a jet of flow acceleration across the LVOT *(white arrowhead)* beginning just below the aortic valve plane *(arrow)*. *Ao,* Aorta; *LV,* left ventricle.

and progressive nature of diffuse arteriopathy, long-term follow-up is warranted.

In asymptomatic patients, the timing of surgical intervention for subvalvar AS is controversial and is related to the degree and progression of LVOT obstruction and other associated heart disease.[53–55] Discrete subvalvar obstruction is treated with membrane resection with or without septal myectomy, while treatment for the tunnel-like obstruction varies with aortic valve size and function. The Konno procedure (i.e., aortoventriculoplasty, including replacement of the aortic valve) and modifications including valve repair or the Ross procedure may be performed (e-Fig. 73.15). Stenosis recurrence and aortic regurgitation are more common after repair of tunnel-like stenosis but occur with both types of subvalvar AS.

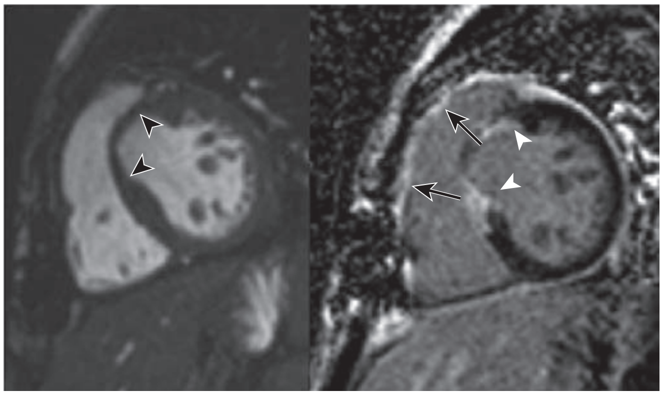
## COARCTATION OF THE AORTA

***Overview.*** Coarctation of the aorta accounts for approximately 7% of cases of congenital heart disease,[56] with a male-to-female ratio of approximately 1.5 : 1.[35] A bicuspid aortic valve is seen in up to 80% of patients,[33] and ventricular septal defect (VSD) is seen in 11% to 18% of patients.[57,58] Other associated lesions include ASD, left-sided obstructive lesions, transposition of the great arteries, double-outlet right ventricle, and atrioventricular septal defect.[57] Berry aneurysms are seen in up to 10% of patients.[59] Approximately 5% of girls presenting with aortic coarctation have Turner syndrome,[60] and up to 15% of girls with Turner syndrome have coarctation.[61,62] Atypical, complex aortic coarctation (e.g., long-segment, with aneurysmal segments) is present in 15% of patients with PHACES syndrome (posterior fossa defects, hemangiomas, arterial anomalies, cardiac defects and coarctation, eye anomalies, and sternal defects or supraumbilical raphe).[63]

***Etiology and Pathophysiology.*** Coarctation of the aorta is a narrowing of the thoracic aorta that generally occurs adjacent to the insertion site of the ductus arteriosus just distal to the left subclavian artery. The coarctation is almost always juxtaductal and discrete, but varying degrees of tubular hypoplasia of the transverse arch and isthmus may be present and are more commonly seen in infancy.[64] The embryology of aortic coarctation is not known, but two theories have been proposed. The ductal sling theory suggests that contractile ductal tissue abnormally extends around the aortic lumen, leading to a shelflike aortic narrowing in the juxtaductal region with ductal closure.[64] The flow theory postulates that aortic coarctation develops as a result of decreased blood flow through the aortic isthmus with left-sided obstructive lesions. In fetal life, the isthmus normally receives a relatively low volume of blood flow from the left ventricle, while most of the flow to the descending aorta arises from the right ventricle through the PDA; isthmic flow is even lower with left-sided obstructive lesions.[64,65]

The pathophysiology of coarctation of the aorta is related to the severity of the arch obstruction, the presence of collateral vessels, and associated cardiac lesions.[57] Initially, the neonate with coarctation will have a PDA, allowing blood flow to bypass the obstruction. However, associated left-sided obstructive lesions may further increase left ventricular afterload, and the presence of a VSD may increase left ventricular volume load, leading to early pulmonary venous and arterial hypertension and heart failure. With severe coarctation, closure of the PDA acutely increases left ventricular afterload, resulting in acute heart failure and shock. With less severe obstruction, collateral blood vessels develop to bypass the obstruction, and this may mask the presence of the coarctation until later in childhood or adulthood. Upper extremity hypertension is present in 90% of children, with three proposed mechanisms: mechanical aortic obstruction, abnormal baroreceptor function and altered vascular reactivity proximal to the obstruction, and hyperactivation of the renin-angiotensin system caused by the underperfused kidneys.[57,66,67]

***Clinical Presentation.*** Infants with critical coarctation of the aorta, especially when it is associated with other cardiac defects, typically present by 7 to 14 days of life as the PDA begins to close and they have dramatic signs of congestive heart failure and poor systemic perfusion. In fact, congestive heart failure presenting between the first and fourth weeks of life strongly suggests



**e-Figure 73.15. Ross-Konno procedure for aortic and subaortic stenosis in a 17-year-old.** MRI short-axis steady-state free-precession *(left)* and postcontrast phase-sensitive inversion recovery delayed enhancement *(right)* views show thinning of the myocardium in the region of the left ventricular outflow tract *(black arrowheads)* with corresponding late enhancement *(white arrowheads)* consistent with the Konno ventriculoplasty and Ross procedure. Also, note the postoperative late enhancement in the region of the right ventricular outflow tract related to placement of the pulmonary homograft *(arrows)*.

coarctation. Clinical symptoms include dyspnea, poor feeding, tachycardia, and signs of shock, including oliguria, anuria, and severe acidemia. Femoral pulses are weak or absent, and differential blood pressures generally show a gradient between the upper and lower limbs.[57]

Coarctation of the aorta also may be diagnosed from infancy to adulthood in asymptomatic or mildly symptomatic patients, with a reported median age of 10 years (range, 1–36 years).[68] These patients present later because the coarctation is not significant or because adequate collateral circulation has developed. The diagnosis usually is made on the basis of routine physical examination findings such as an incidental murmur, hypertension, or absent or diminished lower extremity pulses.[68]

***Imaging.*** Infants with severe coarctation demonstrate evidence of congestive heart failure, including cardiomegaly and increased pulmonary vascular markings (e-Fig. 73.16). Chest radiographs in children older than 1 year and younger than 5 years usually show a normal heart size, but cardiomegaly due to left ventricular hypertrophy can be seen. The hallmark of aortic coarctation is rib notching, grooves on the undersurfaces of the posterior ribs (typically fourth through eighth) formed by dilated intercostal collateral arteries, which is usually seen after 5 years of age.[69] Rib notching is bilateral unless one subclavian artery arises distal to the coarctation or is stenotic. A "figure three" sign frequently is seen along the left upper mediastinal border, representing the prominent aortic knob and left subclavian artery proximally, the indentation from the coarctation, and the poststenotic aortic segment (Fig. 73.17). The imprint of the aorta on the adjacent barium-filled esophagus, which is known as the "E" sign or "reversed three" sign, is caused by dilation of the aorta proximal and distal to the coarctation.

Echocardiography is the method of choice for imaging coarctation in infancy. CTA and MRI can provide detailed anatomic imaging of the coarctation in older children or adults with limited acoustic windows (Figs. 73.18 and 73.19). MRI also can be used

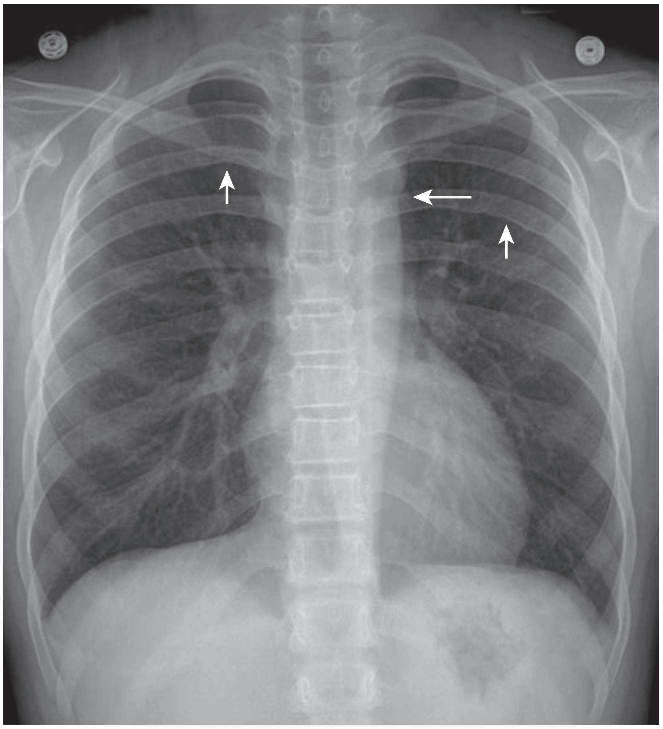


**Figure 73.17. Coarctation of the aorta in a 10-year-old.** A frontal view of the chest shows the "figure three" sign *(long arrow)*, which is indicative of aortic coarctation, and bilateral posterior rib notching *(short arrows)*, which is indicative of collateral vessels.

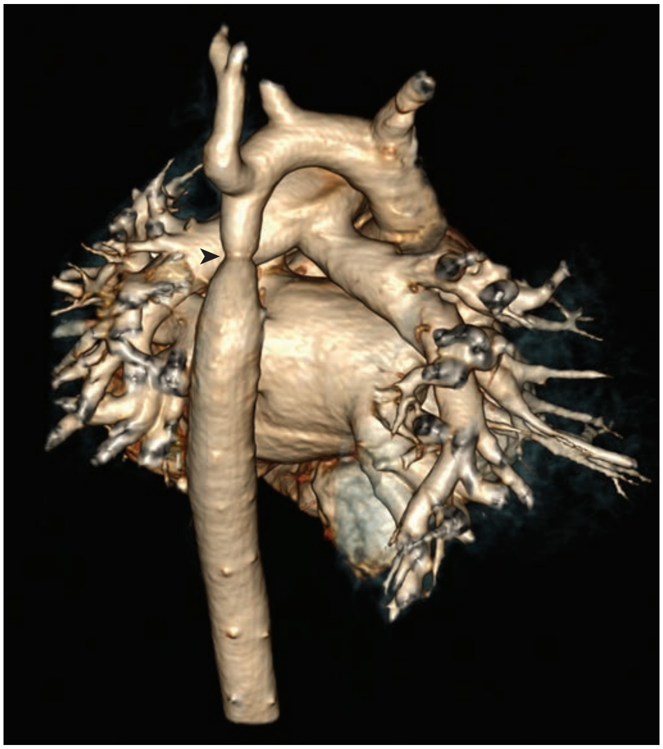

**Figure 73.18. Aortic coarctation in a 3-year-old.** Posterior projection from a volume-rendered MR angiography image shows a discrete aortic coarctation *(arrowhead)* distal to the left subclavian artery.

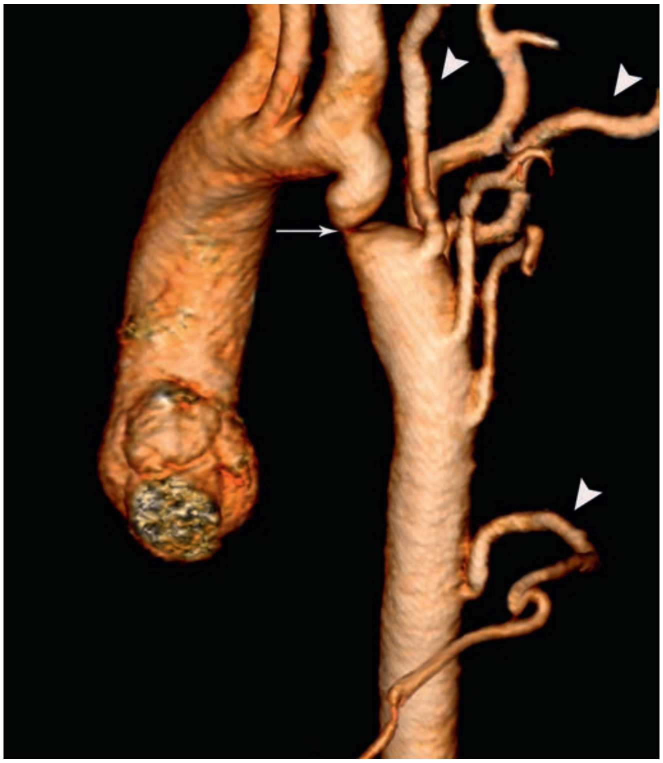

**Figure 73.19. Aortic coarctation in an 11-year-old.** A three-dimensional CT angiography reconstruction lateral view shows a discrete aortic coarctation *(long arrow)* distal to the left subclavian artery, with multiple dilated tortuous collateral vessels *(arrowheads)* arising from head and neck arteries proximal to the coarctation and feeding the descending aorta distal to the coarctation.

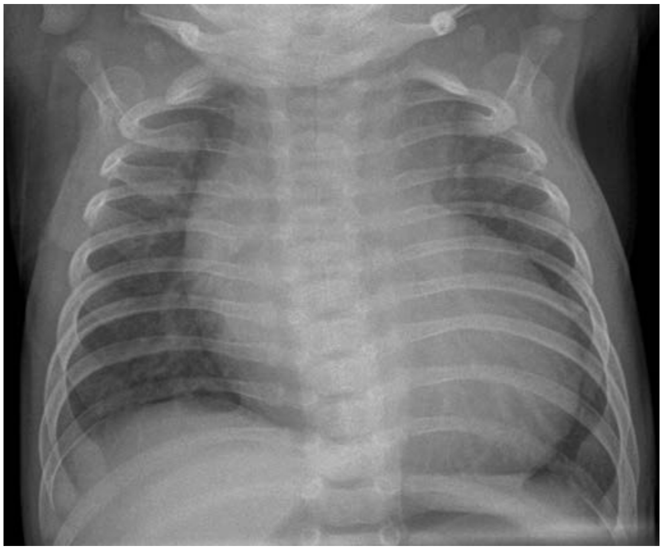

**e-Figure 73.16. Critical aortic coarctation in a 2-week-old.** Frontal view of the chest shows cardiomegaly with mild pulmonary vascular congestion.

to assess the hemodynamic significance of the coarctation. A complete examination involves imaging for ventricular systolic function, volume and mass; atrioventricular and semilunar valve assessment with particular attention to the aortic valve; and imaging of the aortic root, ascending aorta, arch, coarctation, and descending aorta to the renal arteries. Maximum blood flow velocity, blood flow volume, and flow pattern in the aorta just distal to the coarctation can be assessed using phase-contrast MRI sequences (e-Fig. 73.20 and Video 73.4). The maximal flow velocity obtained across the coarctation can be used in the Bernoulli equation (see aortic stenosis imaging section) to estimate the pressure gradient.[70] Aortic flow volume at the diaphragm also can be assessed and may be increased relative to flow volume just distal to the coarctation as a result of recruitment of collateral flow through the intercostal arteries; this can be an indicator of the significance of the coarctation.[71–73]

***Treatment.*** Neonates presenting with congestive heart failure due to aortic coarctation are initially stabilized with inotropic drugs and $PGE_1$ to maintain ductal patency and improve blood flow to the descending aorta. After stabilization, urgent surgical repair is the treatment of choice.[74,75] Balloon angioplasty can be considered as an initial procedure for neonates at high surgical risk.[74]

Repair is performed on a more elective basis in patients who present in infancy or childhood with a murmur or upper extremity hypertension. Conventional therapy for aortic coarctation is surgical, most typically resection of the coarctation with end-to-end or extended end-to-end anastomosis.[57,74,75] Other surgical procedures, including patch aortoplasty and subclavian flap repair, are less commonly performed because of the risk of aneurysm formation at the patch site with patch aortoplasty and left arm complications and remnant residual ductal tissue with the subclavian flap repair.[57,74] The use of balloon angioplasty for native aortic coarctation in infants and children is controversial because rates of aneurysm formation,[76] iliofemoral artery injury,[76] and reintervention for recurrent stenosis[74] may be higher than for conventional surgical therapy. Larger children may be candidates for stenting of native coarctation, using a stent with diameter potential sufficient for the adult-sized aorta.[77] For recoarctation, the transcatheter approach is accepted therapy in all age groups.[74] Late complications after surgical or endovascular treatment include recurrent coarctation, aneurysm or pseudoaneurysm formation, aortic dissection, and hypertension.[57,74,78]

## KEY POINTS

- Surgical palliation of HLHS is a staged reconstruction that involves three surgical procedures, with the ultimate goal of creating in-series pulmonary and systemic circulations supported by the right ventricle.
- A bicuspid aortic valve is the most common cause of congenital aortic stenosis and is associated with aortic root dilation and aortic wall abnormalities.
- Aortic coarctation morphology, collateral circulation, and associated lesions have important implications for presentation, management, and prognosis.

## IMAGING OF THE RIGHT HEART

The algorithms used for left ventricular assessment cannot always be applied to the right ventricle (RV), which differs in morphology, shape, and function. The RV has a complex geometrical shape with a thinner and more trabeculated myocardium than the left ventricle (LV).[1] The chest x-ray is a preliminary imaging tool, with the lateral view best suited to detect RV enlargement. Echocardiography is the mainstay for assessment of the RV, with published adult[2] and pediatric guidelines.[3] Cardiac magnetic resonance imaging (CMR) is the current gold standard for RV assessment and tissue characterization. Gated cardiac computed tomography angiography (CTA) is an alternative when CMR is contraindicated.[4]

The retrosternal location of the right ventricular outflow tract (RVOT) and pulmonary valve (PV) makes echocardiography difficult, especially in adolescents and adults. CMR and CTA allow detailed assessment of anatomy, valve mobility, presence of poststenotic dilation, and associated condition of the branch pulmonary arteries (PAs).[5] With current CT scanners, image acquisition can be completed within seconds or less and with a short breath hold. CTA is excellent for assessment of proximal and distal PAs. CMR is excellent for sequential assessment of the PV. Anatomy and function of the RVOT and PV can be assessed by balanced steady state free precession (SSFP) CMR imaging. Turbo spin-echo with blood suppression technique is very useful for imaging RVOT and branch PAs especially in patients with metallic implants causing artifacts. Through-plane and in-plane phase contrast quantification of flow across the PV and branch PAs provides comprehensive functional assessment including valve stenosis or regurgitation, and differential pulmonary blood flow. Magnetic resonance angiography (MRA) is an alternative to CTA for assessment of extracardiac structures.[5]

## EBSTEIN ANOMALY

***Overview.*** Ebstein anomaly accounts for fewer than 1% of all cases of congenital heart disease.[6] Associated malformations include atrial septal defect (ASD), ventricular septal defect (VSD), pulmonary stenosis and atresia, tetralogy of Fallot, congenitally corrected transposition of the great arteries, and patent ductus arteriosus (PDA).[6] Conduction system abnormalities and arrhythmias, including Wolff–Parkinson–White syndrome, have been seen in 22% to 42% of patients.[7]

***Etiology, Pathophysiology, and Clinical Presentation.*** Wilhelm Ebstein provided the first description of this abnormality in 1866.[8] It is characterized by abnormal development and positioning of the tricuspid valve (TV) leaflets, with apical displacement of the septal and posterior leaflets. This phenomenon leads to partitioning of the RV into an atrialized basal inlet segment and an apical outflow chamber. The displaced valve leaflets may be adherent to the RV wall. The anterior valve leaflet tends to be normally positioned, however, it is frequently large and redundant, and sometimes adherent to the RV free wall with a "sail-like" appearance.[9]

The pathophysiology of Ebstein anomaly varies, depending on the degree of dysplasia and displacement of the TV leaflets and the presence and severity of associated defects. With greater degrees of dysplasia and displacement, the severity of tricuspid insufficiency increases, resulting in elevated right atrial pressures and thus right-to-left shunting at the atrial level. Patients with mild forms of Ebstein anomaly may be asymptomatic in childhood and present with symptoms of cyanosis, right heart failure, or arrhythmia in adulthood. Patients with severe forms present in early neonatal life with severe combined cyanosis and acidosis, and a ductal-dependent circulation.[10]

***Imaging.*** Classically, the chest radiographic appearance includes a globular or box-shaped heart as a result of right atrial enlargement associated with normal to diminished pulmonary vascularity (Fig. 74.1).[11] Findings can vary by clinical presentation. Patients with significant valvar dysplasia and severe tricuspid insufficiency have marked right heart enlargement and decreased antegrade pulmonary blood flow. With less marked valve displacement and tricuspid insufficiency, only mild right heart enlargement may be present (e-Fig. 74.2).

Ebstein anomaly can be readily diagnosed by both prenatal and postnatal echocardiography.[10] Echocardiography and CMR allow for detailed anatomic and functional evaluation. The characteristic features include displacement and tethering of the septal and posterior leaflets of the TV, dilation of the right atrium, and atrialization of the RV (Fig. 74.3). Imaging goals include evaluation of the TV and severity of tricuspid regurgitation; evaluation of right-to-left shunting through the ASD or patent foramen ovale, evaluating volume and function of the RV including the atrialized portion; delayed enhancement in the thin atrialized ventricular wall and septum; PV and branch PA stenoses; left ventricular size and systolic function; and aortic arch anomalies.[7,12–14] Axial imaging provides reliable information about the atrialized RV.[15] A total right/left ventricular volume index obtained by CMR has been found to correlate with heart failure markers and disease severity.[16]

***Treatment.*** Patients with mild forms of Ebstein anomaly may not require surgical treatment, or the need for surgery may not arise until later in life until right heart dysfunction develops. Indications for surgical intervention/reintervention and/or medical therapy include limited exercise capacity (greater than New York Heart Association class II), increasing heart size (cardiothoracic ratio >65%), cyanosis (resting oxygen saturations <90%), severe tricuspid regurgitation with symptoms, progressive right ventricular dilation or dysfunction, transient ischemic attack, or stroke.[17,18]

Surgery includes valvuloplasty with either the Carpentier or Da Silva's cone procedures. The Carpentier procedure involves reimplantation of the anterior and posterior TV leaflets at the level of the neotricuspid annulus, resulting in a monocuspid or bicuspid valve configuration.[19] More recently described "cone reconstruction" includes mobilization and re-anastomosis of the TV leaflets and subvalvar apparatus to form a cone-shaped valve with improved competence.[9] Other possible treatments include TV replacement or, rarely, oversewing of the TV and creation of a central shunt in infancy with an ultimate single ventricle type palliation. Transcatheter closure of the ASD may be considered if severe cyanosis is present without tricuspid insufficiency necessitating valve repair.[20] Rarely, cardiac transplantation may be indicated.[10] Clinically significant arrhythmias develop in some patients and require transcatheter or surgical ablation procedures.[7]

## Abstract:

Cardiovascular magnetic resonance (CMR) and computed tomography angiography (CTA) allow detailed assessment of right ventricular anatomy, pulmonary valve mobility, presence of post-stenotic dilation and associated condition of the branch pulmonary arteries. For Ebstein anomaly, CMR provides detailed evaluation of the atrialized and functional segments of the right ventricle. For tricuspid atresia, cross-sectional imaging after the Glenn or Fontan procedures includes assessment of anatomy and flow through the cavopulmonary and Fontan pathways, atrioventricular valve function, and quantification of ventricular size and systolic function and the presence of collaterals. For pulmonary atresia with intact ventricular septum, preoperative imaging goals include evaluation of associated coronary artery anomalies. For pulmonary valve stenosis, the peak velocity obtained by either echocardiography or phase contrast MRI can be used to calculate the peak pulmonary valve pressure gradient in mmHg.

As a result, a large atrialized portion of the right ventricle *(ARV)* is present. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium.

## TRICUSPID ATRESIA

***Overview.*** Tricuspid atresia features an absence of the TV with a resultant lack of a direct connection between the right atrium and RV. It accounts for approximately 3% to 4% of congenital heart disease.[21] Most cases are sporadic, but familial cases and association with 22q11 microdeletions have been reported.[22]

***Pathophysiology and Clinical Presentation.*** The TV is usually absent; instead, muscular tissue or, less commonly, fibrous tissue is present on the floor of the right atrium. An interatrial communication is present to allow blood to reach the left side of the heart from the right, and a VSD is usually present. The degree of RV development is related to the size of the VSD.[21] In tricuspid atresia, there is complete mixing of systemic venous and pulmonary venous return and a variable degree of cyanosis. The severity of cyanosis is related to the degree of RV outflow obstruction, the size of the VSD, the origins of the great arteries (ventriculo-arterial connections are concordant in 70% of cases and discordant or transposed in 30% of the cases), the presence or absence of a PDA, pulmonary vascular resistance (associated variable degree of pulmonary or subpulmonary stenosis), and LV outflow obstruction. The most commonly used classification system was developed by Tandon and Edwards in 1974 describing tricuspid atresia as types I, II, and III (Table 74.1).[23] An unrestrictive VSD with no pulmonary outflow obstruction leads to greater pulmonary than systemic blood flow, resulting in mild cyanosis with overcirculated, congested lungs. In contrast, restricted pulmonary blood flow results in more severe cyanosis.[21]

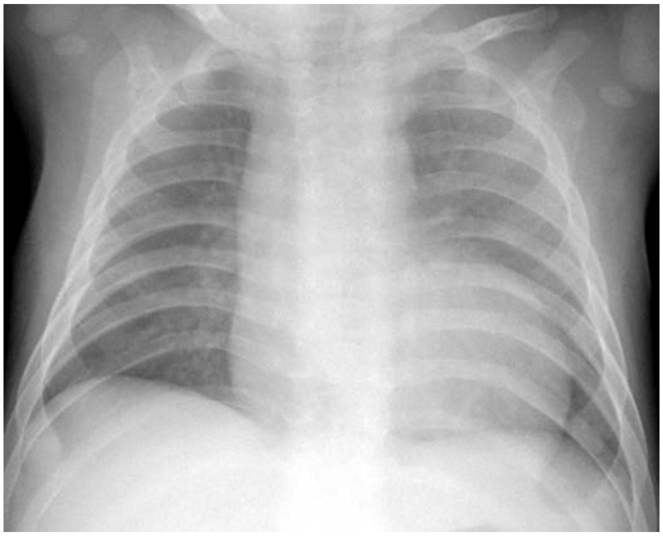
***Imaging.*** The heart usually appears normal or may be mildly enlarged on chest radiography. With pulmonary outflow obstruction, normal to decreased pulmonary vascularity is noted. With no obstruction, there is cardiomegaly and increased pulmonary vascularity (e-Fig. 74.4).

The characteristic imaging feature of tricuspid atresia is replacement of the TV with a ridge of muscular and fatty tissue positioned between the enlarged right atrium and the hypoplastic RV (e-Fig. 74.5). The size of the VSD and the relationship of the great arteries should be characterized. Echocardiography is the imaging modality of choice in infancy, but CMR and CTA can be used to determine anatomy in more complex cases. These modalities are playing an increasing role in preoperative evaluation in this disease, sometimes obviating the need for cardiac catheterization (see Treatment section).[24] Important components of cross-sectional imaging after Glenn or Fontan procedures include assessment of anatomy and flow through the cavopulmonary and Fontan pathways, atrioventricular valve function, quantification of ventricular size and systolic function, and the presence of collaterals. New MR techniques like 4D flow can be used to evaluate the vascular geometry and complex blood flow patterns in Fontan patients.[25]

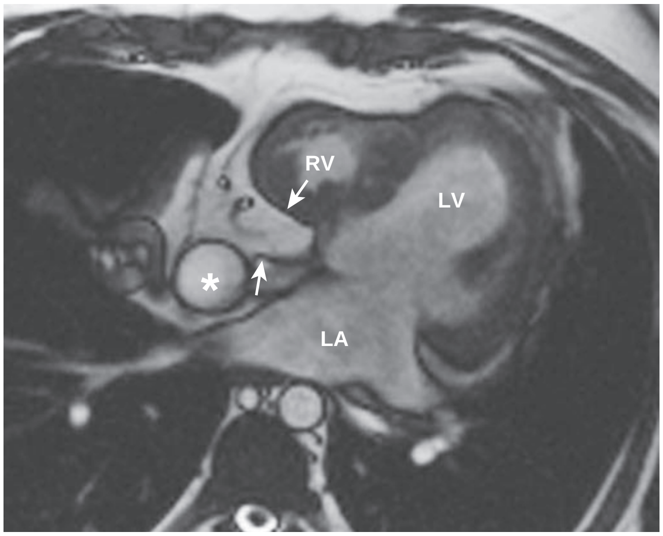
***Treatment.*** Ultimately, patients with tricuspid atresia require univentricular palliation because the hypoplastic RV is not capable of handling the entire cardiac output. The goal of univentricular repair is to have the single LV support the systemic circulation and for the systemic venous return to directly enter the PAs, thus bypassing the nonfunctional RV. The first stage of single ventricle palliation is performed in early infancy. Those with cyanosis may

**TABLE 74.1** Anatomic Classification of Tricuspid Atresia

| Type | A | B | C |
|---|---|---|---|
| I, normally positioned great arteries (70%) | Pulmonary atresia | Small ventricular septal defect, pulmonary artery hypoplasia | Large ventricular septal defect, normal pulmonary artery |
| II, dextro-transposition of the great vessels (25%) | Pulmonary atresia/stenosis | Pulmonary or subpulmonary stenosis | Large pulmonary artery |
| III, levo-transposition of the great vessels (5%) | Pulmonary or subpulmonary stenosis | Subaortic stenosis | |



**e-Figure 74.4. Tricuspid atresia in a 4-month-old boy.** A frontal chest radiograph shows mild cardiac enlargement with a rounded apex and a concave left upper heart margin as a result of pulmonary atresia.



**e-Figure 74.5. Tricuspid atresia after extracardiac Fontan palliation *(asterisk)* in a 27-year-old.** An axial steady-state free-precession image shows a ridge of fatty tissue *(arrows)* in the floor of the right atrium at the site of the atretic tricuspid valve. A small caliber right ventricle *(RV)* also is present. *LA,* Left atrium; *LV,* left ventricle.

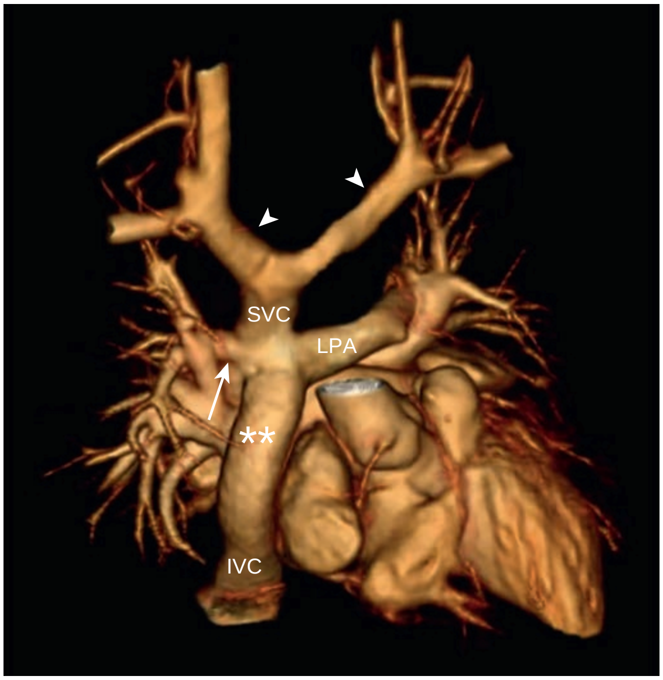


**Figure 74.6. Fontan palliation in an adult.** An extracardiac Fontan baffle *(asterisks)* extends from the inferior vena cava *(IVC)* to the right pulmonary artery *(arrow)*. A bidirectional Glenn anastomosis is seen between the superior vena cava *(SVC)* and right and left pulmonary arteries. *LPA*, Left pulmonary artery; *arrowheads* right and left innominate veins.

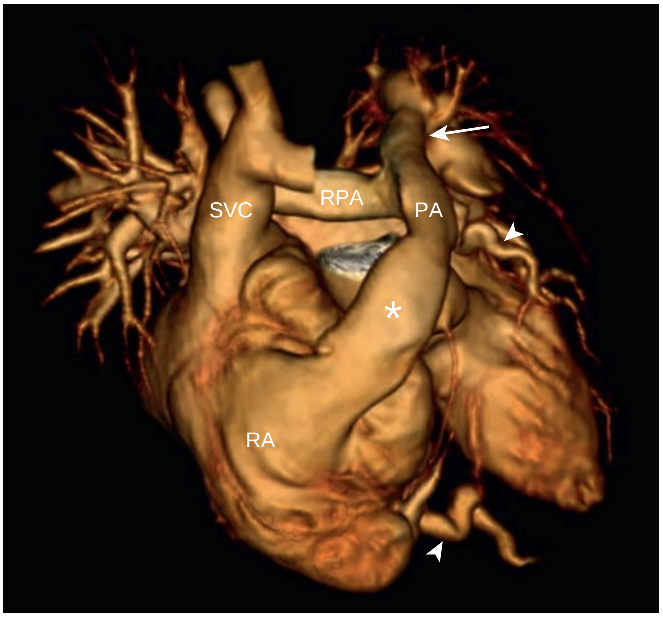

**Figure 74.7. Right atrial** ***(RA)*** **to pulmonary artery** ***(PA)*** **Fontan conduit anastomosis for palliation of tricuspid atresia.** *Asterisk* indicates the conduit that extends from the *RA* to the main pulmonary artery *(PA)*; *RPA*, right pulmonary artery; *LPA*, *white arrow; SVC*, superior vena cava. Venovenous collaterals to the coronary venous circulation *(white arrowheads)*.

require a prostaglandin infusion to keep the PDA open until a surgical aorto-pulmonary shunt (like the modified Blalock–Taussig shunt) is placed. In overcirculated infants with no pulmonary stenosis, diuretics and a surgical PA band are needed.

The second stage of the palliation is generally performed between 3 and 9 months of age in the form of a bidirectional Glenn shunt, anastomosing the superior vena cava to the right PA. The aorto-pulmonary shunt is taken down. Completion of the total cavopulmonary anastomosis with the Fontan procedure, performed between 1 and 5 years of age, involves anastomosing the inferior vena cava to the PAs via an extracardiac conduit or an intracardiac "lateral tunnel" (current Fontan pathway modifications) (Fig. 74.6).[26] This procedure completes the separation of the systemic and pulmonary circulations and eliminates cyanosis. Other approaches to creating a cavopulmonary connection, including direct anastomosis of the right atrium to the PA, have been used in the past (Fig. 74.7).[27]

Surgical mortality rates for the modified Fontan procedure range between 1.1% and 2.7%.[26] Acute complications after the Fontan procedure include pleural effusions and ascites that may be slow to resolve.[28] Long-term complications of Fontan palliation include thrombosis within the cavopulmonary pathway, especially in a dilated right atrium; stenoses within the cavopulmonary pathway; cyanosis due to the development of pulmonary arteriovenous malformations or systemic venous to pulmonary venous collateral shunts; arrhythmias; congestive hepatopathy or cirrhosis; and protein-losing enteropathy (Fig. 74.8).[28] Cardiac transplantation remains the only definitive treatment for patients with failing Fontan procedure circulation.[28]

## PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

***Overview.*** Pulmonary atresia (PA) with intact ventricular septum (PA/IVS), a rare cardiac disorder that is highly variable in its appearance and presentation, represents approximately 1% to 3% of all cases of congenital heart disease.[29] RV outflow tract obstruction is present because of atresia of the PV or the pulmonary infundibulum with an intact ventricular septum. Obstruction of the outflow from the right heart necessitates an interatrial communication or PDA to allow for pulmonary blood flow.[30]

***Etiology, Pathophysiology, and Clinical Presentation.*** In contrast to patients with PA with VSD, patients with PA/IVS generally have well-developed, confluent central PAs.[31] Morphology of the TV however is highly variable, with both severe stenosis and marked insufficiency seen. The spectrum of RV development is also variable, with varying degrees of hypoplasia (hypoplastic right heart syndrome). The RV is less hypoplastic in the setting of severe tricuspid regurgitation. Significant RV hypertrophy is common. Associated coronary artery anomalies may include RV to coronary connections. Some may exhibit an RV-dependent coronary circulation.[32] In this condition, blood from the hypertensive RV perfuses the coronary arteries with possible associated coronary stenosis or even atresia. Significant drop in RV pressure (after pulmonary valvotomy) may result in myocardial ischemia and hemodynamic collapse in those cases. RV-dependent coronary circulation is typically seen in patients with small RVs and no significant tricuspid regurgitation.[33] The major clinical manifestation of PA/IVS is cyanosis, which is typically seen shortly after birth when the PDA begins to close.

***Imaging.*** In infancy, the size of the heart on a chest radiograph correlates with the degree of tricuspid insufficiency, with larger cardiac size correlating with increasing tricuspid regurgitation. Severe cardiomegaly producing the "wall-to-wall" heart may be present with severe tricuspid regurgitation (Fig. 74.9).[34]

Echocardiography yields diagnostic imaging in infancy, and CMR may be used in complex cases.[35] Imaging features include atresia of the PV or infundibulum, hypoplastic RV and TV, an interatrial communication, and a PDA. Preoperative imaging goals include a comprehensive evaluation of the right heart structures. Attention to the anatomy and function of the hypoplastic TV

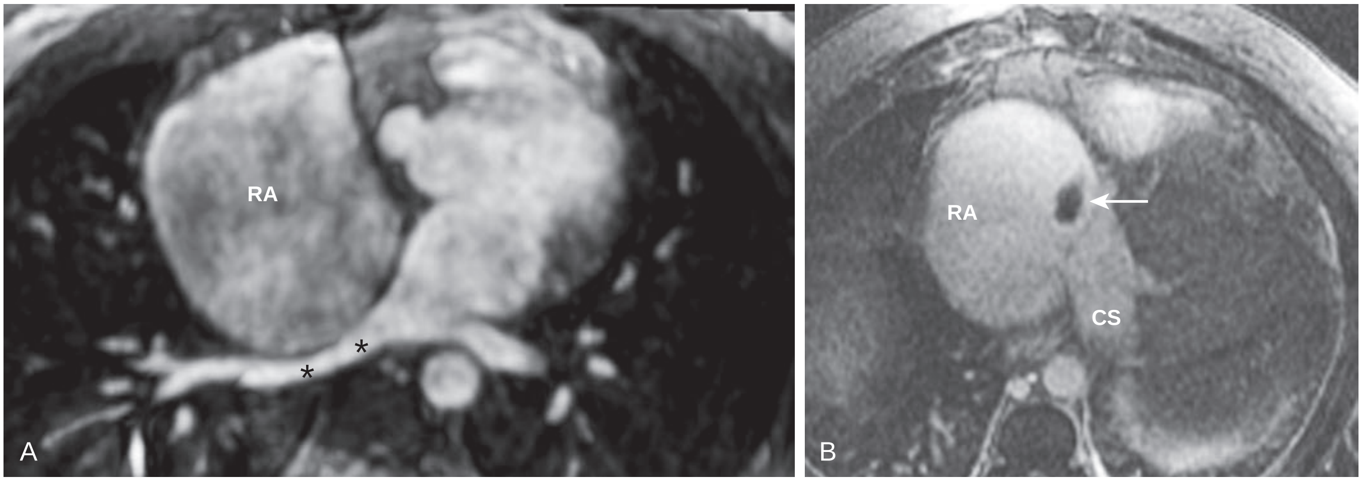

**Figure 74.8. Fontan complications.** (A) A 25-year-old with tricuspid atresia after right atrial to pulmonary artery Fontan palliation. **Figure 74.9. Pulmonary atresia with intact ventricular septum (PA/IVS).** (A) Frontal chest radiograph demonstrates mild cardiac enlargement in a cyanotic newborn boy. Additionally, asymmetric pulmonary vascularity is present with decreased pulmonary blood flow on the right compared with the left related to stenosis of the right pulmonary artery just proximal to the insertion of the patent ductus arteriosus. (B) Frontal chest radiograph in a cyanotic newborn boy showing severe cardiomegaly because of significant tricuspid regurgitation producing severe cardiomegaly with a "wall-to-wall" appearance of the heart.

and RV is necessary (Fig. 74.10). Coronary artery anatomy and ventriculo-coronary communications may not be well visualized on echocardiography, and thus additional evaluation with angiocardiography, CTA, or MRA may be necessary. Postoperatively, the type of imaging that is used will depend on the type of repair that has been performed. CMR may be important in these postoperative patients since RV evaluation is limited with echocardiography.

***Treatment.*** Initial management of a neonate with PA/IVS includes the administration of prostaglandins to prevent PDA closure and maintenance of pulmonary blood flow. Interventions depend on the degree of RV and PA development and the coronary circulation pattern. A pulmonary valvotomy is contraindicated in the presence of an RV-dependent coronary circulation.[32] A transcatheter pulmonary valvotomy and balloon dilation is performed if the morphology of the imperforate PV is favorable.[36] When the pulmonary anatomy is not favorable for a transcatheter intervention, a surgical valvotomy may be performed.[37] In the setting of significant RV hypoplasia, a one-and-one-half ventricular repair may be considered.[38] This repair uses a bidirectional Glenn shunt to partially unload the right heart so that it receives venous return only from the inferior vena cava. Univentricular repair or cardiac transplantation may be considered with significant coronary anomalies.[39]

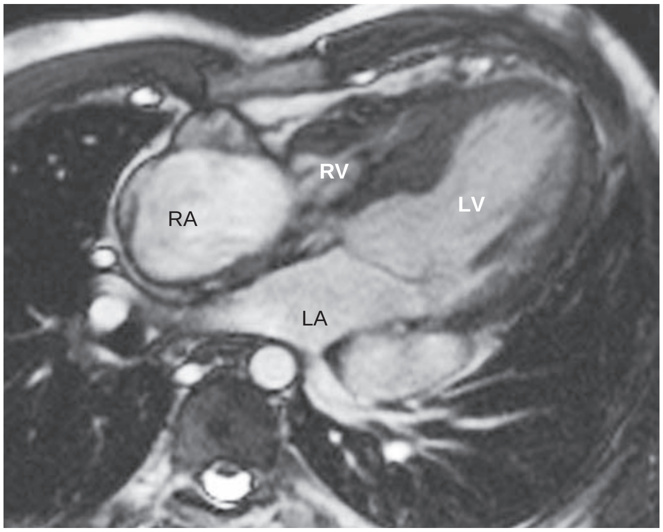

**Figure 74.10. Pulmonary atresia with intact ventricular septum after undergoing right classic Glenn and right atrium *(RA)* to pulmonary artery Fontan procedures in a 21-year-old.** A four-chamber steady-state free-precession MR image shows the hypoplastic right ventricle *(RV)*. The *RA* is mildly dilated. *LA,* Left atrium; *LV,* left ventricle.

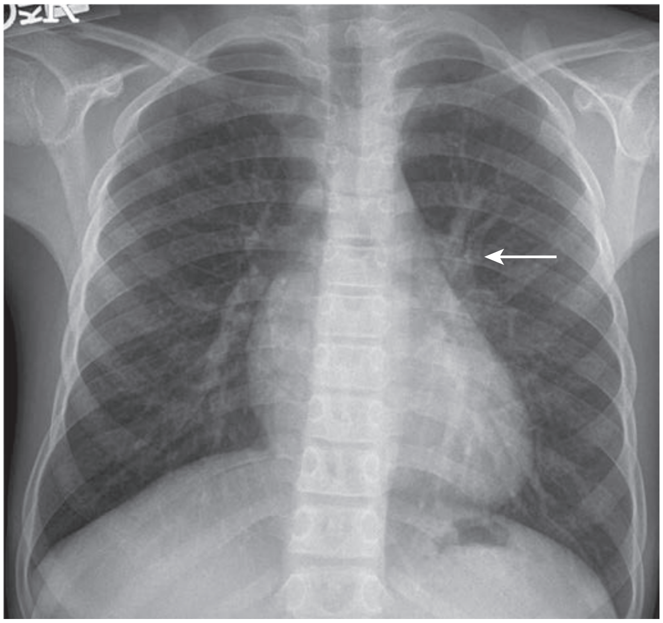

**Figure 74.11. Pulmonary valve stenosis.** Frontal chest radiograph in a 10-year-old shows a normal heart size and pulmonary vascularity. Mild enlargement of the pulmonary trunk and left pulmonary artery is present *(arrow)*.

## PULMONARY VALVE STENOSIS

***Overview.*** Pulmonary valve stenosis (PVS) accounts for approximately 8% to 10% of all cases of congenital heart disease[40] and 80% to 90% of cases of RV outflow obstruction.[41] Less commonly, pulmonary outflow stenosis occurs at the subvalvular, supravalvular, or peripheral PA levels. Peripheral pulmonary stenosis can be seen after maternal rubella infection and in Noonan, Alagille, and Williams syndromes (see Chapter 78).[42–44]

***Etiology, Pathophysiology, and Clinical Presentation.*** In most cases of PVS, the valve leaflets are thickened, and fusion of the leaflets produces a domelike PV with a small central or eccentric opening. The stenotic valve may be trileaflet, bicuspid, unicuspid, or dysplastic. In severe forms (10%–20% of cases) and when associated with syndromes, the PV is dysplastic, with markedly thickened, nonfused cusps and a hypoplastic annulus.[45] The peripheral pulmonary stenoses seen in Williams and Alagille syndromes may be single or multiple.[42,43]

When severe or critical PVS manifests in infancy, the stenosis leads to decreased right ventricular output.[46] The RV and TV may be hypoplastic because limited forward flow through these structures during embryonic life decreases the stimulus for their development. Right atrial pressures are increased, resulting in cyanosis caused by right-to-left shunting through an atrial level shunt. Pulmonary blood flow may depend on the PDA. Closure of the PDA can lead to decreased pulmonary blood flow, cyanosis, hypoxemia, and death.[46]

Clinical presentation in childhood depends on the degree of RV outflow obstruction. Most children with mild to moderate PVS are asymptomatic and only have a systolic murmur. In cases of severely stenotic and dysplastic valves, symptoms include dyspnea, fatigue, and chest pain with right heart failure.[47]

***Imaging.*** Significant cardiomegaly due to right atrial and left heart enlargement may be seen in infants with critical PVS. In cases of moderate to severe PVS, poststenotic dilation of the PAs may be seen (Fig. 74.11). The chest radiograph of patients with mild PVS may appear normal. Enlargement of the main and left PAs may be seen as a result of the extension of the flow jet from the pulmonary trunk directly posterior into the left PA.[48] The pulmonary vascularity is normal if adequate RV output is present. RV hypertrophy with elevation of the cardiac apex and associated filling in of the upper retrosternal space can be seen.

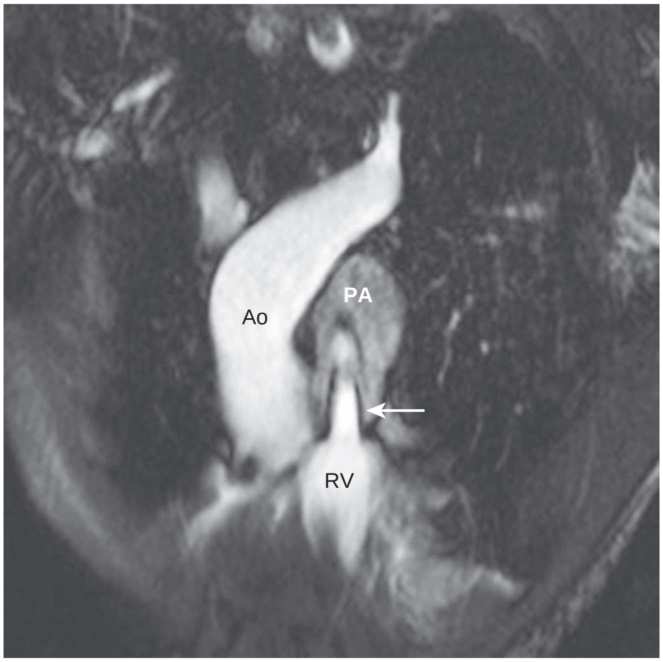

**Figure 74.12. Pulmonary valve stenosis.** A steady-state free-precession MR image coronal to the right ventricular outflow tract *(RV)* shows a poststenotic jet of turbulent flow *(arrow)* across the pulmonary valve. *Ao,* Aorta; *PA,* pulmonary artery.

Echocardiography is the initial imaging method of choice. The role of CMR has increased and is particularly important in adult patients with limited echocardiographic windows.[49] Imaging findings include valve thickening and systolic doming with poststenotic enlargement of the PAs (Fig. 74.12). With a dysplastic valve, the pulmonary annulus is small. Imaging goals include evaluation of the level of the obstruction, valve anatomy, and determination of the peak systolic velocity and pressure gradient across the obstruction. The pressure gradient can be estimated from the flow velocity obtained by echocardiography or CMR phase contrast imaging using the modified Bernoulli equation, $\Delta P = 4V^2$ (where $\Delta P$ is the pressure gradient and $V$ is the peak velocity across the PV in m/sec). Lower peak velocities may be obtained on CMR relative to echocardiography.[50,51] Quantitative assessment of the RV size and systolic function is necessary, as is assessment of the left heart.[45] MRA or CTA allows determination of peripheral PA stenosis. After intervention, imaging is used to determine the degree of residual pulmonary stenosis and the severity of pulmonary regurgitation, and to evaluate RV size and systolic function.

***Treatment.*** Infants with critical PVS are treated medically with prostaglandin $E_1$ infusion to maintain ductal patency; inotropic support and intubation may be needed.[46,47] Balloon valvuloplasty is the treatment of choice for isolated PVS in a nondysplastic valve, with excellent outcomes.[46,52–54] A systemic-to-pulmonary artery shunt is rarely indicated for continued cyanosis.[55] Balloon valvuloplasty often is used as the initial treatment for "dysplastic" PVs, but surgery is frequently needed because of the lower response rate.[40,56] Peripheral pulmonary stenoses often require repeat angioplasties and/or stent placement.[57,58]

Indications for catheter reintervention or surgery include residual RV outflow obstruction from severe infundibular hypertrophy, residual PVS, or peripheral arterial stenosis. PV replacement is indicated for symptomatic severe pulmonary insufficiency, RV dysfunction and dilation, or significant ventricular arrhythmia.[59–62]

## KEY POINTS

- CMR and CTA allow detailed assessment of right heart anatomy, PV mobility, presence of poststenotic dilation, and associated conditions of the branch PAs.
- Ebstein Anomaly: Assessment of atrialized and functional segments of the RV is key.
- Tricuspid Atresia: Studies should focus on anatomic and flow evaluation of the Glenn and Fontan pathways, atrioventricular valve function, ventricular size and systolic function, and presence of collateral vasculature.
- PA with intact ventricular septum: In addition to right and left heart assessment, evaluation for associated coronary artery anomalies and RV-dependent coronary circulation should be undertaken.

# Conotruncal Anomalies

Maryam Ghadimi Mahani, Prachi P. Agarwal, Jimmy C. Lu, and
Adam L. Dorfman

Conotruncal anomalies are a group of congenital heart defects involving the outflow tracts of the heart. The conotruncal anomalies include tetralogy of Fallot (TOF), transposition of the great arteries (TGA), double-outlet ventricles, truncus arteriosus, and interrupted aortic arch (IAA) type B.

Conotruncal abnormalities are the result of abnormal division or rotation of the primitive truncus during embryologic development.[1,2] The common outlet of the embryonic univentricular heart normally undergoes a complex sequence of events to separate into the right ventricular outflow tract (RVOT) and left ventricular outflow tract (LVOT), the aorta, and the main pulmonary artery (see Chapter 62).[3] Control by numerous genes and migration of the mesenchymal cells from the embryonic neural crest are required for this development.[1] Mutations in a number of genes have been associated with conotruncal anomalies in humans and animal models.[4]

Echocardiography is the mainstay of clinical diagnosis. Conventional angiography is used primarily to evaluate coronary artery anatomy and aortopulmonary collaterals. Magnetic resonance imaging (MRI) and computed tomography (CT) occasionally are used to clarify anatomic details that are not fully delineated by echocardiography in the preoperative patient; these details often are related to the aortic arch, pulmonary arteries and their supply, and pulmonary veins. MRI and CT more often are requested for routine follow-up of patients with conotruncal anomalies, particularly as they reach their teenage and adult years.

## TETRALOGY OF FALLOT

***Overview.*** TOF is the most common cyanotic congenital heart defect. The median described incidence of TOF is 356 per 1 million live births in the United States.[5] Classic manifestations include RVOT obstruction, ventricular septal defect (VSD), overriding of the aortic root above the VSD, and right ventricular (RV) hypertrophy (Fig. 75.1A). These findings are a result of underdevelopment of the subpulmonary infundibulum,[6] which is associated with anterior deviation of the conal septum. Rather than sitting between the anterior and posterior limbs of the trabecula septomarginalis (a Y-shaped bundle of muscle along the right side of the ventricular septum), the conal septum in TOF typically is fused with the anterior limb, bringing the aorta over the ventricular septum and leading to the malalignment VSD.[7,8] The septal malalignment and hypertrophy of the trabeculations of the infundibular free wall result in RVOT obstruction (Fig. 75.1B). The VSD in TOF is located between the malaligned conal septum superiorly and the muscular septum inferiorly,[9] and typically is large, nonrestrictive, and subaortic.

TOF can include pulmonary atresia or dysplastic (absent) pulmonary valve syndrome, in addition to the more common pulmonary stenosis. The extent of RVOT obstruction is variable, ranging from minimal to complete atresia.[10] The pulmonary valve is often thickened with doming leaflets and a hypoplastic annulus causing valvular stenosis. The size of the main and branch pulmonary arteries also varies. Patients with pulmonary valve atresia have pulmonary blood flow supplied by a patent ductus arteriosus, aortopulmonary collateral arteries, or both (e-Fig. 75.2). The central pulmonary arteries can be absent, discontinuous, or diminutive. In TOF with a dysplastic pulmonary valve, congenital severe pulmonary regurgitation occurs, which often is associated with severe dilatation of the central pulmonary arteries and resultant airway compression (e-Fig. 75.3A and B).[11]

***Etiology, Pathophysiology, and Clinical Presentation.*** Genetic abnormalities such as chromosome 22q11 deletion, which also leads to DiGeorge or velocardiofacial syndrome, may play an important role in some patients with TOF.[12] Many cases are sporadic, without any specific genetic abnormality identified.

Clinical manifestations are variable. Most patients have adequate pulmonary blood flow at birth, and increasing cyanosis develops early in life.[13] If RVOT obstruction is severe, right-to-left shunting occurs, resulting in cyanosis. When the obstruction is less severe, the shunting is predominantly left to right; patients with this condition can present with congestive heart failure. If patients who have TOF with pulmonary atresia are dependent on the patent ductus arteriosus, an infusion of prostaglandin $E_1$ is necessary to maintain ductal patency until a more stable pulmonary blood flow can be established. In patients who have TOF with dysplastic pulmonary valve syndrome, presentation may be with tracheobronchomalacia and air trapping, as well as cyanosis.

Other congenital heart anomalies can accompany TOF, including right aortic arch (25%) and coronary artery anomalies such as abnormal origin of the left anterior descending (LAD) coronary artery arising from the right coronary artery (5%–6%) or dual LAD coronary arteries.[14] When the LAD coronary artery arises from the right coronary artery, it passes over the RVOT before supplying its usual territory (e-Fig. 75.4).

***Imaging.*** RV hypertrophy causes uplifting of the cardiac apex. Concavity is present at the location of the main pulmonary artery because of underdevelopment, causing a “wooden shoe “or “boot shape” appearance of the heart (in French, *Coeur en sabot)* on frontal chest radiographs, a classic sign for TOF (Fig. 75.5). The shadow of the main pulmonary artery is absent, and pulmonary vascularity is decreased.[15] Rarely, dilatation of the pulmonary artery occurs as a result of an aneurysm, or asymmetric pulmonary vascularity is present as a result of differential pulmonary artery stenosis and collateralization. In the absence of a thymus, the possibility of DiGeorge syndrome should be considered. A right-sided aortic arch also can be seen on the frontal chest radiograph (see Fig. 75.5).

Complete anatomic diagnosis in a neonate with TOF usually is made by echocardiography, with an infrequent need for cross-sectional imaging. CT or MRI typically is requested to determine pulmonary artery anatomy and sources of pulmonary blood flow, including the central pulmonary arteries, patent ductus arteriosus, and aortopulmonary collaterals. CT angiography is an effective modality for delineating pulmonary artery and collateral anatomy in these patients but has the disadvantage of using ionizing radiation.[16] MRI also can accurately describe these anatomic details without the risks of ionizing radiation. Turbo spin echo techniques can display vessels clearly and demonstrate airway anatomy. The mainstay of MRI for these anatomic questions is three-dimensional, gadolinium contrast-enhanced magnetic resonance angiography (MRA), which is highly accurate compared with diagnostic catheterization.[17]

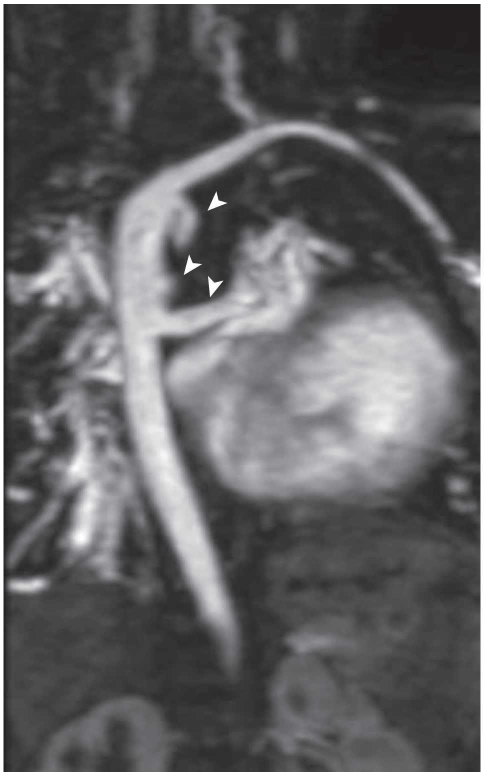
***Treatment and Follow-up.*** Current management of TOF in most large centers is early single-stage reconstructive surgery, typically performed at 3 to 6 months of age.[18] Staged reconstruction can be required if significant hypoplasia of the central pulmonary arteries is present; a palliative shunt is placed from the systemic to the

## Abstract:

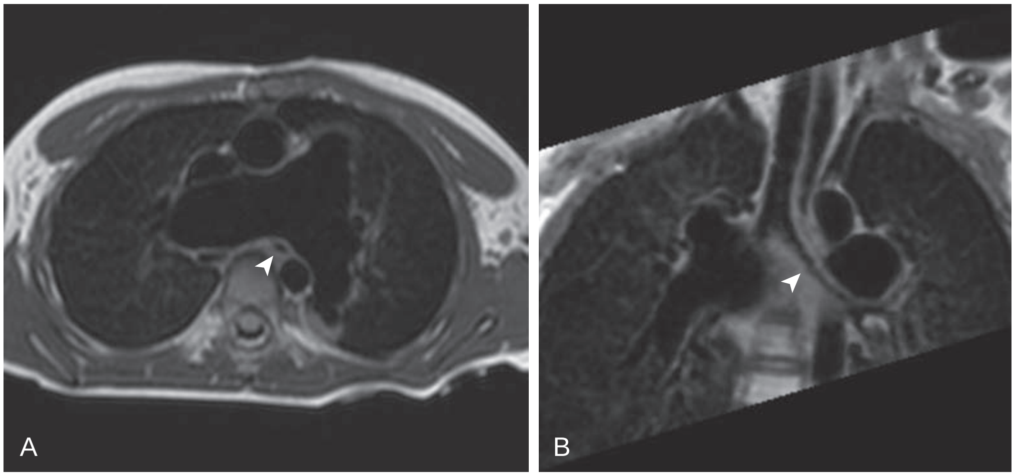
Conotruncal anomalies are a group of congenital heart defects involving the outflow tract of the heart and great vessels. The conotruncal anomalies described in this chapter include tetralogy of Fallot (TOF), transposition of the great arteries (TGA), double-outlet ventricles, truncus arteriosus and interrupted aortic arch (IAA) type B. An overview of each disease is presented, along with clinical course and treatment. Focus is on imaging characteristics, particularly for indications and findings of MRI and CT.

## Keywords:

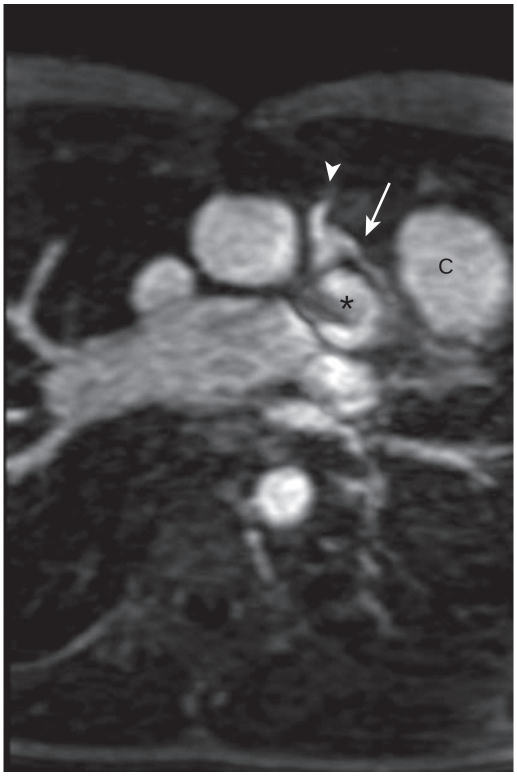
Conotruncal anomalies
Tetralogy of Fallot
Transposition of the great arteries
Double outlet right ventricle
Truncus arteriosus
Interrupted aortic arch type B



**e-Figure 75.2. Tetralogy of Fallot and pulmonary atresia in a 2-month-old girl.** Coronal-oblique maximum intensity projection from a contrast-enhanced MRA demonstrates aortopulmonary collaterals *(arrowheads)*. This patient also had a right aortic arch with aberrant left subclavian artery.



**e-Figure 75.3. Tetralogy of Fallot and an absent pulmonary valve after repair with a transannular patch in a 5-year-old boy.** (A) Axial black blood turbo spin echo MR image demonstrating markedly dilated branch pulmonary arteries. Note the caliber and position of the left mainstem bronchus *(arrowhead)* relative to the right pulmonary artery. (B) Coronal oblique minimum intensity projection demonstrates a narrowed left mainstem bronchus *(arrowhead)* as it passes posterior to the proximal right pulmonary artery.



**e-Figure 75.4. Tetralogy of Fallot in a 14-year-old boy.** Axial oblique maximum intensity projection from a contrast-enhanced MRA shows a left anterior descending (LAD) coronary artery *(arrow)* arising from the right coronary artery *(arrowhead)* and traveling anterior to the right ventricular outflow tract *(asterisk)*, preventing use of a transannular patch. A right ventricle to pulmonary artery conduit *(C)* was placed instead, anterior to the LAD coronary artery.

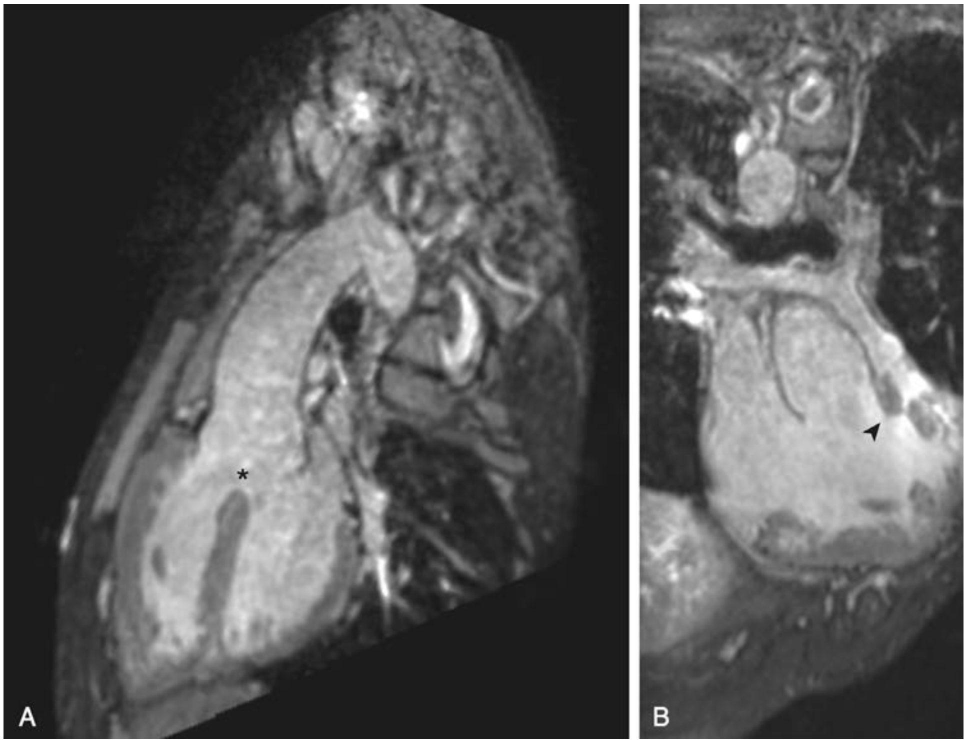


**Figure 75.1. Unrepaired tetralogy of Fallot in an 18-year-old.** (A) Sagittal oblique MRI balanced steady-state free-precession imaging demonstrates the aorta overriding an anterior malalignment ventricular septal defect *(asterisk)*. (B) Coronal oblique projection demonstrates the anterior deviation of the conal septum *(arrowhead)*, leading to subvalvar and valvar pulmonary stenosis.

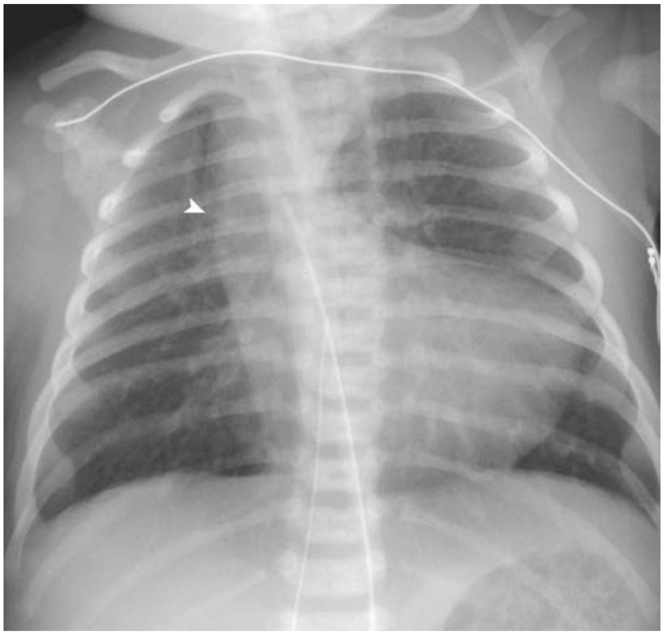

**Figure 75.5. Tetralogy of Fallot and pulmonary atresia in a 1-day-old girl.** Anteroposterior chest radiograph demonstrates the upturned apex and concavity in the region of the pulmonary artery (a boot-shaped heart). Note the shadow to the right of the trachea *(arrowhead)*, which is indicative of a right aortic arch.

pulmonary circulation to provide pulmonary blood flow. When pulmonary supply is from multiple aortopulmonary collaterals, a staged approach of unifocalization of collaterals to either a shunt or the central pulmonary arteries is utilized, eventually bringing the major vessels into continuity with the RV. VSD closure often is not tolerated until later in life in this subgroup of patients.[18]

The goal of surgical repair of TOF is to close the VSD and relieve the RVOT obstruction, thus providing unobstructed flow to the pulmonary vessels from the RV. The approach depends on the severity of the anatomy. The entire repair can be performed transatrially, including VSD closure and division of muscle bundles within the RVOT to relieve obstruction, with no right ventriculotomy. If the pulmonary valve annulus is hypoplastic, a limited transannular patch may be needed to relieve the obstruction.[18] This procedure inevitably results in severe pulmonary regurgitation. In the past, this operation was performed with a large right ventriculotomy, which now usually is avoided. In patients who have TOF with pulmonary atresia, a limited transannular patch may be sufficient to relieve RVOT obstruction. With a longer segment atresia, an RV to pulmonary artery conduit may be required. In patients with an LAD coronary artery arising from the right coronary artery and crossing the RVOT, an RV to pulmonary artery conduit occasionally is necessary to avoid damaging the vessel (see e-Fig. 75.4).[11]

In patients with a transannular patch, a pulmonary valve replacement may be indicated later in life to remove the volume load of pulmonary regurgitation from the RV (Video 75.1). The appropriate timing of this valve replacement is the subject of intense interest.[19] In patients who require an RV to pulmonary artery conduit, a conduit replacement will be needed in time because of somatic growth of the patient. A percutaneous pulmonary valve is also available for placement within a conduit to relieve both stenosis and regurgitation (Video 75.2).

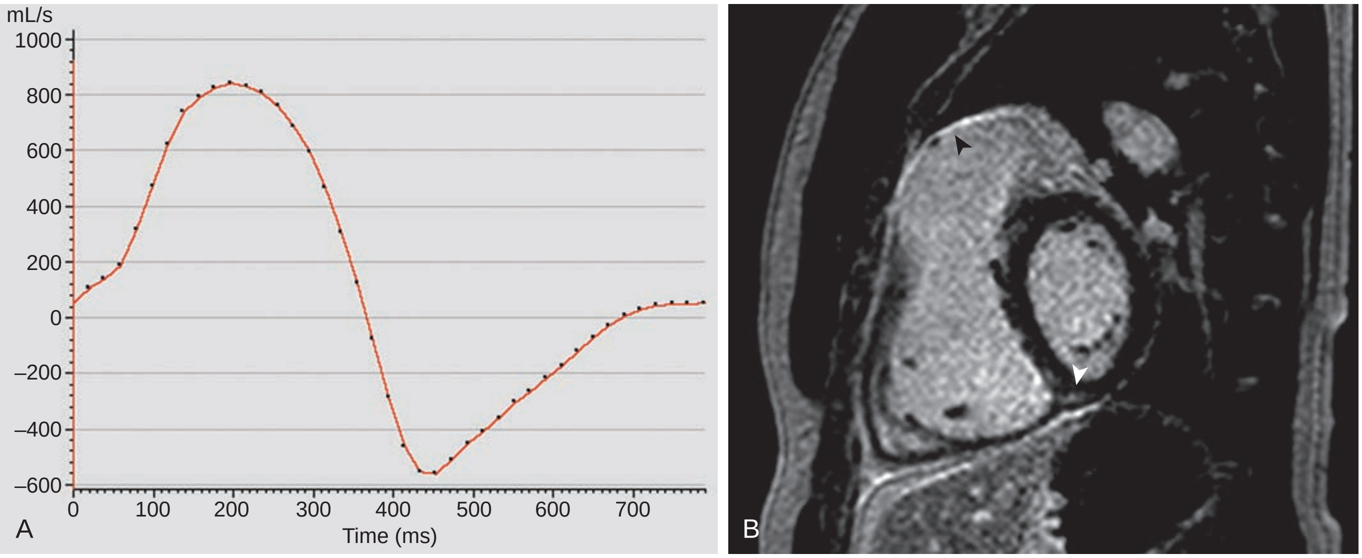

**Figure 75.6. Repaired tetralogy of Fallot in a 31-year-old man.** (A) Graphic representation of quantification of MR phase contrast imaging (flux vs. time) showing antegrade and retrograde flow in the main pulmonary artery. There is severe pulmonary insufficiency, with a regurgitant fraction of 57%. (B) Late gadolinium enhancement MRI in the short axis demonstrates enhancement *(arrowheads)* along the right ventricular outflow tract and at the inferior insertion point of the interventricular septum. See Videos 75.3, 75.4, and 75.5.

Repaired TOF is a frequent referral diagnosis for cardiac MRI. Chronic, severe pulmonary regurgitation can lead to RV pathology. Cardiac MRI is widely considered the gold standard for assessment of RV size and function, making it particularly useful in this patient population (Video 75.3). Other questions in this patient population include anatomy of the RVOT (Video 75.4), quantification of pulmonary regurgitation (Video 75.5 and Fig. 75.6A), assessment of branch and segmental pulmonary artery anatomy, measurement of branch pulmonary artery flow, anatomy of aortopulmonary collaterals, assessment of the left ventricle (LV), and aortic valve and root pathology.

These studies typically are performed with balanced steady-state free-precession (bSSFP) imaging in the vertical and horizontal long-axis planes and short axis of the ventricles, as well as parallel to the RVOT. Gadolinium-enhanced three-dimensional MRA offers high-resolution assessment of the distal pulmonary arteries and can evaluate for aortopulmonary collaterals. Velocity-encoded phase-contrast imaging assesses the ratio of pulmonary to systemic flow, differential pulmonary blood flow, and valve regurgitation. Late gadolinium enhancement imaging reveals scarring or fibrosis in the heart (Fig. 75.6B).[1,11]

CT for patients with repaired TOF is used for evaluation of pulmonary artery anatomy and aortic size, particularly in patients in whom MRI is contraindicated (e.g., patients with an internal defibrillator). Electrocardiographic-gated multidetector array CT can provide RV size and systolic function, although with less temporal resolution than MRI.

## TRANSPOSITION OF THE GREAT ARTERIES

***Overview.*** TGA is defined by discordant ventriculoarterial relations; the aorta is connected to the RV and the pulmonary artery is connected to the LV. The most common type of TGA has {S,D,D} cardiac segmental anatomy—that is, visceral and atrial situs solitus (S), ventricular D loop (D), and dextroposition of the aortic valve (D) (see Chapter 63). The aortic valve is side-by-side or anterior and rightward of the pulmonary valve (Fig. 75.7A) and usually is separated from the tricuspid valve by conal tissue. "D-looped TGA" also is acceptable terminology.[1] {S,D,D} TGA is the second most common cyanotic congenital heart disease.[11] The median described incidence of {S,D,D} TGA is 303 per 1 million live births.[5]

***Etiology, Pathophysiology, and Clinical Presentation.*** TGA usually is not associated with extracardiac anomalies or syndromes.[15] It is associated with VSD in approximately 40% to 45% of cases. Other anomalies that can be seen in patients with TGA are LVOT obstruction, aortic coarctation or interrupted aortic arch, tricuspid valve abnormalities, or, less commonly, mitral valve abnormalities, leftward juxtaposition of the atrial appendages, and RV hypoplasia.[20]

Patients present with cyanosis as a result of parallel systemic and pulmonary circulations. Deoxygenated blood returns to the right side of the heart via systemic veins, then circulates back to the aorta. Pulmonary venous blood returns to the left atrium and LV, then back to the pulmonary artery. Survival depends on communication between the systemic and pulmonary circulations, typically via an atrial septal defect, patent ductus arteriosus, and/or VSD.

***Imaging.*** The radiographic appearance is variable. The classic finding of TGA by chest radiography is the "egg on a string" sign (Fig. 75.7B), which is caused by a narrow mediastinum and the cardiac shadow. The narrow mediastinum is a result of stress-related thymic atrophy and the parallel position of the great vessels, with the pulmonary artery obscured by the aorta. The heart size varies from normal to enlarged.[15]

Cross-sectional imaging is seldom used for preoperative evaluation of TGA, but it can be helpful for specific questions that are unanswered by echocardiography, typically complex associated abnormalities of the aorta or pulmonary arteries. MRI often is preferred instead of CT to avoid the risks of ionizing radiation. In some centers, CT may be preferred because it offers greater accessibility and decreases the need for anesthesia or sedation as a result of shorter scanning times. CT scans should be performed with parameters optimized to minimize exposure of the patient to ionizing radiation.

***Treatment and Follow-up.*** In newborn infants with {S,D,D} TGA, adequate communication between the pulmonary and

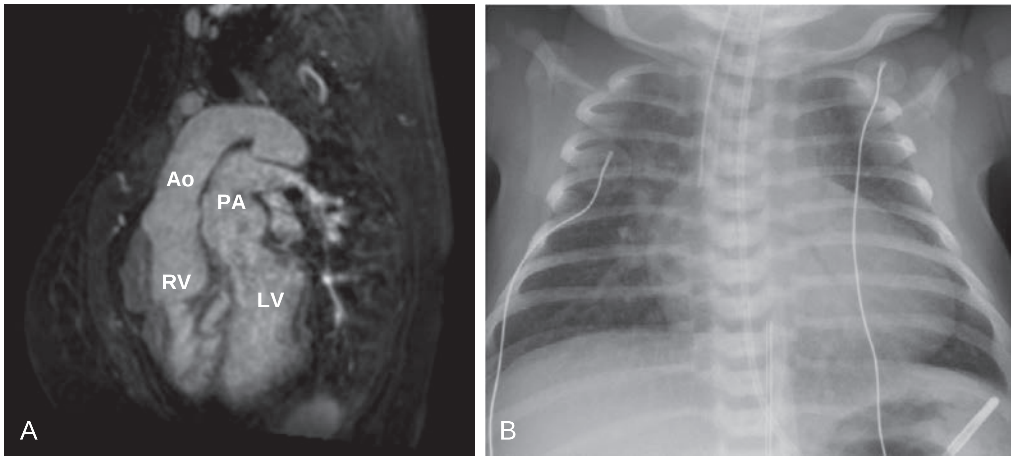

**Figure 75.7. {S,D,D} transposition of the great arteries (TGA).** (A) Sagittal oblique projection from three-dimensional balanced steady-state free-precession MRI in a 29-year old woman after the atrial switch procedure demonstrates parallel outflow tracts, with the aorta *(Ao)* arising from the right ventricle *(RV)* and the pulmonary artery *(PA)* arising from the left ventricle *(LV)*. (B) Chest radiograph of a neonate with {S,D,D} TGA before repair. As a result of the parallel, anterior-posterior relationship of the great arteries, there is a narrow mediastinum that combined with cardiomegaly and increased vascular flow, produces the classic "egg on a string" appearance.

systemic circulations is critical. Infusion of prostaglandin $E_1$ maintains ductal patency. If the atrial septum is restrictive, urgent cardiac catheterization for balloon atrial septostomy is often required.[21] In this procedure, a catheter is passed across the atrial septum into the left atrium. The balloon is inflated, and the catheter is sharply pulled back, fracturing the septum and enlarging the opening, allowing for greater mixing of oxygenated and deoxygenated blood.

In the first decades of surgical repair of TGA, the atrial switch was used (i.e., "Mustard" or "Senning" procedures). In these procedures, an intraatrial baffle is created with use of pericardium or native atrial tissue, which directs systemic venous return to the morphologic LV and pulmonary artery, and pulmonary venous return to the morphologic RV and aorta (Fig. 75.8A and B).

The atrial switch has been replaced by the arterial switch operation, which has been used widely in the United States since the mid to late 1980s. In this operation, the ascending aorta and pulmonary artery are transected at the sinotubular junction and anastomosed to the concordant ventricle, after the pulmonary artery is relocated anterior to the aorta (the "Lecompte maneuver") (Fig. 75.9A). The coronary arteries are relocated from the native aorta to the neoaorta (Fig. 75.9B).[22]

In the presence of a VSD and LVOT obstruction, a Rastelli repair can be performed,[23] with baffling of the LV through the VSD to the native aortic valve, along with placement of an RV to pulmonary artery conduit (e-Fig. 75.10).

Each of these procedures can be associated with early and late complications. For the atrial switch procedure, important early and mid-term complications include systemic baffle obstruction, most commonly affecting the superior limb of the baffle at the junction of the right atrium with the superior vena cava,[24] baffle leaks (in approximately 20% of patients) (e-Fig. 75.11),[25] and pulmonary venous obstruction (less common) (e-Fig. 75.12). The most important complication after the atrial switch procedure, early or late, is failure of the systemic RV and tricuspid regurgitation. Less common complications include conduction and rhythm disturbances, which can require mechanical pacing or cause sudden death.[11]

MRI is frequently used for assessment after the atrial switch procedure and is tailored for assessment of the aforementioned complications.[1,11] Specifically, MRI is useful for the following assessments:

1. Evaluation of the size and function of the ventricles (Video 75.6)
2. Evaluation of the systemic and pulmonary venous pathways (e-Fig. 75.13)
3. Assessment of tricuspid valve regurgitation
4. Evaluation of the LVOT and RVOT
5. Late gadolinium enhancement for evaluation of fibrosis in the RV[26]

The arterial switch procedure uses the LV as the systemic ventricle and therefore is favored. Potential complications after the arterial switch procedure is performed can include RVOT obstruction, stenosis at the arterial anastomotic sites (most commonly pulmonary stenosis), branch pulmonary artery obstruction (see Fig. 75.9C), aortic root dilatation, neoaortic valve regurgitation, and coronary artery ostial stenosis.[27]

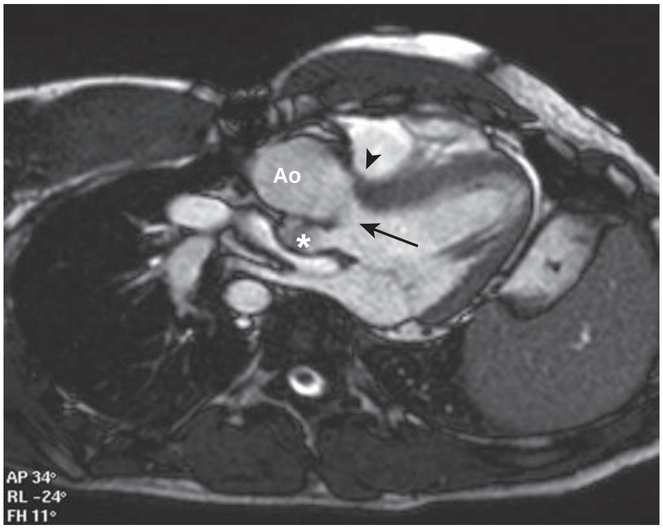
MRI is used frequently for assessment of patients who have undergone an arterial switch procedure, with clinical questions dictated by the aforementioned potential complications[1,11]:

1. RV and LV size and function
2. Evaluation of the RVOT and LVOT
3. Evaluation of the great arteries
4. Evaluation of the semilunar valves
5. Evaluation of the coronary arteries

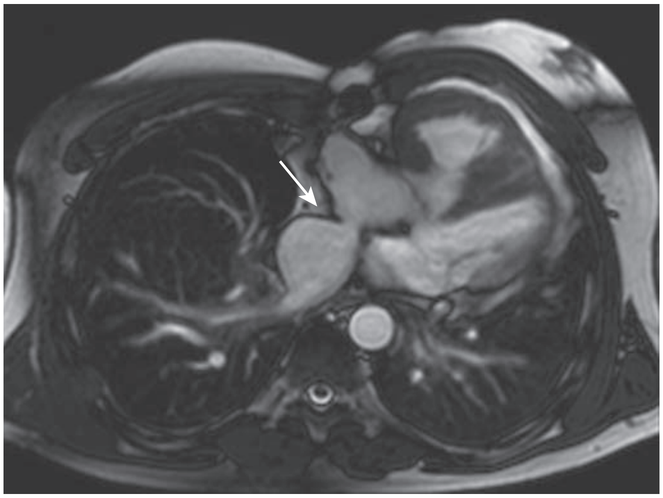
The Rastelli repair includes a conduit that can become stenotic and/or regurgitant. In addition, the baffle from the LV to the aorta can become obstructed, often at the level of the VSD, resulting in subaortic stenosis. After a Rastelli-type repair, answers to the following primary questions may be sought with MRI:

1. LV and RV size and systolic function
2. Anatomy and potential obstruction of the LV to aorta pathway
3. Stenosis and regurgitation of the RV to pulmonary artery conduit

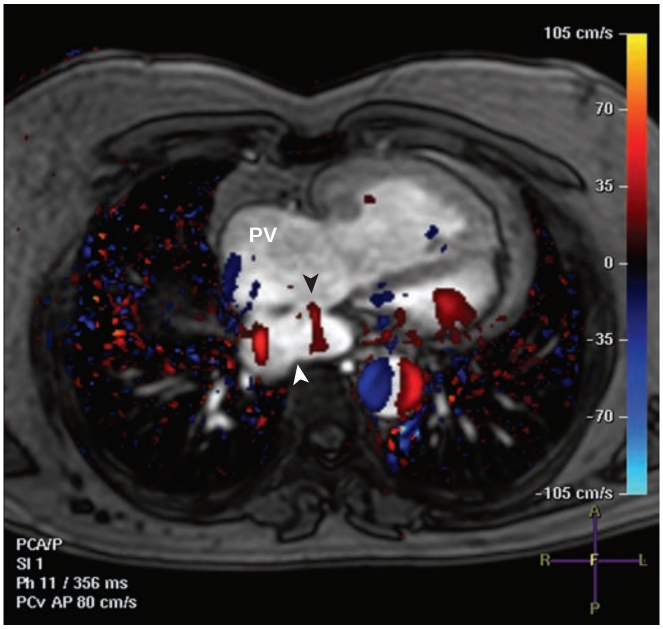
MRI protocols are similar to those previously described for TOF, although additional sequences often are needed. For example, an axial bSSFP image stack can help define post-Lecompte pulmonary artery anatomy and the venous baffles of the atrial switch.



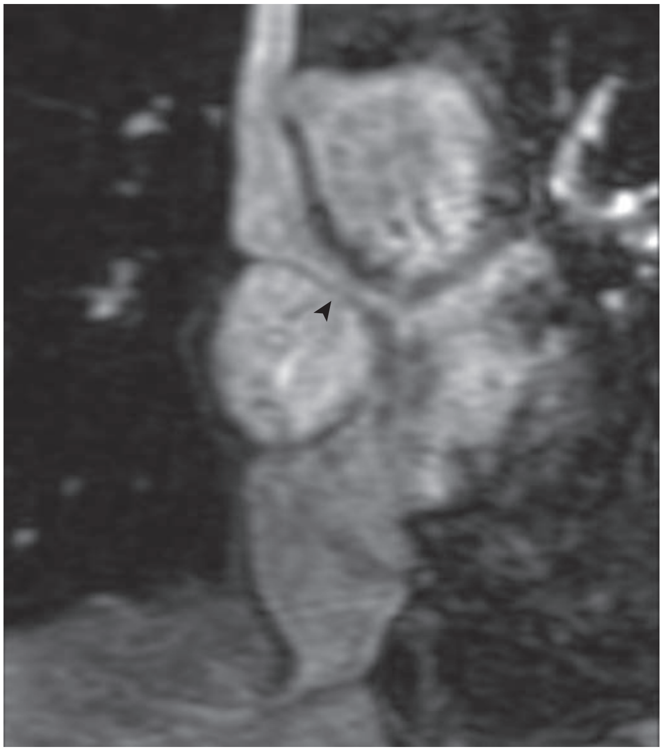
**e-Figure 75.10. {S,D,D} transposition of the great arteries, a ventricular septal defect, and pulmonary stenosis after the Rastelli procedure in a 22-year-old man.** Transverse oblique balanced steady-state free-precession MR image shows flow from the left ventricle being redirected via the ventricular septal defect *(arrow)* to the aorta *(Ao)* via a baffle; arrowhead denotes the lateral aspect of the baffle, which has closed the ventricular septal defect. Note the hypoplastic native pulmonary valve *(asterisk)*, which ends in a blind pouch. A right ventricle to pulmonary artery conduit was placed to reconstitute pulmonary blood flow (not shown in this image).



**e-Figure 75.12. {S,D,D} transposition of the great arteries after the atrial switch procedure in a 36-year-old man.** Axial balanced steady-state free-precession MR image demonstrates narrowing of the pulmonary venous pathway *(arrow)* to the tricuspid valve.



**e-Figure 75.11. {S,D,D} transposition of the great arteries after the Mustard procedure in a 40-year-old man.** Axial phase contrast MRI with in-plane velocity encoding demonstrates a baffle leak, with flow from the pulmonary venous pathway to the systemic venous pathway *(black arrowhead)*. Red denotes flow from anterior to posterior from the pulmonary venous pathway *(PV)* into the inferior vena cava portion of the systemic venous pathway *(white arrowhead)*.



**e-Figure 75.13. {S,D,D} transposition of the great arteries after the atrial switch procedure in a 42-year-old man.** Coronal oblique projection from a contrast-enhanced MRA demonstrates the typical location of narrowing of the superior vena cava pathway *(arrowhead)* to the mitral valve.

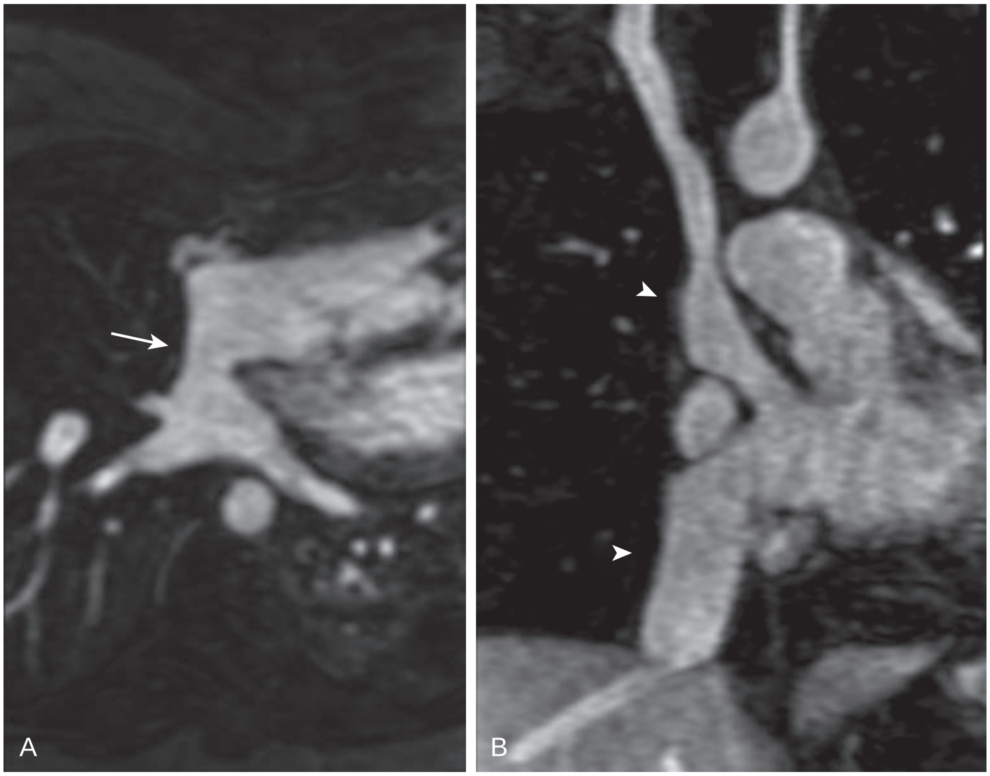


**Figure 75.8. {S,D,D} transposition of the great arteries, after the atrial switch in a 29-year-old woman.** (A) Transverse oblique projection from a contrast enhanced MRA demonstrates an unobstructed pulmonary venous baffle *(arrow)* to the tricuspid valve. (B) Coronal oblique projection demonstrating unobstructed pathways from the superior and inferior vena cavae *(arrowheads)* to the mitral valve. See Video 75.6.

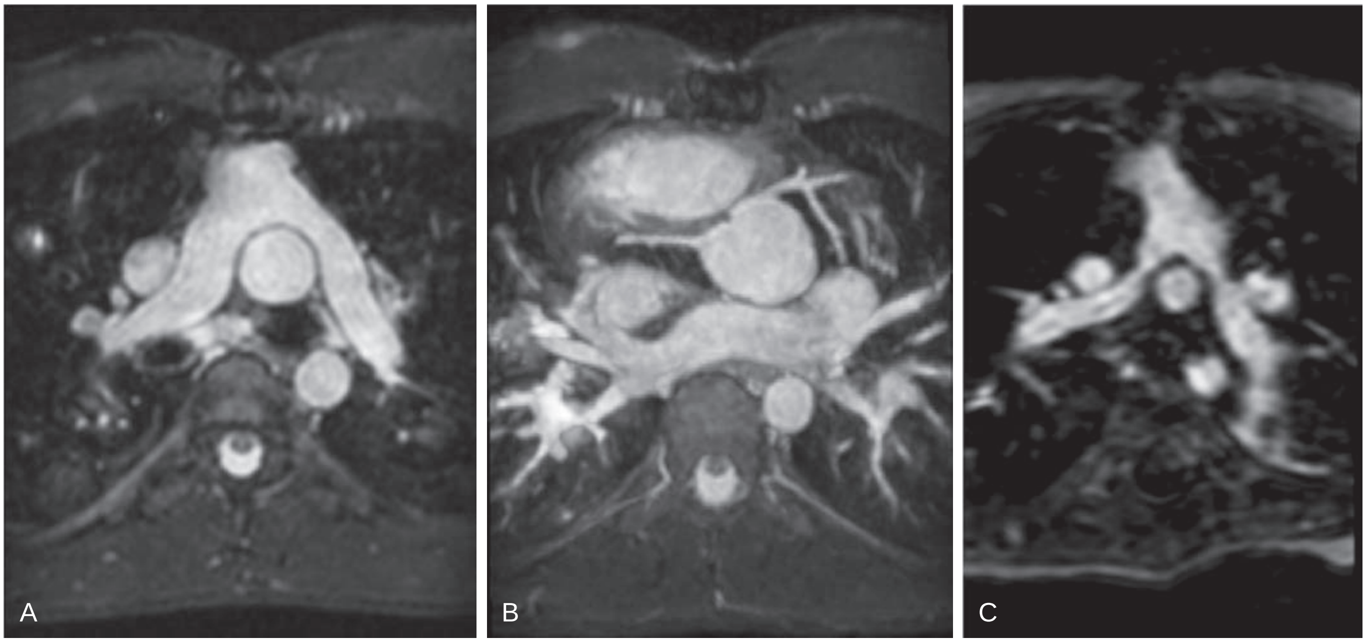

**Figure 75.9. Cardiovascular MR evaluation after the arterial switch operation.** (A) Transverse projection demonstrating the pulmonary artery bifurcation anterior to the ascending aorta, with no narrowing of the proximal branch pulmonary arteries. (B) Maximum intensity projection in the transverse oblique plane from three-dimensional steady-state free precession in a 16-year-old boy with {S,D,D} transposition of the great arteries (TGA), after the arterial switch operation, demonstrates unobstructed proximal coronary arteries that have been translocated to the facing sinuses of the native pulmonary (neoaortic) root. (C) Transverse oblique projection of a contrast-enhanced MRA in a 19-month-old boy with {S,D,D} TGA after an arterial switch operation demonstrates proximal narrowing of both left and right branch pulmonary arteries.

Oblique bSSFP imaging along the LVOT is performed to rule out obstruction of the Rastelli pathway.

CT is used postoperatively in selected cases to answer anatomic questions, particularly when MRI is contraindicated. CT is particularly useful for assessment of extracardiac anatomy such as repaired aortic coarctation, arterial anastomotic sites, and branch pulmonary arteries after an arterial switch procedure is performed (e-Fig. 75.14) and venous baffles after an atrial switch procedure is performed. Functional evaluation of the heart is limited compared with MRI.

## PHYSIOLOGICALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

***Overview.*** Physiologically corrected or {S,L,L} TGA is rare, with an estimated incidence of 30 per 1 million live births.[28] The segmental anatomy of this lesion includes visceral and atrial situs solitus, L-ventricular loop, and levo-transposition of the aortic valve (see Chapter 63). In L-looped TGA, atrioventricular and ventriculoarterial discordance occurs. The morphologic RV receives the pulmonary venous blood via the left atrium and connects to the aorta (Fig. 75.15A and Video 75.7). The LV receives systemic venous blood via the right atrium and connects to the pulmonary artery. The outflow tracts are parallel and the aorta is leftward and anterior to the pulmonary artery.

***Etiology, Pathophysiology, and Clinical Presentation.*** Physiologically corrected TGA is attributed to abnormal cardiac looping during embryologic development. It can be characterized as ventricular inversion, with the systemic and pulmonary circulations in series. If no associated lesions are present, the patient is acyanotic and typically is asymptomatic in early life. Patients with this lesion can present for the first time in adulthood, although this presentation is atypical.

More than 90% of patients with physiologically corrected TGA have additional anatomic abnormalities. Associated anomalies include dextrocardia, tricuspid valve abnormalities such as Ebstein anomaly, VSD (e-Fig. 75.16), RV hypoplasia, subvalvar and valvar pulmonary stenosis (Video 75.8), and conduction abnormalities, including complete heart block.[1]

***Imaging.*** The ascending aorta is not visible on the right, and the descending aorta and pulmonary artery may not be visible on the left. The vascular pedicle looks narrow, and straightening of the left heart border occurs as a result of the anterior and leftward position of the aorta. The cardiac silhouette has a "humped" appearance and is more vertical than usual (Fig. 75.15B).[29] In the presence of systemic atrioventricular valve regurgitation and ventricular dysfunction, the heart may be enlarged. Dextrocardia or mesocardia also occurs with {S,L,L} TGA; if the chest radiograph reveals the gastric bubble on the left (abdominal situs solitus) and the apex of the heart on the right, this lesion should be suspected. Associated cardiac lesions such as VSD and pulmonary atresia also can be detected.

MRI is useful in preoperative assessment of systemic RV function and tricuspid regurgitation. MRI can evaluate RV size and assess the morphology of the cardiac chambers, particularly in relationship to a VSD and the great arteries if a complex intraventricular baffle repair is planned.

CT can evaluate coronary artery and extracardiac anatomy. In patients who undergo pacing because of a complete heart block, electrocardiographic-gated multidetector array CT study can be used to assess RV size and systolic function.

***Treatment and Follow-up.*** The early management of patients with physiologically corrected TGA who have no associated structural anomalies is controversial. Because this lesion is acyanotic and usually asymptomatic, it can be managed medically.[11,30] However, some physicians believe that earlier surgery should be performed, particularly in the presence of tricuspid valve (systemic) regurgitation.[31]

Until the early to mid 1990s, repair of physiologically corrected TGA was intended only to repair the pertinent associated anomalies, including VSD, pulmonary stenosis or atresia, and tricuspid valve abnormalities,[22] leaving the RV as the systemic ventricle. However, in many patients, systemic (RV) ventricular failure develops over time.[32] Tricuspid (systemic atrioventricular) valve regurgitation also is associated with RV dysfunction and heart failure. In addition to RV failure and tricuspid regurgitation, complete heart block develops in many patients. These complications become more prevalent with increasing patient age and have led to greater interest

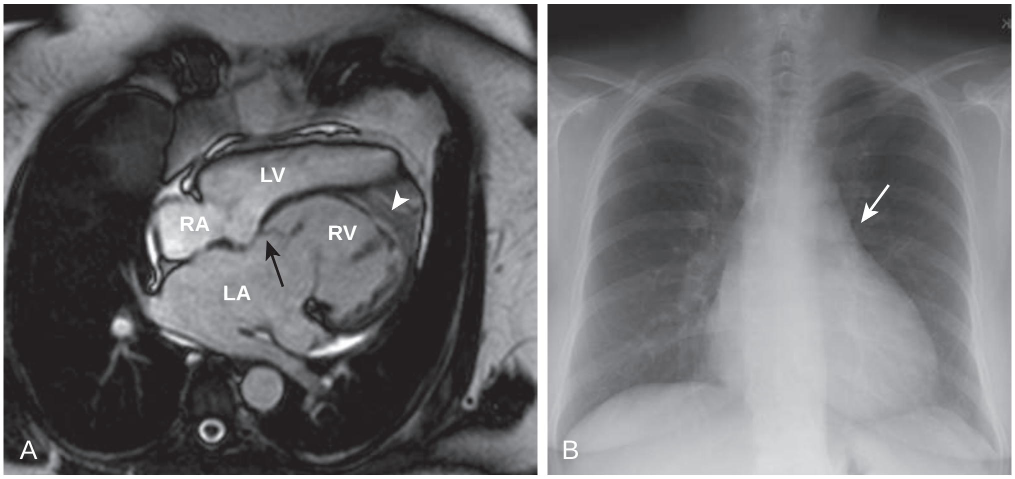

**Figure 75.15. {S,L,L} congenitally corrected transposition of the great arteries in a 56-year-old woman with no previous intervention.** (A) Balanced steady-state free-precession MR image in the four-chamber view demonstrates apical displacement of the septal insertion of the left-sided atrioventricular valve *(black arrow)*, a moderator band *(white arrowhead)*, and coarse trabeculation of the left-sided ventricle, consistent with a left-sided morphologic right ventricle *(RV)*. Note the bowing of the septum into the right-sided, morphologic left (subpulmonary) ventricle *(LV)*. (B) Posterior-anterior chest radiograph demonstrates a straightened upper left heart border *(arrow)* as a result of leftward malposition of the aorta. *LA,* Left atrium; *RA,* right atrium. See Video 75.7.

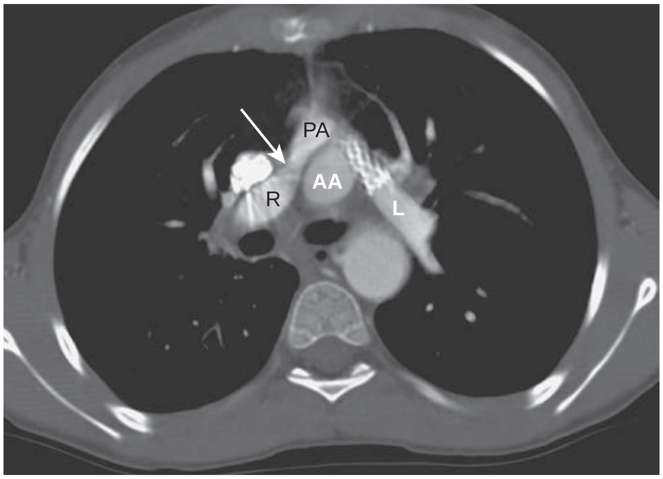
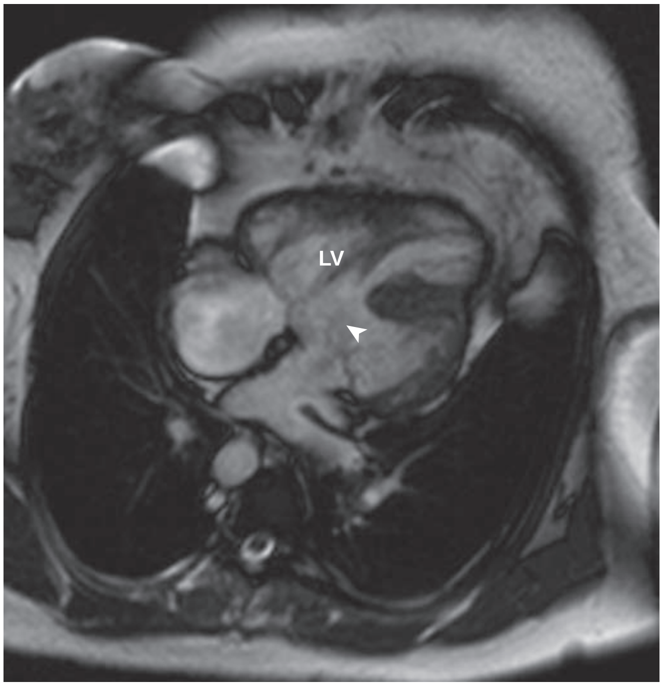


**e-Figure 75.14. {S,D,D} transposition of the great arteries after the arterial switch procedure complicated by pulmonary stenoses.** Axial contrast-enhanced CT image showing mild right pulmonary artery *(R)* narrowing *(arrow)* developed in this patient in between the superior vena cava and the ascending aorta *(AA)*. Previous left pulmonary artery *(L)* narrowing has been alleviated with a stent. *PA,* Pulmonary artery.



**e-Figure 75.16. {S,L,L} congenitally corrected transposition of the great arteries, ventricular septal defect and pulmonary stenosis, after prior subpulmonic resection in a 52-year-old woman.** Four-chamber balanced steady-state free-precession MR image demonstrates ventricular inversion, with a right-sided morphologic left ventricle *(LV)* and a large inlet ventricular septal defect *(arrowhead)*. See Video 75.8.

in performing early surgery for an anatomic correction with a systemic LV. Depending on the individual anatomy, this correction can be accomplished with a combination of an atrial switch with an arterial switch (a "double switch"), or, in the presence of LVOT obstruction and a VSD, with a Rastelli procedure.[22] In the absence of significant LVOT obstruction, the LV is not prepared to function at systemic pressure. A pulmonary artery band is first placed to "train" the LV to pump at higher pressures. After approximately 6 months, the complete repair is undertaken.

The complications associated with these operations are the same as those associated with the individual procedures, previously described in detail. MRI and CT can assess the atrial switch and arterial switch or intraventricular baffle (Rastelli repair), as previously delineated.

## DOUBLE-OUTLET RIGHT VENTRICLE

***Overview.*** According to the Congenital Heart Surgery Nomenclature and Database Project, double-outlet right ventricle (DORV) is "a type of ventriculoarterial connection in which both great vessels arise entirely or predominantly from the right ventricle."[33] DORV has been defined by some investigators as the degree of aortic override, with diagnosis if the aorta is more than 50% over the RV.[34] However, this definition can be difficult to apply practically, because the degree of override may appear different from various anatomic planes, which can lead to lack of clarity, for example, in differentiating DORV from TOF. The absence of fibrous continuity between the aortic and mitral valve also has been referred to as a criterion for diagnosis of DORV; however, according to the Congenital Heart Surgery Nomenclature and Database Project, this finding should not be used as an absolute prerequisite for the diagnosis of DORV.[33,35] Although the definition may be problematic, the median described incidence of DORV is 127 per 1 million live births.[5]

The anatomy and consequent physiology of a person with DORV is differentiated by the position of the VSD, the conal morphology, and the relationship of the great vessels. An understanding of these anatomic-physiologic variants is important to the surgical approach and management of the patients.[1] The VSD usually is found between the limbs of the trabecula septomarginalis (Fig. 75.17). The aorta can be located rightward and posterior, directly rightward, anterior and rightward, directly anterior, or anterior and leftward of the pulmonary artery (Fig. 75.18A). Because both vessels arise from one ventricle, abnormal positioning of the great arteries is termed "malposition" rather than "transposition."[36]

The relationship of the VSD to the conal septum and great arteries has been used as the basis for a widely used clinical classification, in which DORV is classified into four anatomic subtypes (Fig. 75.17):[35,37]

1. DORV with subaortic VSD (most common): the conal septum (outlet septum) is attached to the anterior limbus of the trabecula septomarginalis
2. DORV with subpulmonary VSD: the conal septum is attached to the posterior limbus of the trabecula septomarginalis
3. DORV with doubly committed VSD: the conal septum is hypoplastic or absent
4. DORV with noncommitted VSD: the defect is located at the inlet or at the trabecular zone of the interventricular septum, usually as an atrioventricular canal–type or apical muscular defect

***Etiology, Pathophysiology, and Clinical Presentation.*** In one review, chromosomal abnormalities, including trisomies 13 and 18 and deletion of chromosome 22q11, were the most commonly associated cytogenetic lesions[35].

DORV also can be classified by physiologic subtypes, which dictate clinical presentation[1]:

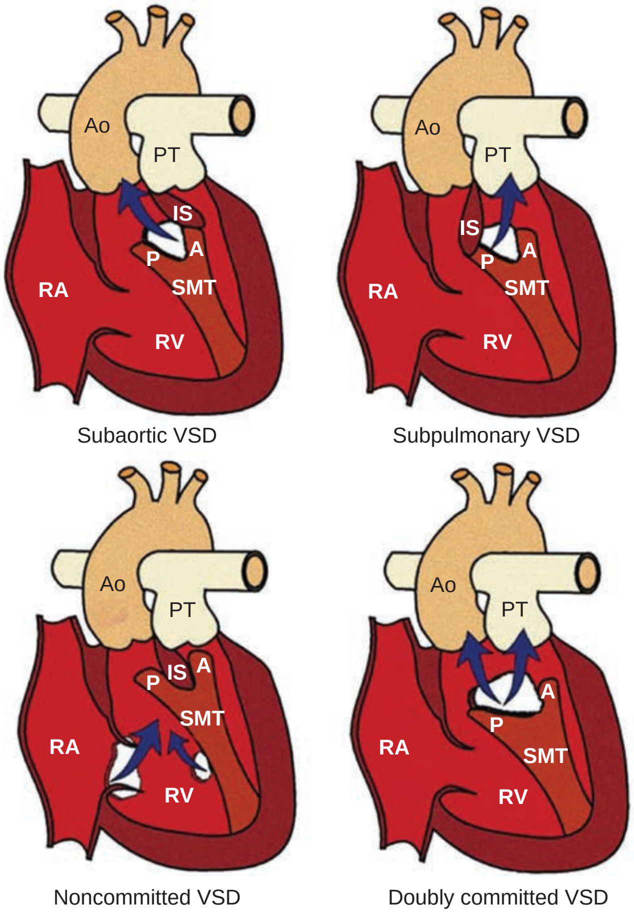


**Figure 75.17.** Types of double-outlet right ventricle, classified by relationship of the ventricular septal defect and great arteries. *A,* Anterior limb; *Ao,* aorta; *IS,* infundibular septum; *P,* posterior limb; *PT,* pulmonary trunk; *RA,* right atrium; *RV,* right ventricle; *SMT,* trabecula septomarginalis; *VSD,* ventricular septal defect. *(From Peixoto LB, Leal SMB, Silva CES, et al. Double outlet right ventricle with anterior and left-sided aorta and subpulmonary ventricular septal defect.* Arq Bras Cardiol. *1999;73:446–450.)*

1. VSD physiology: Subaortic VSD and no pulmonary stenosis
2. TOF physiology: Subaortic VSD and pulmonary stenosis
3. TGA physiology: Subpulmonary VSD, with or without systemic outflow obstruction
4. Single-ventricle physiology: DORV with mitral atresia, unbalanced atrioventricular canal, or severe hypoplasia of one of the ventricular sinuses (often in association with heterotaxy syndrome)

DORV is associated with several cardiac anomalies. VSD is almost ubiquitous. Obstruction to either pulmonary or systemic outflow is common. Coarctation of the aorta is common in patients with a subpulmonary VSD, particularly when aortic outflow is obstructed. Coronary artery anomalies often follow the physiology. For example, in TOF-type DORV physiology, supply of the LAD coronary artery from the right coronary artery can occur. In TGA-type DORV physiology, anomalies can vary, such as the circumflex coronary artery supplied from the right coronary artery.[11]

***Imaging.*** Given the many anatomic and physiologic variants of DORV, no specific pattern is described in the chest radiograph. Chest radiograph findings follow the anatomic-physiologic type of DORV, such as an enlarged heart and increased pulmonary

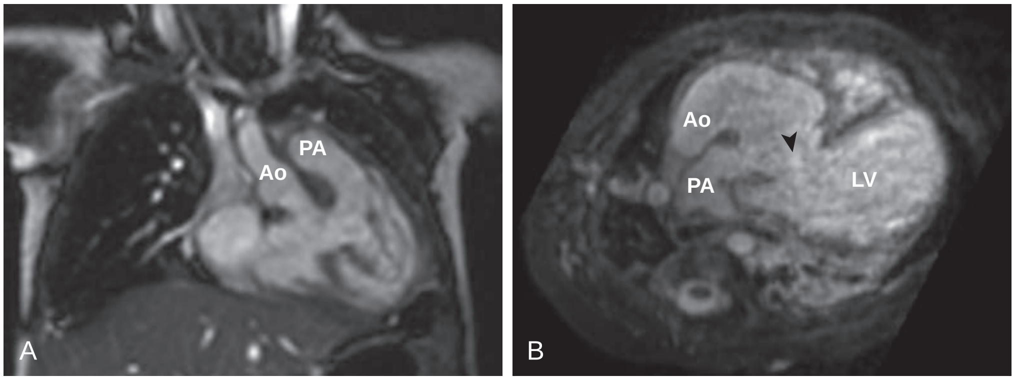

**Figure 75.18. Double-outlet right ventricle (DORV) variations.** (A) Coronal oblique SSFP MR image in a 5-month-old girl with DORV, side-by-side great arteries (aorta to the right), with no subaortic or subpulmonary stenosis, requiring previous pulmonary artery banding. (B) Transverse oblique three-dimensional balanced steady-state free-precession MR image in a 4-month-old boy with DORV, shows anterior-posterior great arteries (aorta anterior to the pulmonary artery), subpulmonary ventricular septal defect (VSD) *(arrowhead)*, and subvalvar and valvar pulmonary stenosis. This patient subsequently underwent a Rastelli procedure, with complicated baffle of the VSD to the anterior aortic valve and a right ventricle to the pulmonary artery conduit. *Ao,* Aorta; *LV,* left ventricle; *PA,* pulmonary artery.

vascular markings with a VSD, decreased pulmonary vascularity, a concave main pulmonary artery shadow and upward lifted heart apex in the TOF type, or varied findings with the TGA type, sometimes including cardiomegaly and increased pulmonary vascularity.

Echocardiography is adequate for diagnosis and surgical planning in most newborns or infants with DORV. Cardiac MRI or CT is helpful in the evaluation of complex anomalies of the aortic arch, pulmonary arteries, aortopulmonary collaterals, and systemic or pulmonary venous anomalies that are not completely delineated by echocardiography. Considerations for CT versus MRI have been discussed previously. Assessment of the relationship between the VSD and the position of the great vessels in relation to the conal septum also can be answered by cardiac MRI (Fig. 75.18B)[1] and can be helpful in planning complex surgical baffling of the LV to the aorta. In addition, MRI can accurately assess the size of the RV when its adequacy for a two-ventricle repair is in question.

***Treatment and Follow-up.*** The goal of surgical treatment of DORV is the connection of the LV to the systemic circulation and the RV to the pulmonary circulation. The preferred approach is to use an intraventricular tunnel repair, but such a repair may not be possible because of anatomic barriers, which may preclude a two-ventricle circulation. Alternative surgical procedures have been applied in these situations.[33]

With a subaortic VSD, an intraventricular patch directing LV outflow to the aorta is the usual approach. Resection of RVOT obstruction may be necessary. With a subpulmonary VSD, an intraventricular patch can be used to direct LV outflow to the pulmonary artery, which is accompanied by an arterial switch operation. Alternatively, the pulmonary artery can be closed proximally, the LV baffled through the VSD to the aorta, and a valved conduit placed between the RV and distal pulmonary artery (Rastelli procedure).[36] More complex forms of DORV with heterotaxy syndrome, severe hypoplasia or absence of one of the ventricular sinuses, major straddling of an AV valve, or mitral atresia are palliated as a functional single ventricle.[1]

MRI is an important modality in the assessment of patients with repaired DORV. Questions for MRI depend on the anatomic-physiologic subtype of DORV and follow the descriptions in the previous sections for MRI of TOF and {S,D,D} TGA. In addition, assessment of the LV to aortic pathway for potential obstruction is crucial, similar to the aforementioned description for a Rastelli repair. Imaging for patients with single ventricle physiology can be found under the section regarding Fontan imaging in Chapter 74.

Similarly, CT is useful in assessing patients with repaired DORV, with questions analogous to those previously described for TOF and {S,D,D} TGA.

## TRUNCUS ARTERIOSUS

***Overview.*** Truncus arteriosus is defined as a single vessel arising from the heart that has a single semilunar valve, giving rise to the coronary arteries, aorta, and at least one branch of the pulmonary artery. Truncus arteriosus is uncommon, with a reported incidence of 94 per 1 million live births.[5]

The classification of truncus arteriosus is based on the branching pattern of the pulmonary arteries[1,38]:

- Type I: The branch pulmonary arteries arise from a short main pulmonary artery
- Type II: The branch pulmonary arteries arise directly from the arterial trunk through separate orifices (Fig. 75.19A and B)
- Type III: One branch pulmonary artery arises from the ascending segment of the trunk; collateral vessels usually supply the contralateral lung
- Type IV: Truncus arteriosus with aortic arch hypoplasia, coarctation, or interruption (usually type B, between the common carotid and subclavian arteries)

***Etiology, Pathophysiology, and Clinical Presentation.*** Truncus arteriosus results from failure of septation of the conotruncus into a separate aorta and pulmonary artery. It is associated with DiGeorge syndrome and chromosome 22q11 deletion.[39]

The semilunar valve of the truncus is most often tricommissural. A bicommissural or quadricommissural truncal valve occurs less frequently. The truncal valve often is thickened with deformed leaflets, causing stenosis or insufficiency. The conal septum is usually absent, and a malalignment VSD is present in almost all patients (>80%). An IAA is a commonly associated lesion (occurring in 11%–14% of patients). Abnormalities of the mitral valve, coronary arteries, and pulmonary venous connections also are among the associated cardiac abnormalities.[11,38]

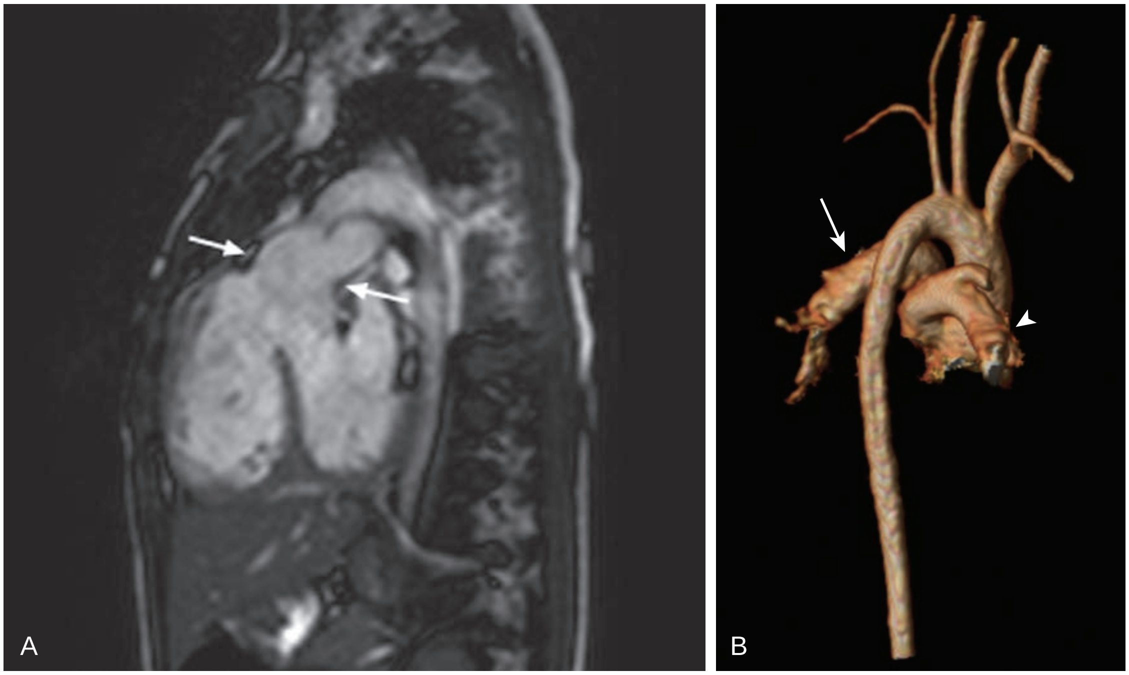

**Figure 75.19. Unrepaired truncus arteriosus type II in a 3-year-old girl.** (A) Sagittal oblique balanced steady-state free-precession MR image demonstrates the truncal root *(arrows)* overriding a conoventricular ventricular septal defect, with the origin of the pulmonary arteries from the truncal root. (B) Three-dimensional reconstruction (viewed posteriorly) from a contrast-enhanced MRA demonstrates the origin of the left *(arrow)* and right *(arrowhead)* branch pulmonary arteries from the truncal root.

Neonates with truncus arteriosus generally are asymptomatic while pulmonary vascular resistance remains elevated. As pulmonary vascular resistance decreases in early life, excessive pulmonary blood flow and symptoms of congestive heart failure develop. These children are at high risk for pulmonary vascular disease if they are not treated in the first 3 to 6 months of life.[18]

***Imaging.*** Cardiomegaly, increased pulmonary vascularity, and right-sided aortic arch (in 30% of cases) are consistent with truncus arteriosus (e-Fig. 75.20). A depressed diaphragm and thymic atrophy may also be noted.

In most neonates with this diagnosis, echocardiography is sufficient for anatomic diagnosis and surgical planning. Evaluation with MRI or CT is helpful for extracardiac anatomy that is difficult to fully delineate by echocardiography, such as complex aortic arch or pulmonary arterial anomalies.

***Treatment and Follow-up.*** Surgical repair is undertaken within the first few weeks of life. In 1968, McGoon et al.[40] described the first surgical repair of truncus arteriosus; the pulmonary arteries were separated from the aorta, and a valved homograft was placed from the RV to the pulmonary arteries. The VSD was closed with a patch to align the truncal valve with the LV. This technique remains the predominant method of repair.[18] Aortic arch interruption or coarctation is repaired at the same time. A severe valve abnormality can be addressed at the time of repair as well.[41]

In the absence of associated lesions, repair can be accomplished with very good survival rates in the neonatal and early infancy period.[42] Newborns with truncus arteriosus and associated IAA have a poorer prognosis.[43]

Important complications after truncal repair are RV–pulmonary artery conduit stenosis or regurgitation, branch pulmonary artery stenosis, neoaortic valve (truncal) insufficiency or stenosis, residual VSD, and aortic arch obstruction. Conduits require replacement over time.[18,43] As previously discussed, a percutaneously placed pulmonary valve is available for relief of conduit obstruction and regurgitation.

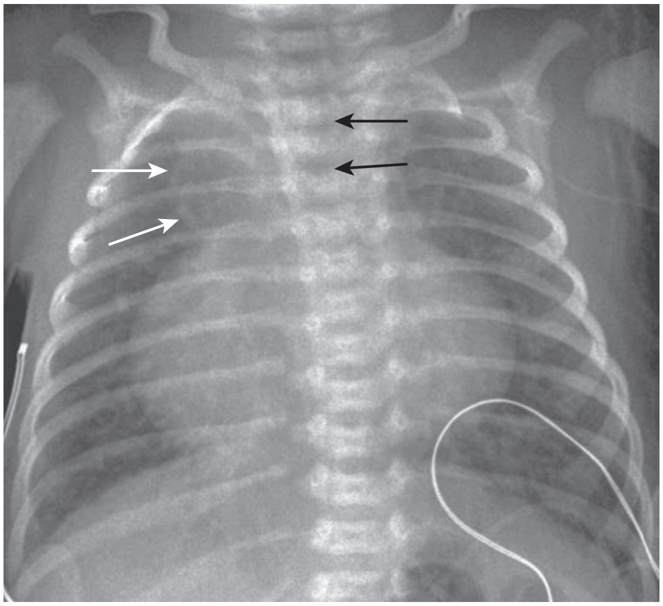
The anatomic and functional issues in patients who have undergone this repair are similar to those in patients with repaired TOF, specifically those with an RV to pulmonary artery conduit. Neoaortic valve dysfunction and aortic arch obstruction may require additional investigation. The postoperative MRI should address the following questions (e-Fig. 75.21)[1]:

1. Quantitative assessment of LV and RV volumes, function, and mass
2. Measurements of pulmonary (conduit) and neoaortic valve regurgitation
3. Imaging of the RVOT, conduit, and pulmonary arteries
4. Assessment of residual shunts
5. Imaging of the aortic arch and isthmus

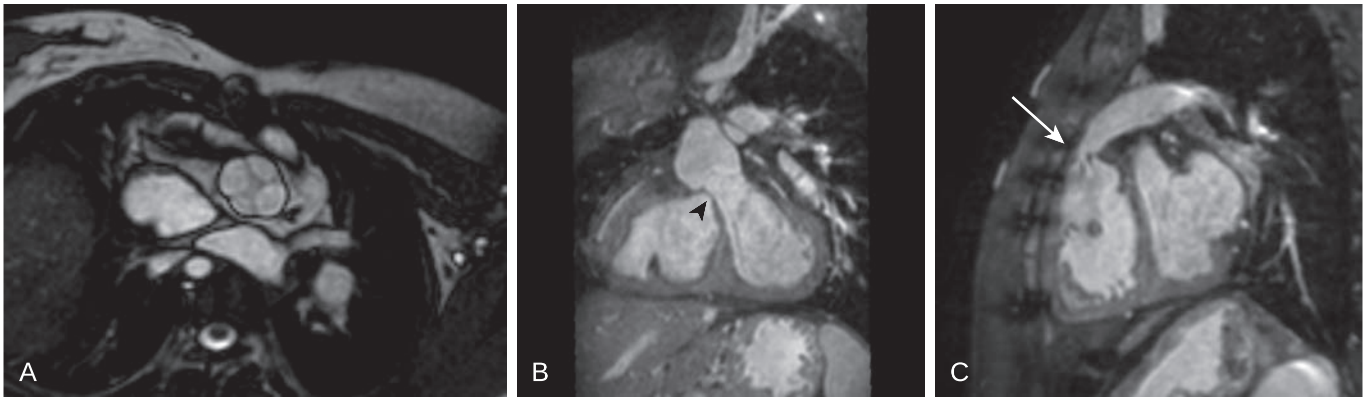
## INTERRUPTED AORTIC ARCH TYPE B

***Overview.*** IAA is a rare congenital abnormality, with estimated incidence of 19 per 1 million live births.[44] IAA type B, the most common type of IAA, is a luminal interruption of the aorta (Fig. 75.22) between the left common carotid and left subclavian arteries, which accounts for approximately two-thirds of the cases of IAA.[44] IAA is distinguished from aortic arch atresia, in which a fibrous band is present at the area of the arch defect. Type B IAA is usually associated with VSD with posterior malalignment of the conal septum and is often categorized with other conotruncal anomalies.

***Etiology, Pathology, and Clinical Presentation.*** IAA type B results from an early regression of the fourth arch before migration of the left subclavian artery. Chromosome 22q11.2 deletion is



**e-Figure 75.20. Truncus arteriosus in a neonate.** Frontal chest radiograph shows an enlarged heart with right heart predominance and increased pulmonary vascularity. The trachea is deviated to the left *(black arrows)* by the large, right-sided truncal arch *(white arrows)*.



**e-Figure 75.21. Repaired truncus arteriosus in a 13-year-old girl.** (A) Short axis balanced steady-state free-precession (bSSFP) MR image of the truncal root demonstrates a quadricommissural valve. (B) Coronal oblique three-dimensional bSSFP MR image demonstrates a patch *(arrowhead)* closing the ventricular septal defect, connecting the left ventricle to the truncal (neoaortic) valve. (C) Sagittal oblique bSSFP MR image demonstrates the right ventricle to pulmonary artery conduit, which is narrowed proximally *(arrow)*.

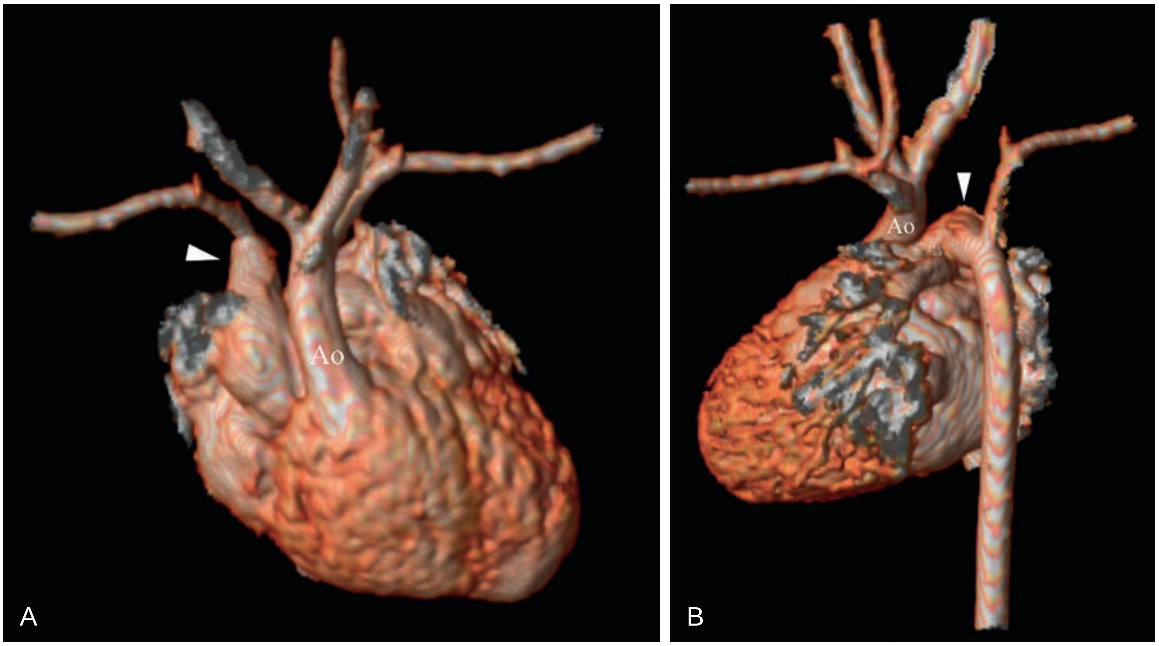


**Figure 75.22. Unrepaired interrupted aortic arch in a 13-day-old girl with D-looped transposition of the great arteries.** Three-dimensional reconstructions from a contrast-enhanced MRA study. (A) Viewed from anterosuperior, the ascending aorta *(Ao)* supplies the common carotid arteries and left subclavian artery, while the patent ductus arteriosus *(arrowhead)* supplies the right subclavian artery and descending aorta. (B) Viewed from posteriorly, the descending aorta descends on the right, supplied by the patent ductus arteriosus *(arrowhead)*.

commonly seen in these patients. Associated congenital cardiac lesions include VSD, atrial septal defect, truncus arteriosus, and bicuspid aortic valve.[44] Aberrant origin of the contralateral subclavian artery from the proximal descending aorta is also seen in 50% of cases of type B IAA.[1] If not recognized prenatally or perinatally, the natural history of IAA is typically development of shock or severe heart failure in the first 2 weeks of life.[45]

***Imaging.*** Echocardiography, including prenatal imaging, is usually sufficient to diagnose IAA and associated defects before surgical repair. CT or MRI is rarely requested but may be used if the arch anatomy is not clearly defined or to evaluate additional cardiac anomalies. Anatomic features that must be defined include the location of the defect, aortic arch sidedness and branching pattern, distance between the proximal and distal ends of the arch, diameter of the aorta proximal and distal to the defect, and location of the patent ductus arteriosus, as well as evaluation of the LVOT and for additional cardiac abnormalities.[46]

***Treatment and Follow-up.*** IAA and associated congenital cardiac anomalies require urgent neonatal repair.[44] Survival of patients with IAA depends on patency of the ductus arteriosus. Prostaglandin $E_1$ infusion begins soon after birth to maintain ductal patency and is followed by surgery, typically in the first week of life. Repair is typically via direct end-to-end anastomosis between the proximal and distal ends of the aortic arch. If the length of the defect prevents direct anastomosis, patch augmentation or reconstruction of the arch can be performed. Modifications of the type of surgery are performed according to additional congenital cardiac lesions and on an individual basis.

Important indications for imaging after repair include evaluation for postoperative complications such as restenosis and pseudoaneurysm at the area of repair (Fig. 75.23), as well as effects on the LV such as hypertrophy or diminished systolic function. Pseudoaneurysms and collaterals are best seen on three-dimensional MRA images. Residual narrowing can be assessed by a combination of findings, similar to the assessment of repaired coarctation of the aorta. These include the smallest cross-sectional area or diameter of the aorta, indexed to body surface area or compared with the aortic size at the diaphragmatic hiatus, the presence of spin dephasing jets on cine imaging, the presence of increased flow velocity at the site of narrowing by phase contrast magnetic resonance (MR), and the pattern of flow in the descending aorta assessed by phase contrast MR.

## KEY POINTS

- In neonates with conotruncal defects, echocardiography is the principal imaging modality for preoperative diagnosis. Cross-sectional imaging is used to clarify anatomy that is not adequately imaged by echocardiography, usually extracardiac vascular structures.
- Cardiac MRI plays a crucial role in the routine follow-up of postoperative patients with conotruncal defects, particularly as they reach their teens and adulthood.
- Assessment of the RV is an important part of follow-up imaging, whether there is a systemic RV (e.g., {S,D,D} TGA after an atrial switch procedure or uncorrected {S,L,L} TGA) or a pulmonary RV with abnormal pressure and/or volume loading conditions (e.g., free pulmonary regurgitation, conduit stenosis and regurgitation, and residual outflow tract obstruction).

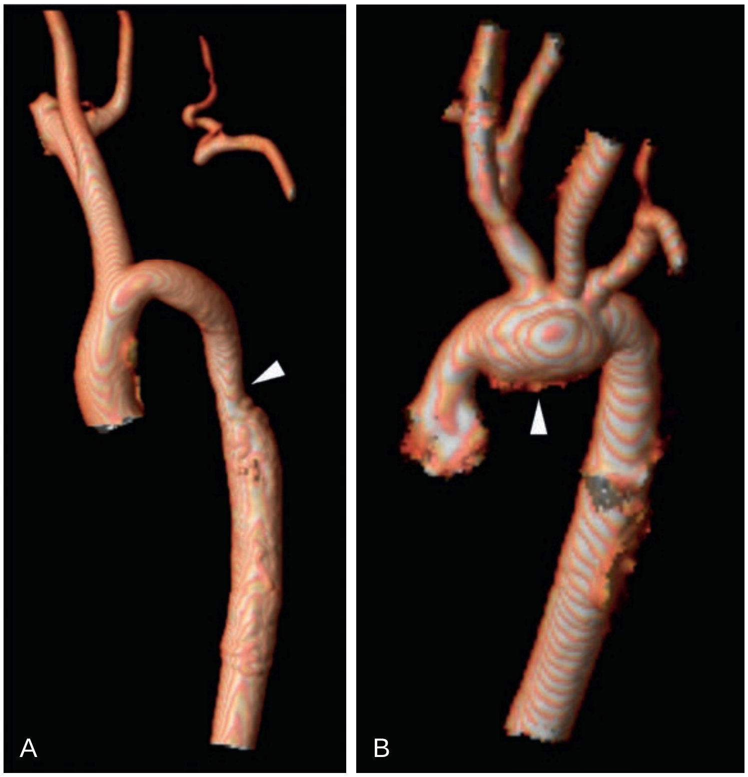

**Figure 75.23. Complications after repair of interrupted aortic arch.** (A) Three-dimensional reconstruction from a contrast-enhanced MRA in a 31-year-old man with interrupted aortic arch (IAA) status postrepair shows discrete narrowing at the repair site *(arrow)*. Note that the left subclavian artery is no longer in continuity with the aortic arch, as it may be divided at the time of repair to facilitate mobilization of the descending aorta. (B) Three-dimensional reconstruction from a contrast-enhanced MRA in a 17-day-old boy postrepair of IAA type B with aneurysmal dilatation of the aortic arch repair.

# Congenital Anomalies of the Thoracic Great Arteries

Simon Lee

This chapter covers congenital anomalies of the great arteries that result in a vascular ring or sling. Overall, anomalies of the aortic arch and the cervical vessels are relatively common, with an estimated prevalence of 0.5% to 3%.[1] They can be understood as the result of abnormal persistence and/or regression of branches in the totipotential arch, which is derived from the theoretical double aortic arch proposed by Jesse Edwards (Fig. 76.1).[2] The most common variations in arch branching are the common brachiocephalic trunk (common origin of the right subclavian and both carotids) and the arch origin of the left vertebral artery, estimated to occur in 8% and 4% of the population, respectively.[3] These are of minimal clinical consequence and are considered normal variants.

## VASCULAR RINGS

***Overview.*** *Vascular ring* is a term that refers to encirclement of the trachea and esophagus caused by the abnormal embryologic development of the aortic arch. This can be caused by the vascular structures of the aorta, the fibrous remnant of a ductus, the ligamentum arteriosum, or an atretic aortic arch. Only a small subset of aortic arch developmental anomalies leads to a vascular ring, accounting for less than 1% of all congenital cardiovascular defects. Although about a dozen different types of vascular rings exist, the most common are a double aortic arch and a right aortic arch with a retroesophageal left subclavian with left ligamentum arteriosum.[4] They can occasionally be associated with other congenital heart defects.

Chromosome 22q11 deletion causes abnormalities in aortic arch and conotruncal development, and has been reported in 24% of patients with isolated arch anomalies.[5,6] Testing for this chromosomal abnormality should be considered if there are other congenital heart defects or dysmorphic features.

***Clinical Manifestations.*** The severity of symptoms and the age of onset depend on the extent of the compression of the esophagus and trachea. Patients may be completely asymptomatic or may present with significant respiratory distress.[7] A high index of suspicion is necessary due to the nonspecific symptoms and rarity of a vascular ring compared with other diagnoses. It is not uncommon for the diagnosis of vascular ring to be preceded by a history of reactive airway disease or recurrent croup.

The clinical presentation most commonly includes respiratory symptoms like stridor, “barky” cough, wheezing, and frequent upper respiratory infections. Symptoms related to constriction of the esophagus are dysphagia, recurrent emesis, and failure to thrive. Esophageal symptoms are more commonly seen in older infants as they start taking solid foods. Because the trachea and esophagus share the same space within the ring, respiratory symptoms can worsen during feedings. Patients with double aortic arch tend to present earlier with more severe symptoms compared with other vascular ring types.[8]

***Imaging.*** Chest radiography may show tracheal compression by a vascular ring, but by itself a chest radiograph cannot confirm or exclude a vascular ring. Because a vascular ring is more likely in the presence of a right aortic arch, symptoms of tracheal compression in the presence of a right aortic arch should raise the possibility of a vascular ring.

Historically a barium esophagram was considered the initial test of choice in the evaluation for a vascular ring.[9] Other imaging modalities are now utilized in lieu of an esophagram, although occasionally a vascular ring can be discovered incidentally when an esophagram is ordered to evaluate for other diagnoses such as gastroesophageal reflux, aspiration, or tracheoesophageal fistula (Fig. 76.2).

Echocardiography with gray scale and color Doppler imaging may visualize the vascular ring directly in neonates and infants because these patients have excellent sonographic windows, particularly if the ductus is patent.[10] Generally echocardiography is not as useful for diagnosing a vascular ring in older children and adolescents due to limited acoustic windows. Its main utility is in the assessment for concomitant congenital heart disease. The presence of a vascular ring has been diagnosed accurately in utero with fetal echocardiography, where the airways are seen reasonably well and the ductus arteriosus remains patent.[11]

Patients with a high suspicion for a vascular ring should undergo vascular imaging to confirm the vascular abnormalities and to gather information for surgical planning. Contrast-enhanced computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) are the preferred modalities. Both can visualize the course and morphology of the intrathoracic vessels well. The advantage of MRA is the absence of ionizing radiation, although sedation or general anesthesia is often necessary before the age of 8 years.[12,13] CTA provides superior spatial resolution and visualization of the airway compared with MRA, and newer multidetector scanners can typically obtain this imaging without sedation.

***Treatment.*** The definitive treatment is surgical division of the ring via a lateral thoracotomy.[14] A double aortic arch is repaired by dividing the nondominant (smaller) arch between its last cervical artery and the point where it joins the descending aorta. Whether the arch is patent or atretic should be noted. If the ductus arteriosus or the ligamentum arteriosum forms a border of the ring, it is ligated. Persistent stenosis or tracheomalacia may develop in the constricted trachea, requiring additional repair.[15]

### Double Aortic Arch

Double aortic arch is the most common vascular ring. The head and neck branches arise symmetrically from the two arches, and their parallel orientation in axial imaging can serve as an imaging hint that a double aortic arch is present. Embryologically, the persistence of both the right and the left fourth aortic arches and distal dorsal aortic segments results in the double aortic arch. Two vessels, the right and left carotid arteries and right and left subclavian arteries, arise symmetrically from the ascending aorta and course dorsally, one on each side of the trachea and esophagus, to join the thoracic descending aorta. The descending aorta is on the left in 80% of cases. The larger aortic arch is considered the dominant arch, with the right being dominant in 75% of cases. The ductus arteriosus is usually left-sided but can be right-sided

## Abstract:

Overall, aortic arch and arch branching anomalies are relatively common. They result from the abnormal persistence and/or regression of branches in the totipotential arch. This can result in clinically significant encirclement of the trachea and esophagus, termed a vascular ring. Cross-sectional imaging is often necessary to make the diagnosis, as a part of the ring may be formed by fibrous tissue or ligaments. Genetic abnormalities, particularly chromosome 22q11 deletion syndrome, are commonly reported in association with aortic arch anomalies. Additional abnormalities, such as bronchotracheomalacia, may require further diagnostic studies and interventions.

Ventral view of Dr. Jesse Edward's "totipotential arch" or hypothetic double aortic arch and bilateral ducti arteriosi.** The *numbered arrows* point to the four key locations where regression occurs in various anomalies. *Arrow 1* indicates the eighth segment of the right dorsal aortic root; *arrow 2,* the right fourth arch; and *arrows 3* and *4,* the corresponding two positions on the left. The *shortest black arrows* point to the ducti arteriosi bilaterally, and the *longest black arrow* indicates the direction of blood flow. *(From Stewart JR, Kincaid OW, Edwards JE.* An Atlas of Vascular Rings and Related Malformations of the Aortic Arch System. *Springfield, IL: Charles C Thomas; 1964.)*

or bilaterally present. Bilateral patent arterial ducts can increase the severity of the tracheal and esophageal compression.

One portion of one aortic arch may be atretic, almost always occurring on the left. Double aortic arches with left arch atresia develop from regression of varying segments of the left aortic arch, with fibrous continuity of the segments completing the vascular ring.[16] The atretic segment may lie between the left subclavian artery and the descending aorta (Fig. 76.3) or between the left common carotid artery and the left subclavian artery. The former configuration is similar to a right aortic arch with a mirror-image branching pattern, and the latter configuration is similar to a right aortic arch with an aberrant left subclavian artery. However, a right aortic arch with mirror-image branching is almost always associated with significant congenital heart disease, and its absence should raise suspicion for a double aortic arch. An aortic diverticulum may be present posterior to the esophagus, which is part of the distal left aortic arch, before connecting to the aberrant left subclavian artery. Patients with atresia of a portion of one of the arches tend to have more severe tracheal and esophageal compression (see Fig. 76.2). Echocardiography does not provide optimal imaging for a double aortic arch, particularly if there is an atretic segment. Although it is recommended to screen for congenital heart defects, double aortic arch is not usually associated with significant abnormalities. CTA and MRA can readily visualize the atretic segment that appears to tether adjacent vascular structures and can be used to identify the associated aortic diverticulum.

## Right Aortic Arch With Aberrant Left Subclavian Artery

A right aortic arch with an aberrant or retroesophageal left subclavian artery is the second most common cause of a vascular ring. With an aberrant left subclavian artery, the left-sided ductus arteriosus/ligamentum arteriosum completes the vascular ring. Although the ligamentum is not seen on cross-sectional imaging, a diverticulum of Kommerell indicates the presence and location of the prior ductus (Fig. 76.4). In some cases, the diverticulum itself may cause symptoms, and a diverticulum resection and subclavian reimplantation may be necessary (e-Fig. 76.5). In 10% of cases, the ligamentum arteriosum is on the right side, and thus there would be no vascular ring. Unlike double aortic arches, this vascular ring typically is loose, and many patients are asymptomatic or present with mild symptoms later in life. There is a significant association with chromosome 22q11 deletion reported, even in the absence of congenital heart disease.[5]

## Left Aortic Arch With Aberrant Right Subclavian Artery

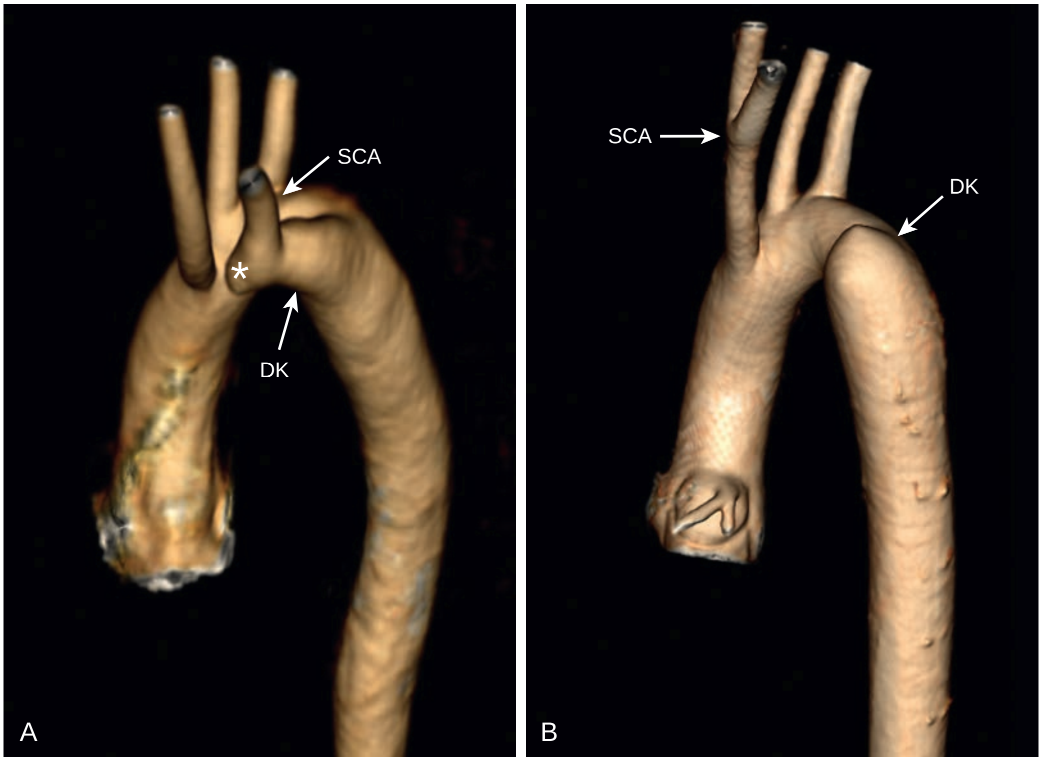
Compared with a right aortic arch, vascular ring formation in a left aortic arch is rare because the ductus arteriosus and ligamentum arteriosum are usually left-sided. In the specific case of a left aortic arch with an aberrant right subclavian artery, very few proven cases of vascular ring have been reported. Occasionally the retroesophageal course of the right subclavian artery can cause difficulty swallowing, in the absence of a vascular ring; this association has been termed *dysphagia lusoria* (Fig. 76.6).

## Right Aortic Arch With Mirror-Image Branching

The right aortic arch with mirror-image branching pattern is associated with congenital heart disease in 98% of cases, most commonly tetralogy of Fallot and truncus arteriosus. In most instances, the aorta descends on the right. If the ductus is left-sided, it usually connects between the anteriorly located innominate artery and the pulmonary artery, which does not form a vascular ring. In rare cases, a true ring forms when a ligamentum arteriosum extends from the left pulmonary artery to an aortic diverticulum.[17]

## Right Aortic Arch With Circumflex Aorta

Unlike the typical right aortic arch, in which the descending aorta is right-sided, a circumflex aorta descends on the left. To do so, the distal aortic arch travels from right to left, posterior to the esophagus, before turning downward (Fig. 76.7). A left ligamentum arteriosum arises posteriorly from a diverticulum of Kommerell and connects the pulmonary artery to the descending aorta, forming a vascular ring. An aberrant left subclavian artery frequently arises from an aortic diverticulum with stenosis at its origin.



**e-Figure 76.5. Right aortic arch with an aberrant left subclavian artery in a 12-year-old boy.** (A) Volume-rendered view of the aortic arch reconstructed from the preoperative MRA examination. The aberrant left subclavian artery *(SCA)* arises from the diverticulum of Kommerell *(DK)* which has an anterior outpouching *(asterisk)* indicating the attachment of the ligamentum arteriosum. (B) Volume-rendered view of the aortic arch reconstructed from a post-operative CTA examination. The left subclavian artery *(SCA)* has been reimplanted into the left carotid artery and the diverticulum of Kommerell *(DK)* has been resected.

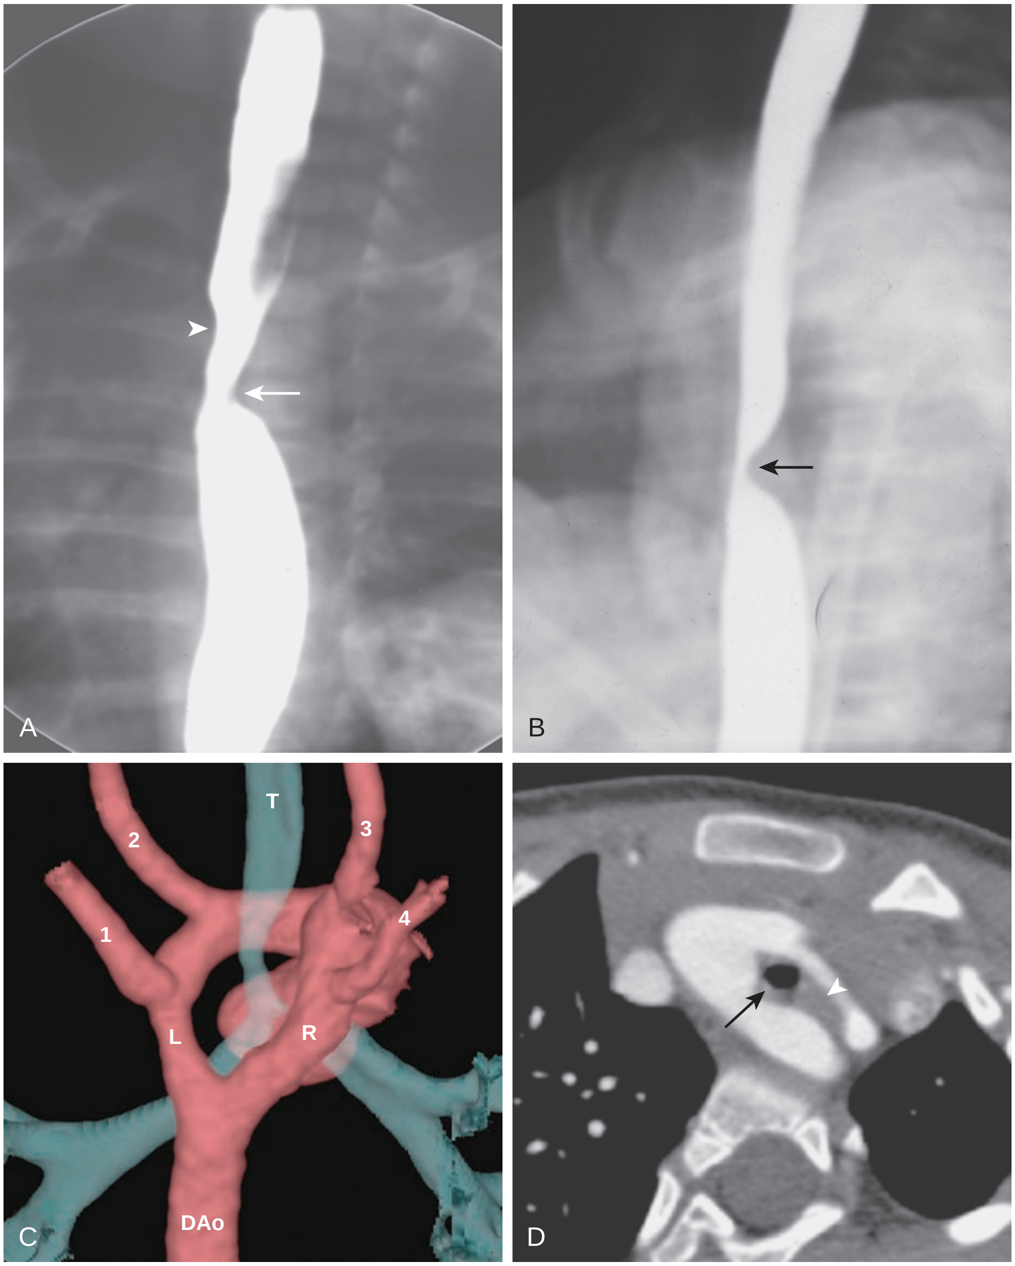


**Figure 76.2. Bilaterally patent double aortic arches in a 7-year-old boy.** (A) Frontal view of a barium esophagram shows bilateral indentations of the barium column. The right arch indention *(arrowhead)* is higher than the left *(arrow)*. (B) Lateral view of a barium esophagram shows a posterior indentation *(arrow)* corresponding to the posterior right arch. (C) Volume-rendered posterior projection CTA image shows the dominant right arch *(R)* and a nondominant left arch *(L)*, both feeding into the descending aorta *(DAo)*. Four cervical arteries arise from the arch: left subclavian artery *(1)*, left common carotid artery *(2)*, right common carotid artery *(3)*, and right subclavian artery *(4)*. The ring encloses the trachea *(T)*, causing tracheal narrowing just above the carina. (D) Axial CT image shows a complete double aortic arch constricting the trachea *(black arrow)* and the esophagus *(white arrowhead)*.

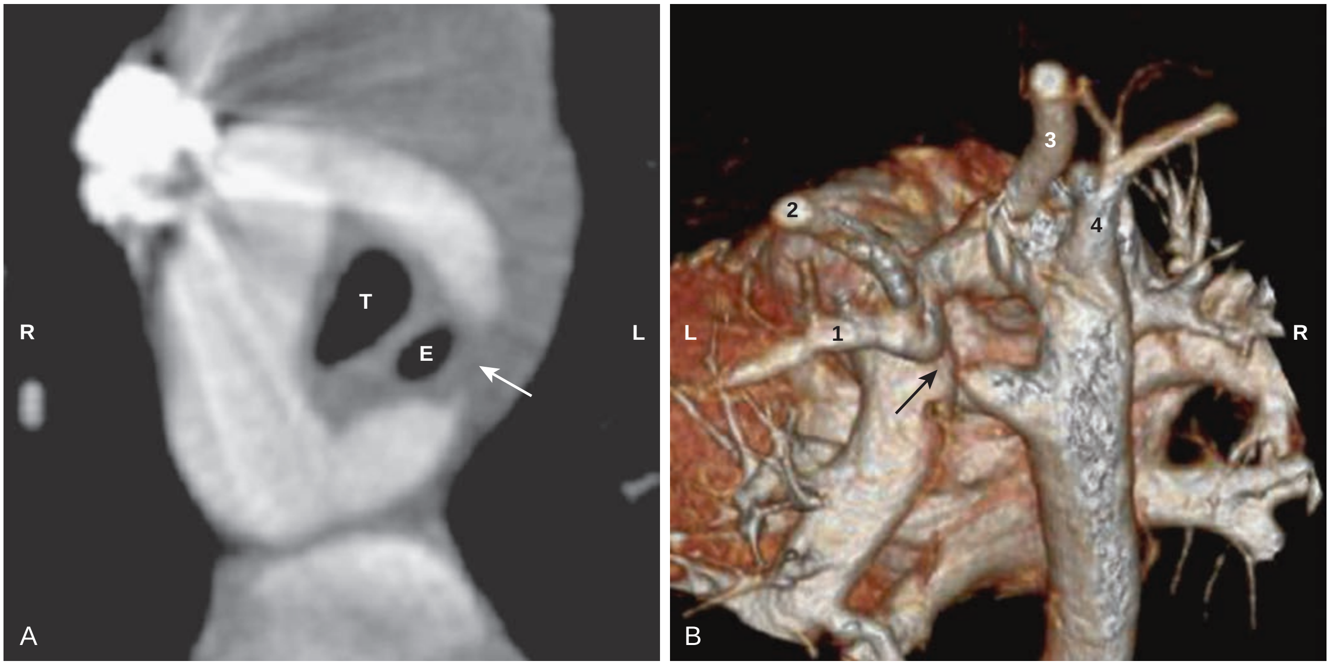

**Figure 76.3. Double aortic arch with an atretic left arch in a 2-year-old girl.** (A) Axial CTA image shows a patent right arch and an incomplete left arch. A ligamentous connection *(arrow)* can be inferred from the tapered contour of the left arch, forming the left border of the vascular ring and constricting the trachea *(T)* and esophagus *(E)*. (B) Volume-rendered view from the CTA shows the atretic left arch segment *(arrow)*. The left subclavian artery *(1)* and the left common carotid artery *(2)* are supplied by the proximal portion of the left arch. The right arch gives off the right common carotid artery *(3)* and the right subclavian artery *(4)*. The patient's right *(R)* and left *(L)* are labeled for reference.

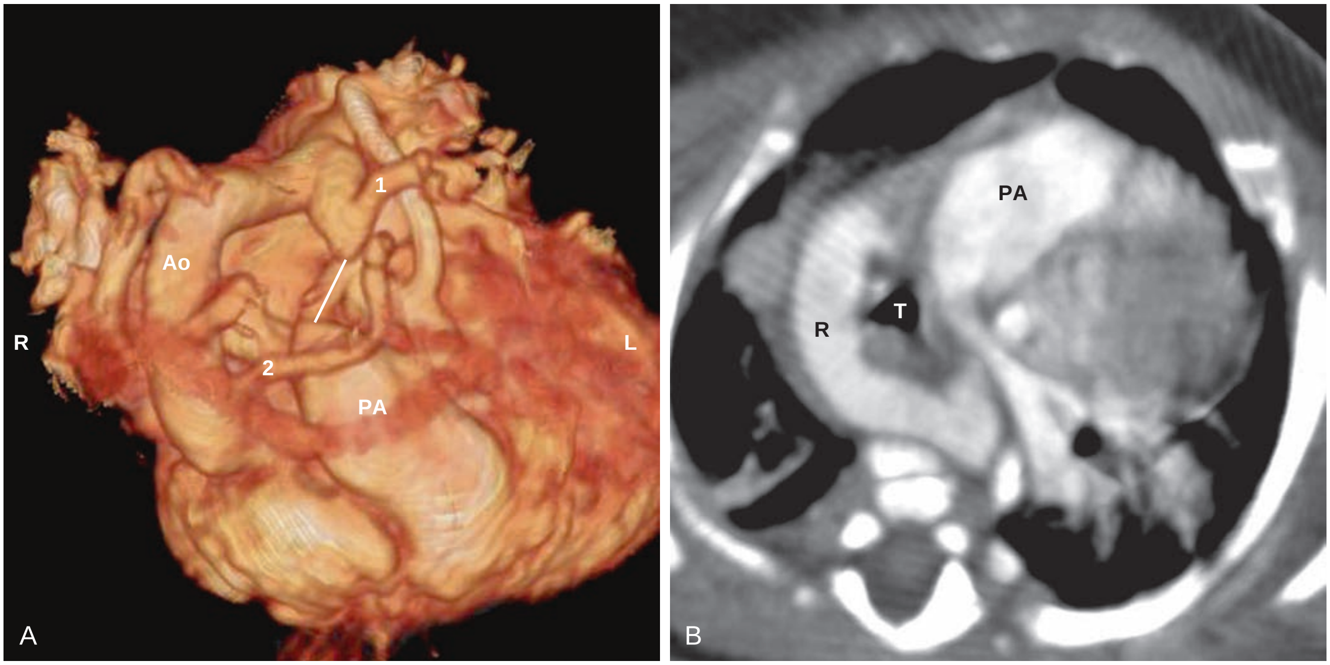

**Figure 76.4. Right aortic arch with an aberrant left subclavian artery in a 1-year-old girl.** (A) Volume-rendered anterior and superior view reconstructed from a CTA study. The right aortic arch *(Ao)* gives off the left common carotid artery *(2)* as the first branch and the left subclavian artery *(1)* as the last branch. A kink is seen between the diverticulum of Kommerell and the left subclavian artery, suggesting the attachment of a tight ligamentum arteriosum. The probable connection of the ligamentum arteriosum is drawn as a white line, which forms the left border of the vascular ring. The patient's right *(R)* and left *(L)* are labeled for reference. (B) Axial CT angiogram of the same patient. The right aortic arch *(R)* forms the right and posterior border of the vascular ring; the ligamentum arteriosum forms the left border, enclosing the trachea *(T)*. *PA,* Pulmonary artery.

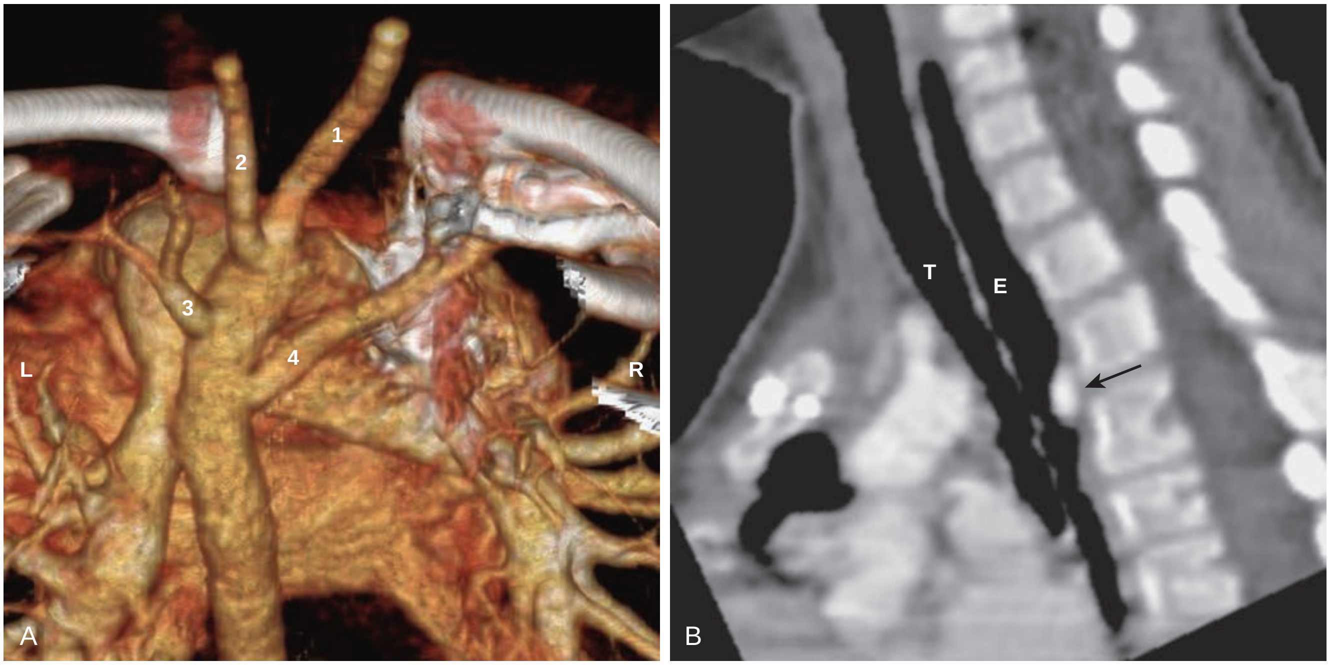

**Figure 76.6. Left aortic arch with an aberrant right subclavian artery in a 4-year-old boy.** (A) Posterior view volume-rendered CTA shows the arch vessels: right common carotid artery *(1)*, left common carotid artery *(2)*, left subclavian artery *(3)*, and aberrant right subclavian artery *(4)*. The patient's right *(R)* and left *(L)* are labeled for reference. (B) Sagittal reformation shows the air-filled trachea *(T)* and the esophagus *(E)*. The esophagus is indented posteriorly by the aberrant subclavian artery *(arrow)*.

## Left Aortic Arch With Circumflex Aorta

A left aortic arch with a circumflex aorta is analogous to a right aortic arch with a circumflex aorta, in that the distal arch travels from left to right behind the esophagus before turning downward to become a right descending aorta. To complete a vascular ring, a right ligamentum arteriosum must connect the pulmonary artery to the descending aorta.[18]

## Right Cervical Aortic Arch

A right cervical aortic arch is a rare anomaly that occurs when there is abnormal cephalic migration of the aortic arch into the supraclavicular and neck region. Embryologically, the cervical aortic arch forms from the third arch rather than the normal fourth arch. The aortic arch branching pattern varies, and separate origins of the internal and external carotid arteries may arise from the cervical aortic arch. The right cervical aortic arch is often associated with an aberrant left subclavian and may cause a vascular ring when associated with a left ligamentum arteriosum. Clinically, a pulsatile mass may be present in the supraclavicular region. Radiographic findings include right superior mediastinal widening, tracheal displacement to the left and anteriorly, a large oblique impression on the esophagram from cephalic right to caudal left, and a left descending aorta (Fig. 76.8).

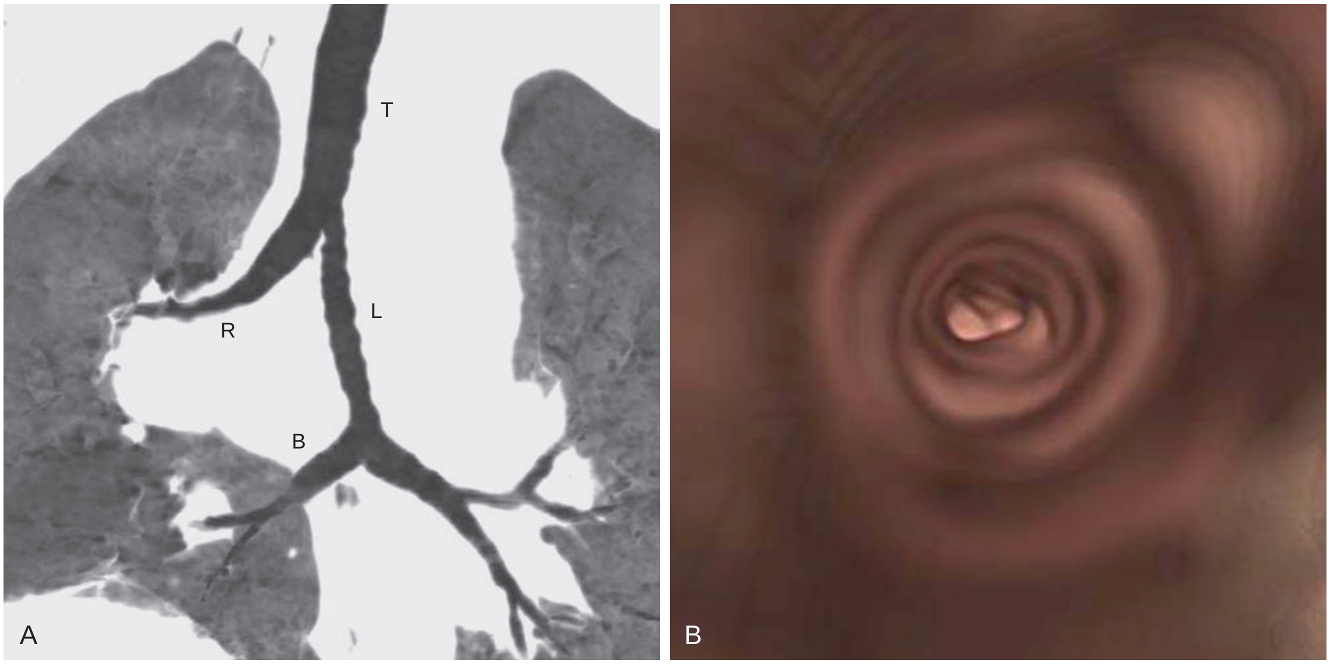
## Left Cervical Aortic Arch

Although a left cervical aortic arch is much less common than the right-sided version, it similarly extends abnormally high in the upper mediastinal–low cervical region on the left side of the trachea. Aortic arch branching anomalies are similar to those mentioned previously. A vascular ring is formed when a right ligamentum arteriosum is present. Clinical and radiographic findings are similar to those previously mentioned.

## PULMONARY ARTERY SLING

***Overview.*** Pulmonary artery sling is a congenital anomaly that produces tracheal compression between the main and left pulmonary arteries. Instead of the normal bifurcation of the main pulmonary artery into the right and left pulmonary arteries (Fig. 76.9A), the left pulmonary artery arises from the posterior aspect of the right pulmonary artery and courses leftward between the trachea and esophagus, at or near the level of the carina (Fig. 76.9B).

The incidence of pulmonary artery sling is not known, with one study suggesting an incidence of 1 in 17,000, with a slight male predilection.[19] Patients present with clinical symptoms in childhood, and 90% of patients present with symptoms before the first year of life.[20] Nonspecific respiratory symptoms include an asthmatic cough and acute and recurrent bronchopulmonary infections. Symptom severity depends on the degree of airway compression and coexisting airway abnormalities. Coexisting airway abnormalities are present in more than 50% of patients, including abnormal branching of the airways, complete tracheal rings, and tracheal stenosis.[21] The vertical position of the left pulmonary artery origin, along with the branching pattern of the airways, has been used to classify pulmonary artery sling.[22] In type 1 pulmonary artery sling, the left pulmonary artery originates at T4–T5 vertebral levels, just above the normal level of the carina. Subtype 1A has normal branching pattern of the airways; subtype 1B has a tracheal bronchus. In type 2 pulmonary artery sling, the left pulmonary artery originates below the T5 vertebral level, below the normal carina. Subtype 2A has a right main bronchus connecting to the right upper lobe only. A separate "bridging" airway arises from the left main bronchus, below the aberrant left pulmonary artery, that supplies the right middle and right lower lobes (e-Fig. 76.10A). In subtype 2B, the right main bronchus is absent and the bridging airway defined in 2A supplies the entire right lung. Except for the level of the left pulmonary artery, the right main bronchus in type 2A superficially resembles the tracheal



**e-Figure 76.10. Abnormal central airways of a 40-year-old woman with a pulmonary artery sling.** (A) Coronal reformation with minimum intensity projection shows type 2A configuration where the trachea *(T)* bifurcates into a right main bronchus *(R)* and a left main bronchus *(L)*. The right main bronchus supplies the right upper lobe airways only. A bridging bronchus *(B)* supplies the rest of the right lung. Superficially, the right main bronchus resembles a tracheal bronchus, except that it arises at the expected location of the carina, instead of high up from the trachea. (B) The endoscopic view in the trachea shows complete tracheal rings.

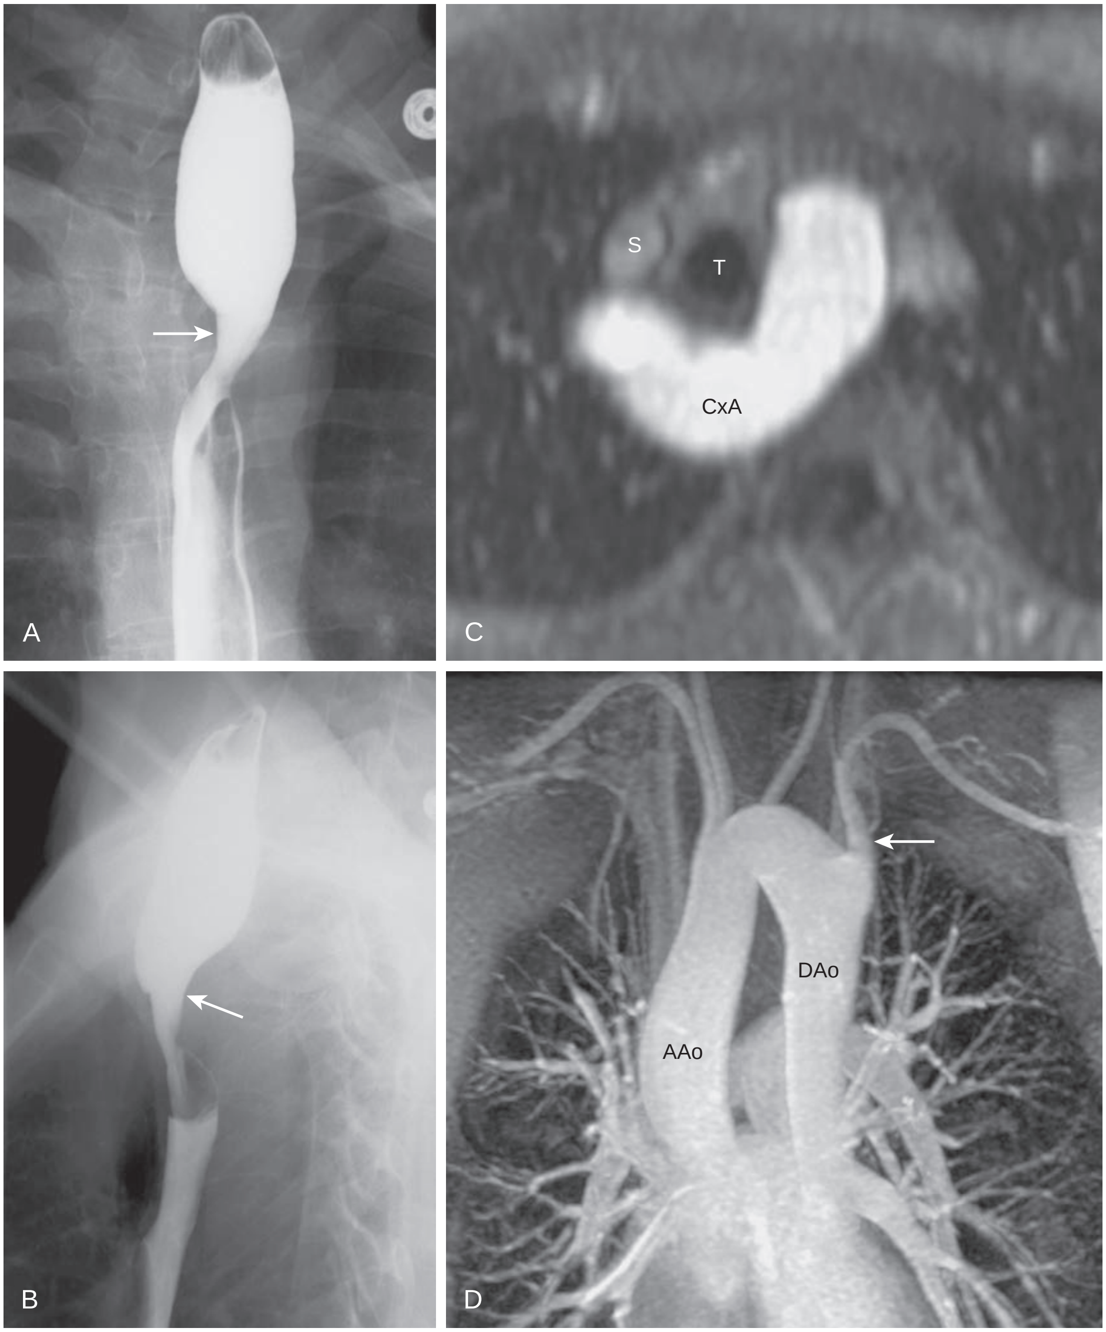


**Figure 76.7. Circumflex aortic arch.** (A) Frontal esophagram of an 18-year-old female shows a large right indentation on the esophagus *(arrow)* corresponding to a right aortic arch. (B) Lateral esophagram shows a posterior indentation *(arrow)* larger than expected for an aberrant left subclavian artery. (C) Axial MRA reconstruction shows that the aorta *(CxA)* passes behind the trachea *(T)* and the esophagus. The superior vena cava *(S)* is labeled for reference. (D) Maximal intensity projection MRA shows a right ascending aorta *(AAo)* and a left descending aorta *(DDo)*. There is an aberrant left subclavian artery *(arrow)* as the last branch off the arch.

bronchus in type 1B. Regardless of the type, complete tracheal rings and stenosis frequently are present (e-Fig. 76.10B).

Unlike with a vascular ring, the obstructive symptoms of the esophagus tend to be mild or absent in pulmonary artery sling. About a third of pulmonary artery sling cases are associated with other cardiovascular anomalies, including ventricular septal defect, atrial septal defect, patent ductus arteriosus, tetralogy of Fallot, single ventricle, and coarctation.[20] Genetic associations include trisomy 18 and 21.[23]

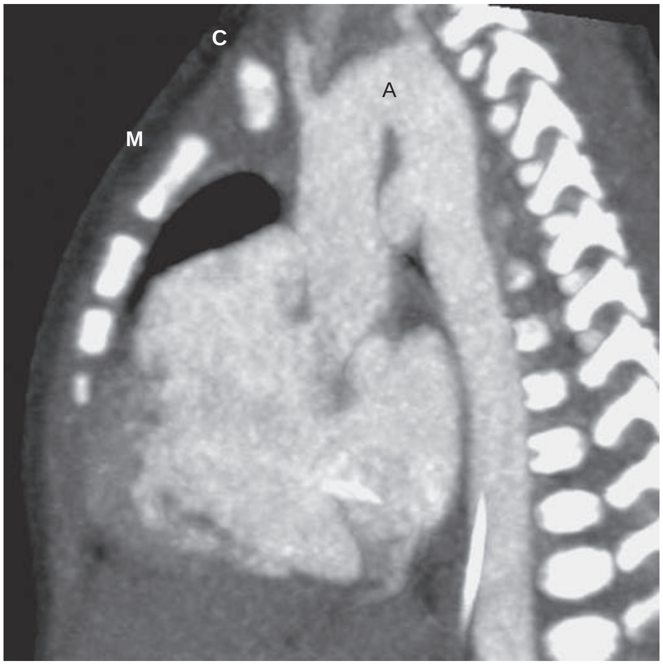

**Figure 76.8. Cervical aortic arch in a 1-month-old boy.** Sagittal chest CTA reformation shows a high aortic arch *(A)* with its apex above the level of the manubrium *(M)* at vertebral level T3–T4. *C,* Clavicle.

***Imaging.*** As the left pulmonary artery wraps around the right side of the trachea, the right main bronchus or the bridging airway can be obstructed. In the newborn, this phenomenon may manifest as retained fluid in the right lung. In older children, this phenomenon may present as a hyperinflated right lung from air trapping. The most specific finding is the abnormal architecture of the central airways, often described as a low carina and an inverted T shape of the central airways (see e-Fig. 76.10A). This finding is a result of the abnormal airway structure found in type 2 pulmonary artery sling. The apparent low carina is the result of the low origin of the bridging bronchus. The horizontal course of the bridging bronchus gives the carina a flattened look, hence the inverted T shape.

Barium esophagography demonstrates an anterior indentation of the esophagus at the level of the carina (Fig. 76.11), unlike the posterior indentation seen with a vascular ring. In addition, on the lateral projection, the trachea is separated from the esophagus by the left main pulmonary artery.

Direct visualization of the anomalous left pulmonary artery can be performed with CTA or MRA.[24] Because assessment of the tracheobronchial tree and lungs is important for pulmonary artery sling, CTA is the preferred imaging modality. CTA images can be postprocessed to provide virtual endoscopic views to evaluate for focal versus diffuse airway stenosis, extrinsic vascular compression, and tracheal rings (see e-Fig. 76.10B). Endoscopic bronchoscopy is recommended to evaluate dynamic airway obstruction from tracheobronchomalacia and to confirm the extent of complete tracheal rings or stenosis for surgical planning.

***Treatment.*** The definite treatment is surgical reimplantation or relocation of the left pulmonary artery and release of the entrapped trachea. In many of these patients, stenosis of the trachea requires a sliding tracheoplasty or pericardial patch to augment the narrowed segment. A diameter of the trachea less than 3 mm is associated with the need for tracheoplasty or a poor outcome.[25] Airway narrowing that involves the carina or the bronchi is particularly difficult to repair.[26]

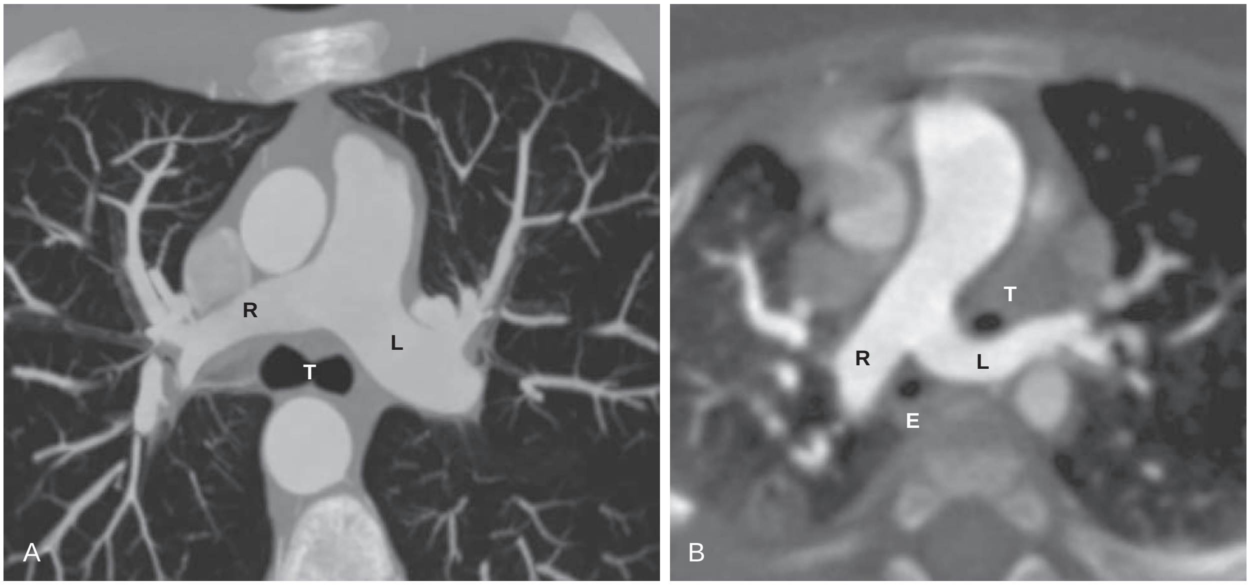

**Figure 76.9. Pulmonary artery sling in a 6-month-old girl.** (A) Axial CTA image showing the normal pulmonary artery branching pattern. The main pulmonary artery bifurcates into the left pulmonary artery *(L)* and right pulmonary artery *(LR)*. The trachea *(T)* is seen posterior to the bifurcation. (B) Axial CTA image shows the anomalous left pulmonary artery *(L)* arising from the right pulmonary artery *(R)*. It courses between the trachea *(T)* and the esophagus *(E)*. The trachea is entrapped between the left and right pulmonary arteries.

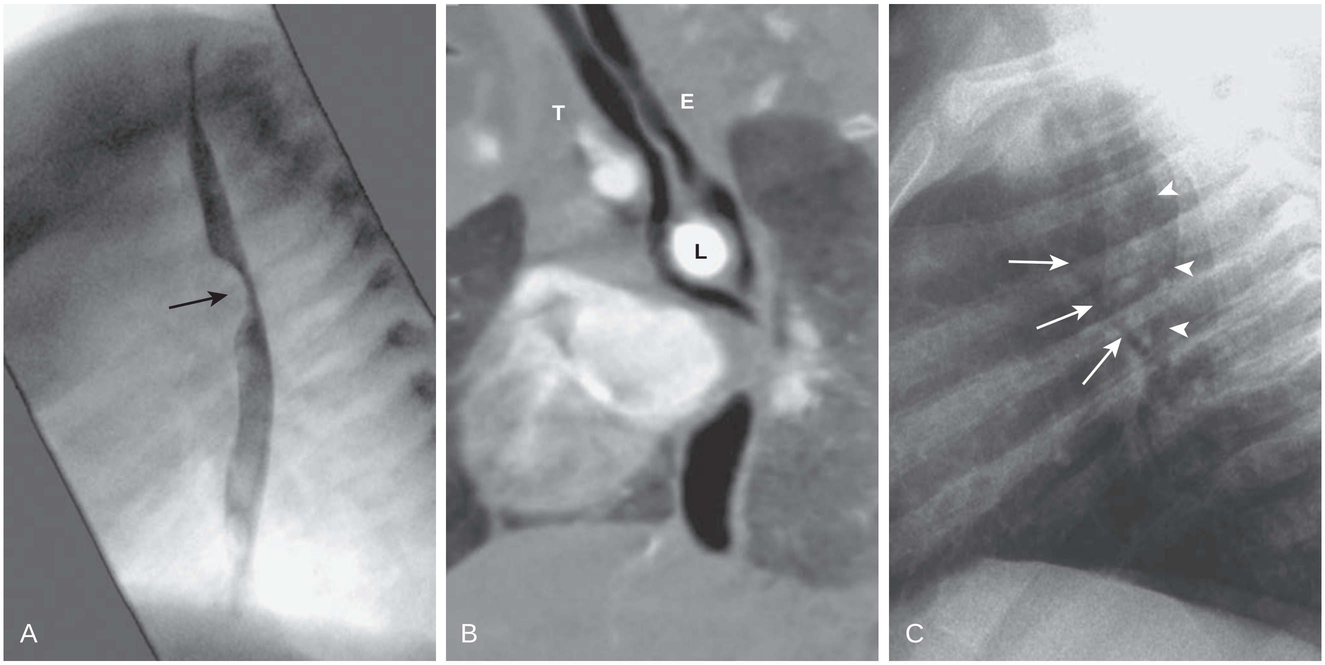

**Figure 76.11. Pulmonary artery sling in a 6-month-old girl.** (A) Lateral esophagram shows an anterior indentation *(arrow)*. (B) Reformatted CTA in the same plane shows the left pulmonary artery *(L)* separating the trachea *(T)* from the esophagus *(E)* at the carina level. The anterior indentation seen in the esophagram is caused by compression by the left pulmonary artery. (C) Lateral chest radiograph shows the same separation of the trachea *(arrows)* and the air-filled esophagus *(arrowheads)*.

## KEY POINTS

- Barium esophagography has historically been performed for the evaluation of a vascular ring, but CTA and MRA are now the studies of choice for diagnosis.
- Vascular rings involving a right aortic arch include these variations:
  - Aberrant left subclavian artery, left ductus arteriosus/ligamentum arteriosum
  - Mirror-imaging branching, left ductus arteriosus/ligamentum arteriosum
  - Circumflex aorta with a left descending thoracic aorta, left ductus arteriosus/ligamentum arteriosum
  - Cervical aortic arch, aberrant left subclavian artery, left ductus arteriosus/ligamentum arteriosum
- Vascular rings involving a left aortic arch includes these variations:
  - Aberrant right subclavian artery, right ductus arteriosus/ligamentum arteriosum
  - Circumflex aorta with a right descending thoracic aorta, right ductus arteriosus/ligamentum arteriosum
  - Cervical aortic arch, aberrant right subclavian artery, right ductus arteriosus/ligamentum arteriosum
- Imaging evaluation of a pulmonary artery sling must include the central airways because of the frequent associations with abnormal branching of the airways, complete tracheal rings, and tracheobronchial stenosis.

# Coronary Artery Disease in Children

*Simon Lee*

Coronary artery disease in children can be acquired, but the majority of anomalies are congenital.[1,2] Among acquired coronary abnormalities, Kawasaki disease (KD) is the most common. Other causes include sequelae from trauma, vasculitides, radiation injury after oncologic treatment, and rare cases of familial hyperlipidemia and idiopathic infantile arterial calcification. Congenital coronary anomalies can be characterized as abnormalities in origin, abnormalities associated with the coronary vessel, and abnormalities associated with congenital heart disease. Boxes 77.1 and 77.2 outline the common acquired and congenital coronary anomalies seen in children.

## IMAGING CONSIDERATIONS

Transthoracic echocardiography (TTE) remains the first-line imaging tool for evaluating children with suspected coronary anomalies. In experienced hands, the coronary origins and proximal coronary courses are reliably imaged. When further anatomic detail of luminal dimensions, ostial morphology, or evaluation of more distal portions of the coronary anatomy is necessary, other imaging modalities are necessary. Catheter angiography is the reference standard for the determination of coronary luminal abnormalities, such as coronary stenosis.[3] Additional techniques that further characterize the arterial wall and myocardial perfusion can be performed during catheterization, such as intravascular ultrasound (IVUS) and fractional flow reserve measurement.[4,5] However given the invasive nature of catheter angiography, electrocardiographic (ECG)-gated coronary computed tomography angiography (CCTA) and cardiac magnetic resonance angiography (CMRA) are the main diagnostic modalities utilized.[6,7] Both techniques yield three-dimensional images of the heart, with the coronary vessels shown in the context of adjacent cardiac structures. Visualization is facilitated by various postprocessing techniques, such as curved multiplanar reformatting and endoluminal views via virtual angioscopy. CCTA has excellent diagnostic accuracy in detecting coronary stenosis, and several studies show that it is now comparable to catheter angiography.[8,9] These capabilities have made CCTA and CMRA the preferred method for the diagnosis and characterization of coronary anomalies.

CCTA provides excellent visualization of coronary anatomy, including the distal coronary branches. Images synchronized to the cardiac cycle can be acquired with prospective or retrospective ECG synchronization. Prospective ECG-triggering yields a snapshot of the heart at a predetermined portion of the cardiac cycle, whereas with retrospective ECG-gating, data is acquired throughout the cardiac cycle and can therefore be reconstructed at multiple time-points in the cardiac cycle and can be used to produce cine images of the heart. However, because data is acquired throughout the cardiac cycle, images obtained with retrospective ECG-gating generally incur a greater radiation dose compared with prospective ECG-triggering. With 64-slice scanners, the typical scan time in either mode is less than 10 seconds. Newer generation dual source and volumetric computed tomography (CT) scanners provide full anatomic coverage of a pediatric thorax in less than a second or in a single heartbeat, freezing respiratory and cardiac motion, and obviating the need for sedation in many cases. As CCTA uses ionizing radiation to produce images, measures should be taken to minimize the dose of ionizing radiation delivered while maintaining image quality. Strategies for CCTA dose optimization are listed in Box 77.3 and have been detailed in Chapter 66.[9–12]

The lack of ionizing radiation makes CMRA an attractive alternative to CCTA. CMRA can also provide information regarding ventricular size, systolic function, and tissue characterization (such as perfusion imaging, myocardial delayed enhancement, and T1 mapping). CMRA for assessment of the heart and great arteries is often performed using a three-dimensional, cardiac-gated, navigated echo, T2-prepared, steady-state, free-precession sequence (see Chapter 67).[13] Coronary vessel visualization with this sequence is based on the intrinsic long-T2 value of blood, so no gadolinium contrast administration is required.[14]

One of the main drawbacks of CMRA is that it lags in spatial resolution compared with CCTA, which can provide isotropic submillimeter resolution. Additionally, despite the lack of ionizing radiation, CMRA often requires anesthesia in patients younger than 8 years of age, and the risks of anesthesia versus radiation exposure must be weighed.[14a]

## NORMAL CORONARY ARTERY ANATOMY

Embryologically, the spatial configuration of the aortic sinuses adjacent to the pulmonary trunk act as a stimulus for coronary bud development. In a structurally normal heart with normal coronary artery anatomy, the left main coronary artery (LMCA) and right coronary artery (RCA) arise from the left and right sinuses of Valsalva, respectively. The LMCA then divides into the left anterior descending (LAD) and circumflex (Cx) coronary arteries. Many anatomic variations of the coronary arteries exist, with normal variants typically having no clinical significance (Fig. 77.1).

In cases where there is associated congenital heart disease, nomenclature of the coronary arteries should refer to the coronary dependent territory as opposed to the site of coronary origin. For example, in congenitally corrected transposition of the great arteries (L-transposition of the great arteries) where the morphologic left ventricle lies to the right, the coronary artery in the right-sided atrioventricular groove is named the left circumflex artery (see Chapter 75). When derangement of the ventricles is so severe that the ventricular morphology cannot be clearly identified, then the coronary arteries should be described relative to physical landmarks—for example, left-sided atrioventricular branch instead of left Cx, right-sided atrioventricular branch instead of RCA, anterior interventricular septal branch instead of LAD, and posterior interventricular septal branch instead of posterior descending artery (PDA).

### Right Coronary Artery

After its takeoff from the right sinus of Valsalva, the RCA courses anteriorly into the right atrioventricular groove and gives rise to several branches. The right conal artery arises as the first branch of the right coronary artery 50% to 60% of the time, arising directly from the right sinus of Valsalva in 40% to 50% of cases. The sinoatrial nodal artery arises from the proximal RCA in the majority of cases and from the proximal left Cx in the other (Fig.

## Abstract:

Coronary artery disease in children can be divided into acquired versus congenital etiologies, with congenital anomalies being far more prevalent. The breadth of coronary anomalies seen in children and young adults is wide. For most children, particularly pre-school age, transthoracic echocardiography is the first-line imaging modality. Further coronary imaging with computed tomography (CT) or magnetic resonance (MR) for diagnosis of a coronary anomaly, confirmation and clarification of echocardiographic findings, mapping out the coronary arteries for surgical planning, and evaluation for a coronary aneurysm or stenosis is often necessary. Dose-optimization strategies for CT should be utilized in all cases. In patients with congenital coronary anomalies that require surgical manipulation, follow up imaging with coronary CT angiography or stress MR perfusion imaging may be necessary.

**BOX 77.3** Computed Tomography Radiation Dose Optimization Strategies

- Limit scan range to anatomy of clinical interest.
- Center the patient within the gantry.
- Lower tube potential and tube current to account for patient size. Consider automated algorithms.
- Technique should be adjusted to the lowest practical radiation dose that will yield diagnostic image quality based on the clinical indication.
- Prospective ECG-triggering should be used when possible.
- For coronary imaging, the narrowest temporal acquisition window possible should be used.
- Iterative reconstruction should be used on all scans.
- Heart rate lowering medications should be considered.

77.2A). The midportion of the RCA gives rise to the acute marginal branches, which supply the RV free wall (Fig. 77.2B). The distal portion of the RCA wraps around the inferior surface of the heart. An atrioventricular node branch often arises from the RCA near the crux of the heart (Fig. 77.2D). In 70% to 85% of the population, the RCA gives rise to a PDA that courses within the posterior interventricular sulcus to supply the basilar inferior wall of the left ventricle (Fig. 77.2C). This pattern is called a *right-dominant coronary system*. There can be codominance, where the RCA supplies the PDA and the Cx supplies additional posterior left ventricular branches. The least common pattern is left-dominance, where the PDA arises from the Cx.

### Left Coronary Artery

The LMCA originates from the left sinus of Valsalva and courses to the left for a short distance before it bifurcates into the LAD and Cx coronary arteries. Occasionally, the LMCA trifurcates into an LAD coronary artery, a Cx coronary artery, and a ramus intermedius branch (Fig. 77.3A). This ramus intermedius branch supplies the anterior left ventricular wall. The LAD artery gives rise to two sets of vessels: an epicardial set called the *diagonal branches* and an intramuscular set called the *anterior septal perforator branches*. The diagonal branches are responsible for perfusing the anterior left ventricular wall, whereas the septal perforator branches are responsible for the anterior septum. The distal LAD artery typically wraps around the cardiac apex and terminates at the inferior wall of the apex (Fig. 77.3B). In a minority of cases, the Cx artery gives off a sinoatrial nodal branch (Fig. 77.3C) before it enters the left atrioventricular groove. The Cx artery then gives rise to a number of obtuse marginal branches, which supply the lateral left ventricular wall (see Fig. 77.3B).

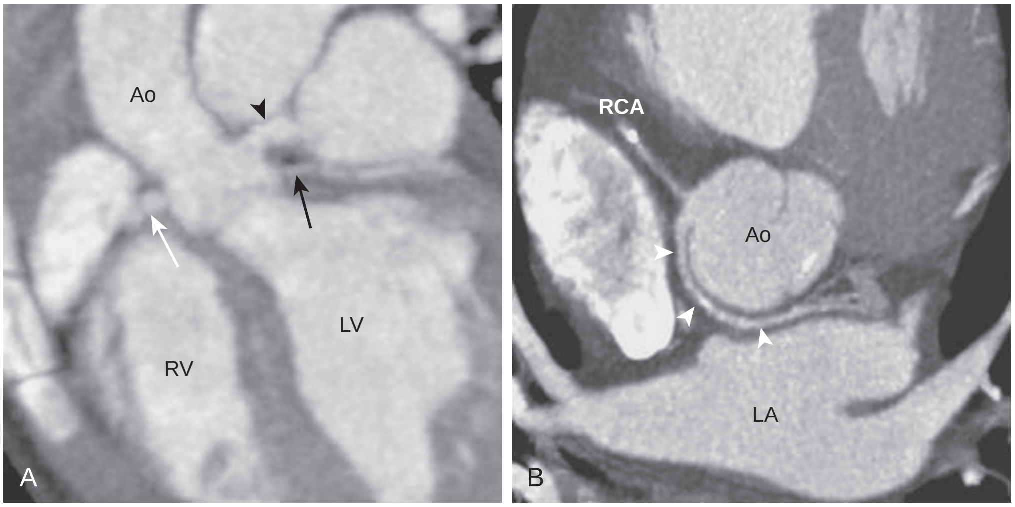
## CONGENITAL CORONARY ARTERY ANOMALIES

### Epidemiology

The true prevalence of congenital coronary artery anomalies is unknown. According to adult catheter angiographic data, 0.6% to 1.5% of patients were found to have coronary artery anomalies.[15,16] The largest study of this type reviewed more than 126,000 coronary studies and revealed a prevalence of 1.3%, with the majority (80%) felt to have no clinical significance.[15,16] The two most common anomalies are separate origins of the LAD and Cx arteries arising from the left sinus of Valsalva (0.41%) (e-Fig. 77.4A) and a retroaortic Cx artery arising from the right sinus or the RCA (0.37%) (e-Fig. 77.4B). Both configurations are clinically benign. Other examples of benign anomalies are an absent Cx artery with a superdominant RCA that reaches the anterior atrioventricular groove and a high takeoff of either coronary (>1 cm above the sinotubular junction).

### Anomalous Aortic Origin of a Coronary Artery

***Overview.*** An anomalous aortic origin of the LMCA (AAOLCA) may originate from the right sinus of Valsalva or may arise as a single coronary artery with the RCA. Before bifurcating into the LAD and Cx arteries, the LMCA must travel toward the left by one of four routes: anterior to the right ventricular outflow tract (RVOT), within the interventricular septum beneath the RVOT (intraseptal), between the aorta and the pulmonary artery (interarterial), or posterior to the aorta.[17,18] Similarly, an anomalous aortic origin of the RCA (AAORCA) may originate from the left sinus of Valsalva or as a single coronary with the LMCA. It typically has an interarterial course toward the right atrioventricular groove, although other routes are possible.[18] While the anterior and posterior courses are considered clinically benign, the interarterial course (Fig. 77.5) is associated with sudden cardiac death.[19] This association was originally described in several autopsy series, with AAOLCA found more frequently than AAORCA.[20–22] Several studies and case reports have subsequently established this association, with congenital coronary anomalies reported as the



**e-Figure 77.4. Common benign variants of the coronary arteries.** (A) Horizontal long-axis view reconstructed from a CCTA of a 1-year-old boy shows separate origins for the left anterior descending *(arrowhead)* and the left circumflex (LCx) *(black arrow)* arteries. The right coronary artery (RCA) *(white arrow)* is in normal position. This variant occurs in 0.41% of the population. (B) Short-axis view from a 40-year-old man shows the LCx artery and the *RCA* arising separately from the right sinus. The LCx artery *(white arrowheads)* wraps around posterior to the aorta *(Ao)* and then enters the left atrioventricular groove. This variant occurs in 0.37% of the population. *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

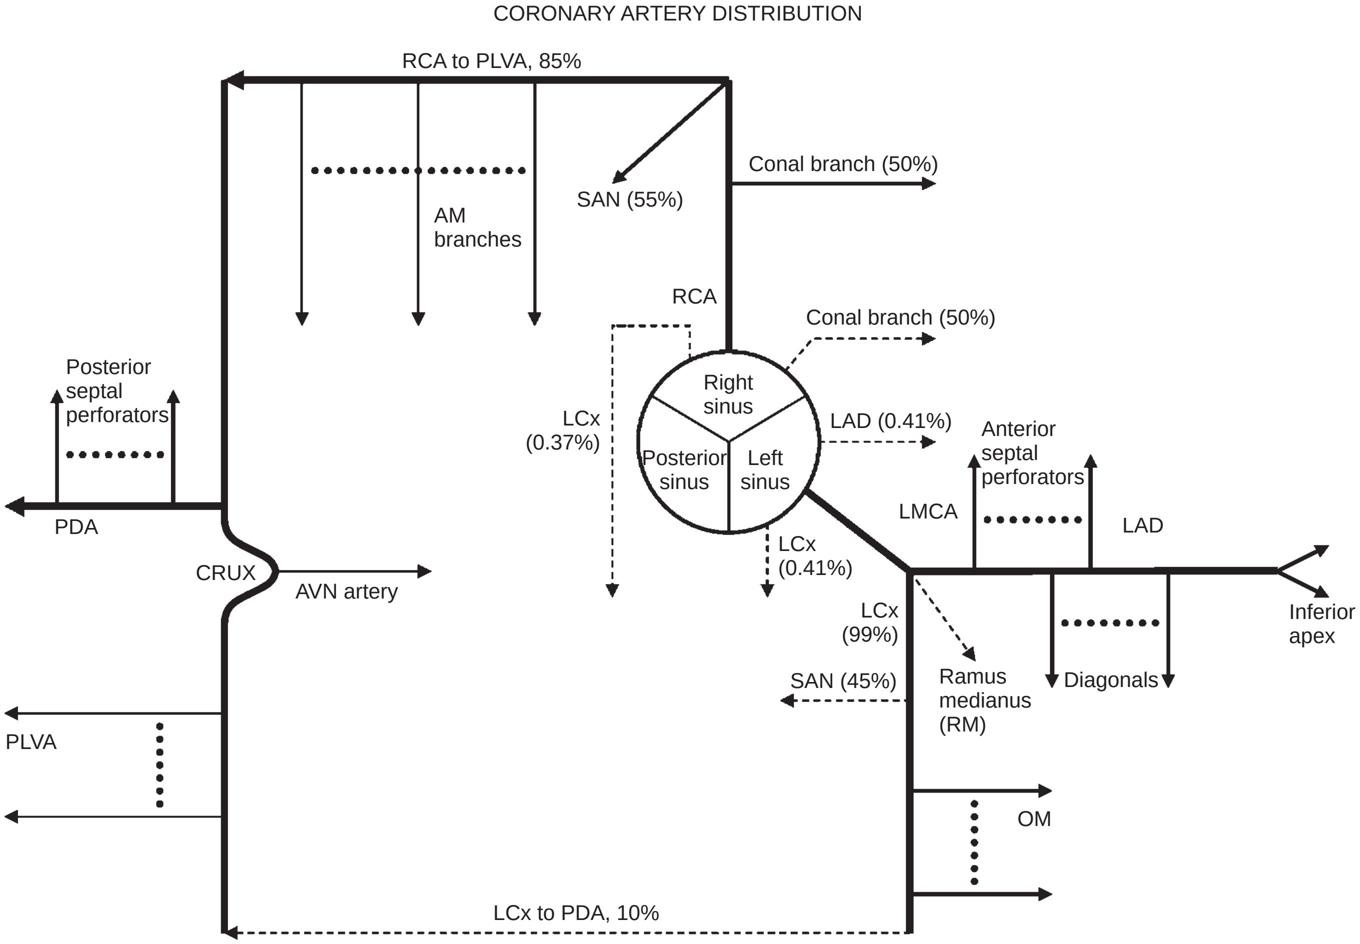


**Figure 77.1. Coronary artery distribution diagram.** *Solid lines* represent the most common coronary artery pattern. *Dashed lines* represent common variants (prevalences in percentages). *AM,* Acute marginal; *AVN,* atrioventricular nodal; *LAD,* left anterior descending; *LCx,* left circumflex; *LMCA,* left main coronary artery; *OM,* obtuse marginal; *PDA,* posterior descending artery; *PLVA,* posterior left ventricular artery; *RCA,* right coronary artery; *RM,* ramus medianus; *SAN,* sinoatrial nodal.

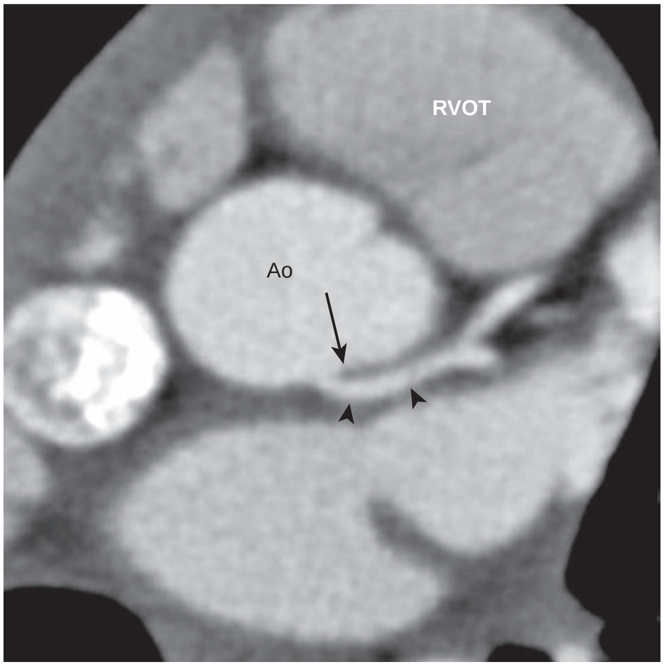
second-most common cause for sudden cardiac death in adolescent athletes.[23]

The true prevalence of anomalous aortic origin of the coronary arteries is unknown. The majority of patients are asymptomatic and a major adverse cardiac event is often the initial presentation. Based on prior angiographic studies, the prevalence of AAOLCA with an interarterial course is estimated at 0.02% to 0.05% of the population, and the prevalence of AAORCA is estimated at 0.1%.[24] Given that AAORCA appears to be three to five times more common than AAOLCA in the general population, the prior autopsy studies suggest that AAOLCA is a higher risk lesion.

The pathophysiology of sudden cardiac death has not been conclusively determined. Most patients with sudden cardiac death had no significant clinical findings or known premonitory symptoms.[25] In about 30% of the cases, syncope or chest pain occurred within 2 years of death, but resting ECG and stress ECG have been reported as normal. The prevailing thought is that the risk of sudden cardiac death is increased with significant physical exertion, such as strenuous athletic activity. Presumed risk factors for a lethal arrhythmia are transient ischemia caused by inadequate coronary flow through a narrowed “intramural” lumen compressed by the aorta and pulmonary artery, a slitlike opening caused by an acute takeoff (<45 degrees) of the anomalous coronary artery, and the presence of an ostial ridge or flap that also occludes the ostium.[26] An intramural lumen refers to a portion of the coronary artery where the tunica media is shared with the aortic wall and there is no interposed adventitial layer.

In addition to interarterial coronary arteries, sudden death has rarely been reported with AAOLCA arising from the noncoronary sinus without an interarterial course.[27] In this configuration, the alignment of the LMCA origin and the anterior interventricular groove is such that the LMCA may have a more acute takeoff angle from the noncoronary sinus (e-Fig. 77.6). This acute takeoff angle creates a narrowing at the ostium that is thought to be a factor leading to ischemia and sudden death.

***Imaging.*** In neonates and young children, echocardiography can delineate the coronary origins to suggest the anomalous coronary types previously discussed. In adolescents and young adults, the coronary arteries may not be adequately assessed with echocardiography. Confirmation of the diagnosis and detailed characterization of the high-risk features previously mentioned is better performed by CMRA and CCTA.[28] In particular, the presence of an intramural course should be evaluated by cross-sectional imaging, as this is poorly characterized by echocardiography.[29] Current data suggests the risk of sudden cardiac death is low before 10 years of age, and so many centers defer surgical intervention until after this age.[30] Further cross-sectional imaging can likely be deferred in most routine cases until around 10 years of age. This has the benefit of avoiding sedation or anesthesia in the majority of cases. Depending on the expertise and equipment



**e-Figure 77.6. CCTA of an anomalous left main coronary artery (LMCA) from the noncoronary sinus.** Short-axis view from a CCTA of a 3-year-old girl shows the LMCA *(arrowheads)* arising from the noncoronary sinus just to the left of the commissure *(arrow)*. *Ao,* Aorta; *RVOT,* right ventricular outflow tract.

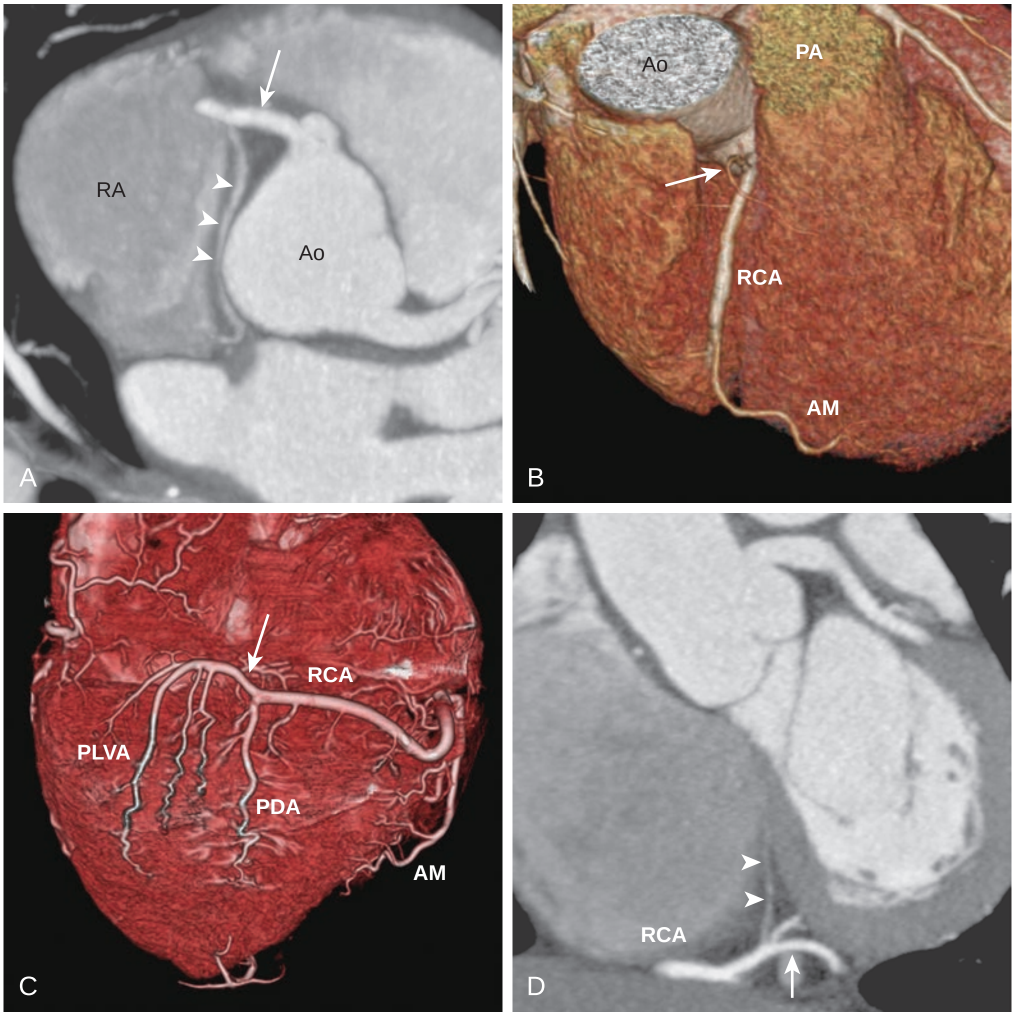


**Figure 77.2. Major branches of the normal right coronary artery *(RCA)*.** (A) Axial ECG-gated CCTA image shows the RCA *(arrow)* originating from the aorta *(Ao)* and extending toward the right atrioventricular groove. It gives off a sinoatrial nodal branch *(arrowheads)* that terminates at the right atrium *(RA)* near the atrial septum. (B) Volume-rendered image shows an acute marginal *(AM)* branch arising from the *RCA* at the right ventricular free wall. The conal branch *(arrow)* is the first branch of the *RCA. PA,* Pulmonary artery. (C) Volume-rendered image shows the inferior surface of a heart. The *RCA* gives off in succession of the *AM* branch, the posterior descending artery *(PDA)*, and the posterior left ventricular arteries *(PLVA)*, which lie on the left side of the crux *(arrow)*. (D) Short-axis view shows the *RCA* at the crux *(arrow)* giving off an atrioventricular nodal branch *(arrowheads)*.

available to individual centers, CMRA can be considered the first test of choice to avoid radiation exposure. If CMRA is not feasible due to technical or diagnostic reasons, then CCTA presents an excellent choice. Diagnostic catheter angiography does not have much of a role for this indication.

Morphologic features considered clinically relevant are: ostial size/morphology (including the presence of an acute angle takeoff from the aorta, a slitlike origin, and the presence of an ostial ridge), interarterial narrowing suggestive of an intramural course, length of the intramural portion, location in relation to the sinotubular junction and aortic commissures, and coronary dominance.[30] Determination of the intramural course can be difficult with CCTA and CMRA. Correlation with surgical pathology suggests that CCTA findings of a slitlike origin, an acute angle at vessel takeoff, and an elliptical cross-section with parallel course along the aortic root are related to an intramural coronary segment (Fig. 77.7).[31] Endoluminal views and volume rendered reconstructions are helpful for ostial characterization and surgical planning.

***Treatment.*** Although there is a strong association with sudden cardiac death, the absolute risk among individuals, particularly in the absence of participation in competitive sports, is unknown. There is marked practice variation among congenital heart surgery centers due to this uncertainty.[31] Recent data from a multicenter registry by the Congenital Heart Surgeons Society involving 23 pediatric centers reported 52% of AAORCA and 67% of AAOLCA had undergone surgery at a median age of 12.6 years.[32,33] The type of surgical repair is dependent on the coronary anatomy. In those with an intramural course, an unroofing procedure is the technique of choice. This involves incising the common wall between the aorta and intramural coronary. Aortic valve commissural resuspension may be necessary in cases where the intramural coronary courses behind the commissure. Direct reimplantation or creation of a neo-ostium and ostioplasty is performed when there are separate ostia and no significant intramural course. A pulmonary artery translocation can be performed in the case of a single coronary with evidence of coronary compression and/or

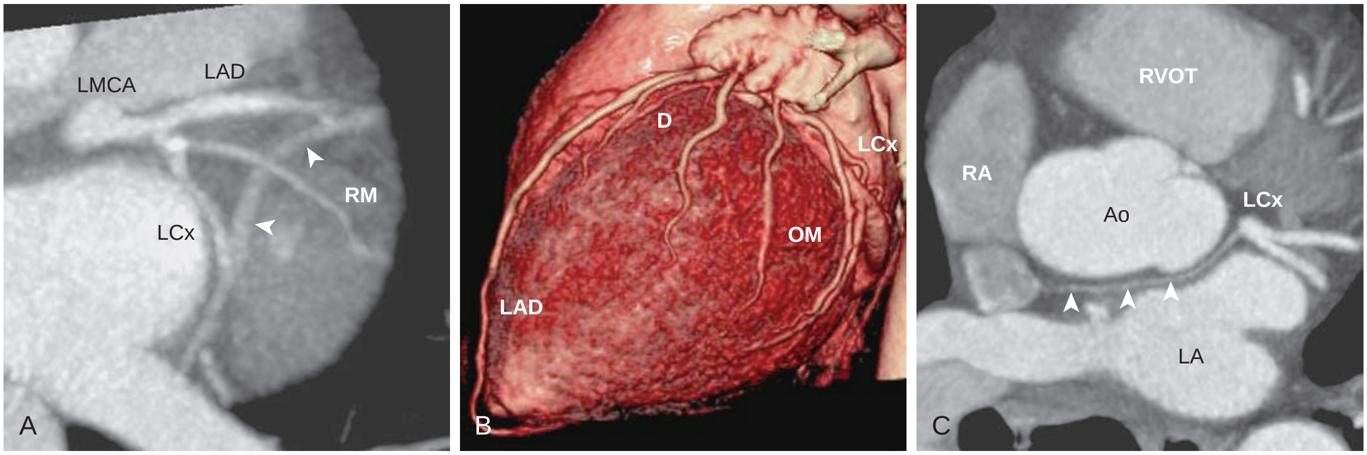

**Figure 77.3. Major branches of the normal left main coronary artery *(LMCA)*.** (A) Oblique axial ECG-gated CCTA image shows the trifurcation of the *LMCA* into a left anterior descending *(LAD)* artery, a ramus medianus *(RM)* branch, and a left circumflex *(LCx)* artery. The crossing vessel *(arrowheads)* is the greater cardiac vein. (B) Volume-rendered image shows the *LAD* and several diagonal *(D)* branches. The *LAD* wraps around the apex to reach the apical inferior surface. The *LCx* artery gives off several obtuse marginal *(OM)* branches. (C) Axial image shows the *LCx* giving off a sinoatrial nodal branch *(arrowheads)* that travels behind the aorta *(Ao)* and terminates at the right atrium *(RA)* near the atrial septum. *LA,* Left atrium; *RVOT,* right ventricular outflow tract.

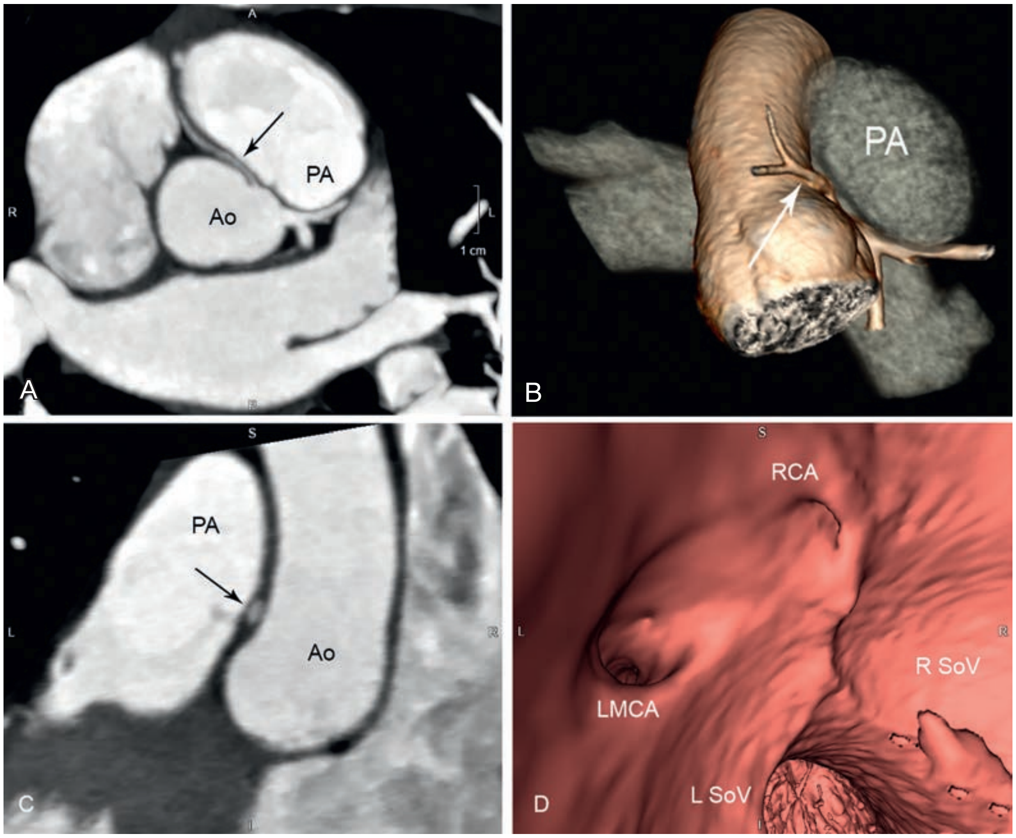

**Figure 77.5. Anomalous right coronary artery with an interarterial course.** (A) Short-axis view of the aortic root from a CCTA shows an anomalous aortic origin of the right coronary artery from the left sinus of Valsalva (AAORCA) with an interarterial course *(arrow)*. Note the acute angle of origin and interarterial narrowing, suggestive of an intramural course. (B) 3D volume rendered reconstruction demonstrating the RCA *(arrow)* as it courses from the left sinus of Valsalva between the aortic root and main pulmonary artery. (C) Multiplanar reformatted image of an interarterial segment of the coronary *(arrow)* demonstrating the elliptical shape and A-P narrowing. (D) Endoluminal reconstruction demonstrating the separate orifices of the left and right coronary arteries. The AAORCA orifice appears slitlike and narrowed, and arises adjacent to the intercoronary commissure (juxtacommissural). *L SoV,* Left sinus of Valsalva; *R SoV*, right sinus of Valsalva.

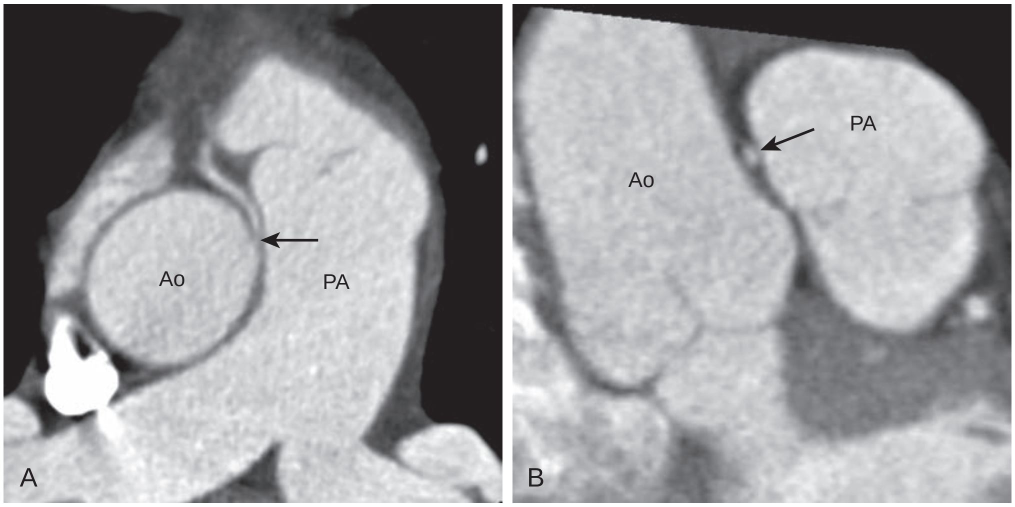

**Figure 77.7. CCTA of an intramural right coronary artery (RCA) arising from the left sinus of Valsalva in an 8-year-old girl.** (A) Short-axis view shows an interarterial RCA *(arrow)* arising from the aorta *(Ao)* in an acute angle. The proximal RCA tapers to a slitlike opening at the ostium. (B) Longitudinal view shows the RCA compressed *(arrow)* by the *Ao* and the pulmonary artery *(PA)*. The cross-section of the RCA is elliptical in shape.

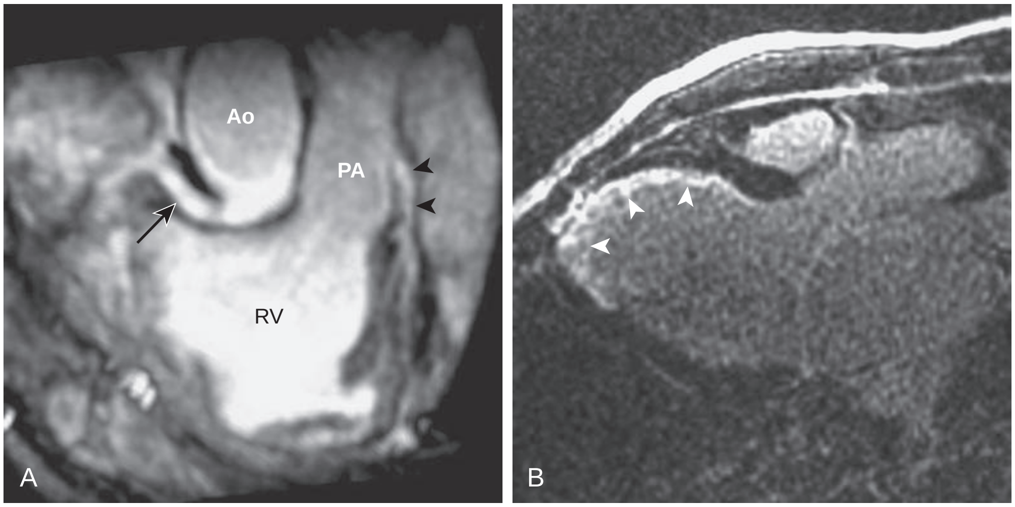

**Figure 77.8. CMRA of a 12-year-old boy with an anomalous left coronary artery from the pulmonary artery *(PA)*.** (A) Oblique image reformatted from a noncontrast coronary CMRA shows the right coronary artery *(arrow)* arising from the aorta *(Ao)* at the normal location and the left main coronary artery (LMCA) *(arrowheads)* originating from the *PA.* (B) Three-chamber view from a delayed-enhancement study shows endocardial infarction at the left ventricular anteroseptal wall and the apex *(arrowheads)* caused by inadequate myocardial perfusion from the LMCA. *RV,* Right ventricle.

ischemia. A bypass graft can be performed but has a very limited role due to concerns with competitive flow from the native coronary.

## Coronary Artery From Pulmonary Artery

***Overview.*** Origination of a coronary artery from a pulmonary artery includes anomalous origin of the LMCA, LAD artery, left circumflex (LCx) artery, or RCA from the pulmonary trunk or the branch pulmonary arteries. The most common type is the anomalous left coronary artery from the pulmonary artery (ALCAPA) (Fig. 77.8). The incidence is approximately 1 in 300,000 live births, accounting for 0.24% to 0.5% of congenital cardiac anomalies.[34] The clinical presentation depends on how much of the coronary flow to the left ventricle is compromised.

In the fetal circulation, ALCAPA does not cause significant abnormalities due to the relatively small difference between the pulmonary artery and aortic pressures and oxygen saturations. After birth, the pulmonary resistance decreases, the ductus arteriosus closes, and the pulmonary pressure and LMCA flow decrease. As the pulmonary resistance reaches its nadir, blood flows retrograde into the pulmonary artery causing coronary "steal." Retrograde flow from the RCA and collaterals supplies the left ventricle, but in the majority of patients (90%) there is inadequate collateralization to sustain myocardial viability. Myocardial ischemia, ventricular dilation, mitral regurgitation, and subsequent congestive heart failure and pulmonary edema develop around the sixth to eighth week of life, representing the infantile form of ALCAPA, also known as *Bland-White-Garland syndrome*. Without intervention, mortality can be as high as 90%.

Clinical symptoms are classically described as episodes of inconsolable crying and discomfort associated with feeding, which represent angina. In 10% of patients with ALCAPA, collateral flow from RCA to LMCA is large enough to sustain myocardial viability, and patients survive into adulthood with few or no significant clinical symptoms. As a result of the high shunt flow, the coronary arteries can be abnormally large. ALCAPA usually is an isolated lesion, but it can be associated with ventricular septal defect, atrioventricular canal, tetralogy of Fallot, truncus arteriosus, and aortic stenosis.

An anomalous right coronary artery from the pulmonary artery (ARCAPA) is four times less common than ALCAPA.[35] The clinical course of ARCAPA is more benign, with most patients being asymptomatic in the first 2 years of life and presenting with exertional chest pain later in adolescence or adulthood.

***Imaging.*** Chest radiographs for patients with the infantile form of ALCAPA usually show an enlarged cardiac silhouette and signs of pulmonary venous congestion or pulmonary edema. Echocardiography is the primary modality for diagnosis. The anomalous coronary connection and the reversed coronary flow by color Doppler imaging are usually well seen. In more complex cases, the connection between the anomalous coronary artery and the pulmonary artery can be seen readily with CCTA or CMRA.[36] Typically diagnostic catheter angiography is not necessary.

***Management.*** The definitive treatment is surgery. The most straightforward approach is to reimplant the anomalous coronary artery from the pulmonary artery to the aorta.[37] With ALCAPA, reimplantation of the LMCA can be difficult because the LMCA may be too short to reach the centrally located aorta. This problem can be solved with the Takeuchi operation,[38] in which an aortopulmonary window is created first. Then a baffled tunnel is created inside the pulmonary trunk to connect the aortopulmonary window to the ostium of the anomalous LMCA. Blood flows from the aorta, through the aortopulmonary window, into the baffled tunnel, and then into the anomalous LMCA ostium.

## Coronary Artery Fistula

***Overview.*** A coronary artery fistula is a common coronary abnormality seen in 0.3% to 0.8% of patients referred for cardiac catheterization.[39] It is an abnormal communication between a normal coronary artery and another cardiovascular structure. Although it usually is congenital, it can form after trauma or after a surgical procedure such as a myomectomy. Anatomically, a coronary fistula most frequently originates from the RCA system (55%), followed in frequency by the LMCA system (35%), both arteries (5%), and others (5%). A coronary fistula terminates in the right side of the heart far more often than in the left side of the heart. Recent echocardiography-based studies have shown the most common sites of termination are the pulmonary artery (58%–75%) (e-Fig. 77.9), followed by the right ventricle (11%–29%) (Fig. 77.10), the right atrium (6%–12%), left ventricle (6%), and left atrium (2%).[40,41] Coronary artery fistulae usually are isolated without associated cardiac anomalies. However, in pulmonary atresia with intact ventricular septum, coronary fistulae to the right ventricle are an integral part of the disease, with important consequences for treatment options. Coronary fistulae in pulmonary atresia with intact ventricular septum are discussed later in the context of complex congenital heart disease.

The clinical significance of a coronary artery fistula depends on the size of the fistulous communication, as well as its termination site. Most fistulae are small, and recent reports suggest a higher incidence of spontaneous closure than previously reported. Patients with small fistulae usually are asymptomatic and may have a continuous murmur. A large fistula can result in left heart volume overload, with resultant left ventricular dilation, coronary steal, and a risk of endocarditis, aneurysm formation, thrombosis, or rupture. Some studies have also noted significant coronary ectasia proximal to the fistula, with residual dilation and a risk of thrombosis even after closure.

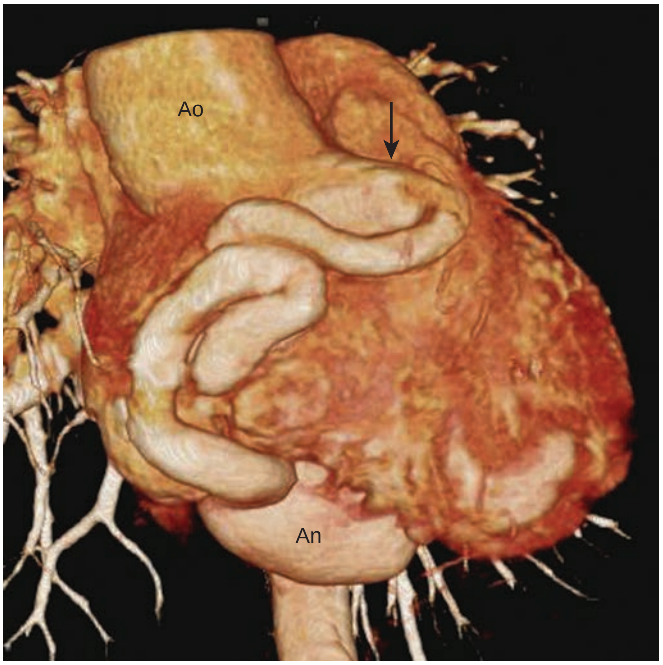

**Figure 77.10. Coronary fistula to the right ventricle.** Volume-rendered image from a CCTA of a 22-year-old woman shows a large and extremely tortuous right coronary artery arising *(arrow)* from the aorta *(Ao)*. At the inferior surface of the heart, this coronary fistula connects to a giant aneurysm *(An)*, which empties into the right ventricle *(not shown)*.

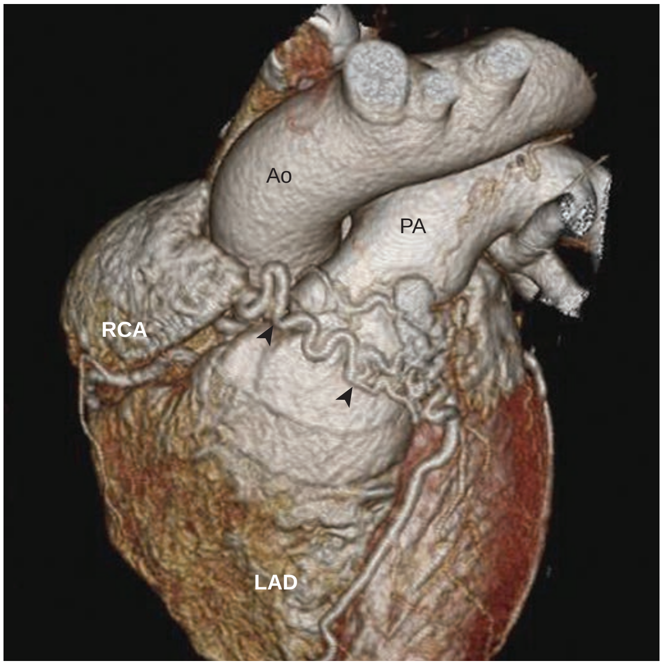
***Imaging.*** A small coronary artery fistula may be detected incidentally when a screening echocardiography is ordered for an unexplained murmur or for unrelated symptoms. If the fistula is large, the course and connections of the fistula, as well as aneurysmal or stenotic segments, should be defined with catheter angiography, CCTA, or CMRA. In addition, MRI can quantify the shunt flow, shunt ratio, and assess myocardial perfusion.

***Management.*** In patients with a small coronary artery fistula without a murmur and no evidence of coronary ectasia, there is no evidence of adverse clinical outcomes in childhood and adolescence. Some groups recommend continued follow up due to the unknown risk of endocarditis, coronary ectasia, aneurysm formation, and rupture. For patients with a small fistula and a murmur or those with a large fistula, closure is typically recommended to prevent myocardial ischemia, endocarditis, and aneurysm formation. Fistulae with favorable connections and shapes can be closed with catheter embolization. Otherwise, they can be closed with surgical ligation.[42,43] Aneurysmal segments should be surgically reduced to prevent rupture. There is some evidence of an increased risk of coronary stenosis and/or thrombosis after transcatheter fistula closure, and close monitoring with anticoagulation may be necessary.[44]

## Anomalous Coronary Artery in Structural Heart Disease

The prevalence of anomalous coronary arteries is much greater in the presence of underlying cardiac malformations, especially conotruncal anomalies, such as truncus arteriosus, transposition of the great arteries (TGA), tetralogy of Fallot (TOF), and pulmonary atresia with intact ventricular septum (PA/IVS). The origins and courses of the anomalous coronary arteries can affect important surgical decisions. The role of the imager is to map out the coronary



**e-Figure 77.9. Coronary fistulae to the pulmonary artery.** Volume-rendered image from a CCTA of a 30-year-old man shows multiple, small, tortuous coronary fistulae *(arrowheads)* arising from both the right coronary artery *(RCA)* and the left anterior descending *(LAD)* artery, feeding into the pulmonary artery *(PA)*. *Ao,* Aorta.

pattern in relationship to other cardiovascular structures to help a surgeon plan the surgical approach. Instead of describing all the possible coronary variations associated with cardiac malformations, the importance of certain coronary anomalies in the surgical repair of TOF, TGA, and PA/IVS will be explained.

## Tetralogy of Fallot

***Overview.*** TOF is the most common cyanotic congenital heart disease, accounting for up to 10% of all congenital heart defects (see Chapter 75). The majority of centers today perform a complete repair as a neonate for symptomatic patients, and semielectively between 3 and 12 months of age. The surgical repair has two components: a patch closure of the ventricular septal defect (VSD) through which the aorta is overriding, and a transannular patch augmentation of the RVOT and the pulmonary trunk. In 4% of patients with TOF, an anomalous LAD artery arises from the RCA and crosses anterior to the RVOT before entering the anterior interventricular septal groove (Fig. 77.11).[45] This LAD artery lies in the path of the transannular incision and can prevent adequate relief of RVOT obstruction. If it cannot be adequately mobilized, it may necessitate conduit placement.[46]

***Imaging.*** Diagnosis of TOF is made with TTE. Coronary branching pattern can usually be delineated by echocardiography in the neonatal period. In those with poor acoustic windows or inadequate delineation, CCTA or catheter angiography are performed.

## Transposition of the Great Arteries

***Overview.*** TGA accounts for 5% of all congenital heart defects (see Chapter 75). Most patients with TGA have normal ventricular positioning (D-looping), atrioventricular concordance, and ventriculoarterial discordance with the aorta anterior and to the right of the pulmonary trunk.

***Imaging and Treatment.*** The preferred surgical treatment for TGA is the arterial switch, or Jatene operation. This surgery is a definitive operation in which the aorta and the pulmonary trunk are surgically transposed, thereby returning the circulatory anatomy to a "normal" state. In this operation, the coronary arteries also must be reimplanted from the aortic sinuses to the pulmonary sinuses. In normal truncal anatomy, the left and right coronary arteries arise from the facing sinuses. This relationship usually is preserved even when the aorta and the pulmonary trunk are congenitally transposed. The close proximity of the coronary origins from both great arteries makes surgical translocation of the coronary arteries technically uncomplicated. However, frequent variations of coronary origins and course occur that make this operation difficult or even impossible (Fig. 77.12).[47] By mapping out the coronary anatomy, CCTA or CMRA can be very useful for surgical planning.[48]

After the arterial switch operation, the surgically manipulated coronary arteries are at risk for stenosis or even occlusion. In the past, patients who had this operation underwent regular catheter coronary angiography to assess this complication. Today, CCTA and CMRA are useful noninvasive alternatives, and catheter angiography is reserved for patients in whom signs and symptoms of myocardial ischemia develop.

## Pulmonary Atresia With Intact Ventricular Septum

***Overview.*** PA/IVS is believed to be caused by the in-utero obstruction of the pulmonary valve after the formation of the pulmonary infundibulum and the central pulmonary arteries (see Chapter 74). The reduced right ventricular flow prevents the normal growth of the right ventricle and the tricuspid valve, causing hypoplasia of both structures. Without an outlet, the right ventricular systolic pressure can rise above the left ventricular systolic

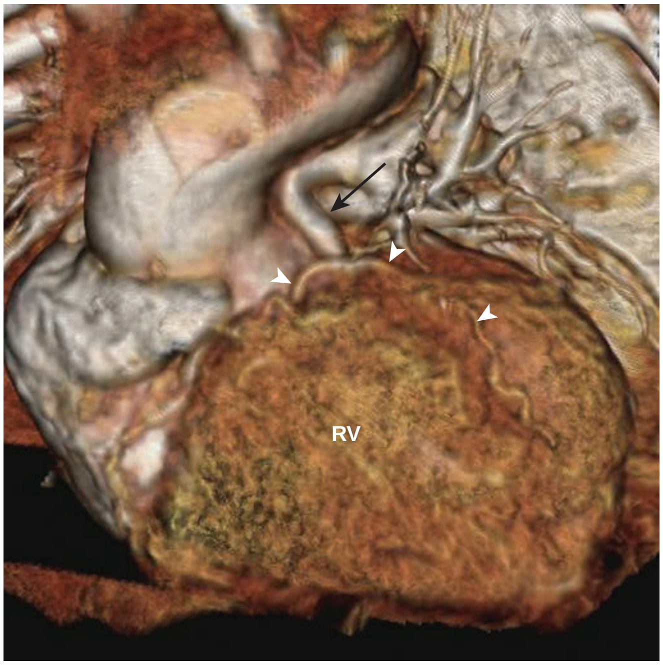


**Figure 77.11. Aberrant left anterior descending (LAD) artery in a child with tetralogy of Fallot.** Volume-rendered CCTA image from a 1-year-old boy viewed from the front shows an LAD artery *(arrowheads)* that travels in front of the stenotic pulmonary trunk *(black arrow)*. The position of this LAD artery may complicate the surgical repair. *RV,* Right ventricle.

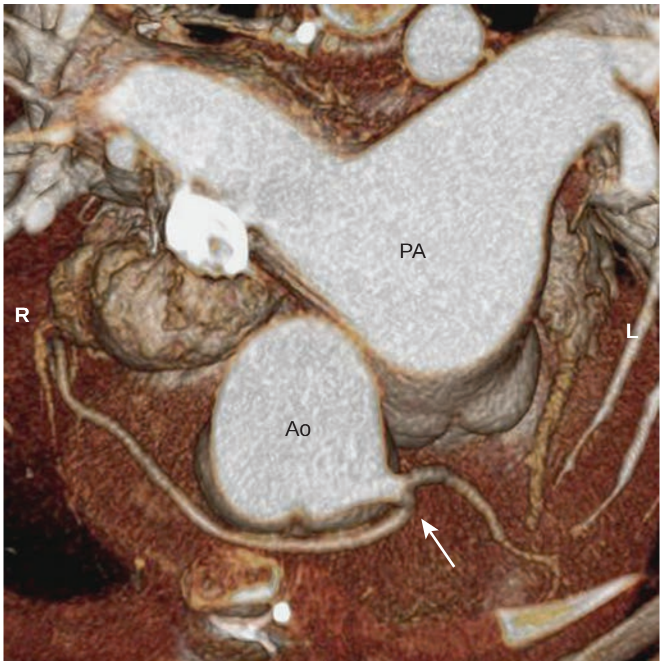

**Figure 77.12. Coronary artery arrangement in d-transposition of the great arteries (d-TGA).** Volume-rendered image from a CCTA of a 12-year-old girl shows an aorta *(Ao)* that is situated in front and to the right of the pulmonary artery *(PA)*, consistent with a d-TGA. A single coronary ostium is present *(arrow)*, and the right coronary artery courses in front of the *Ao.* This coronary pattern is not favorable for the arterial switch operation.

pressure and the coronary arterial pressure. This mechanism, in turn, disrupts the normal regression of embryologic communications between epicardial coronary arteries and the right ventricle, resulting in coronary fistulae between the two in 75% of the patients at birth. This can also result in areas of coronary stenosis and, in some cases, coronary ostial atresia. This is considered a “right ventricular-dependent coronary circulation.”[49]

After birth, the right ventricular pressure remains high and blood flows from the right ventricle into the coronary system. If there is a right ventricular dependent coronary circulation and the right ventricle is decompressed by surgically relieving the pulmonary obstruction, blood flow in the coronary fistulae abruptly reverses, leading to “coronary steal” and myocardial ischemia and infarction. Myocardial perfusion, then, depends on a pressurized right ventricle and precludes a biventricular repair. These patients undergo the staged Fontan palliation. In the absence of a right ventricular dependent coronary circulation, a biventricular repair can be considered.

***Imaging and Management.*** Catheter coronary angiography is the standard imaging study to detect PA/IVS-related coronary fistulae. Classic findings on coronary angiography include systolic retrograde filling of the RCA and the LAD artery during right ventriculography (Fig. 77.13) and end-diastolic filling of the right ventricle during coronary angiography. Due to the need for dynamic imaging, CCTA and CMRA are often not indicated in the initial management.

## Coronary Artery Hypoplasia

***Overview.*** Coronary artery hypoplasia (CAH) is a rare condition characterized by a diffusely narrowed, underdeveloped major coronary segment or branch.[50] The prevalence of CAH is estimated to be 0.03% based on adult coronary angiography, and it represents 6% of all coronary anomalies. Most reported cases involve the left coronary system (Fig. 77.14). The pathogenesis of this lesion is unknown, but an in-utero embolic event affecting a coronary artery may be a cause. The clinical significance of CAH also is unknown. In a few cases, it was related to sudden death, but other persons with this anomaly led normal lives, with the diagnosis being made at autopsy after they died from unrelated causes.

***Imaging and Management.*** CCTA can be used to visualize the threadlike epicardial coronary artery. However, catheter angiography is required to delineate all collateral vessels. The optimal treatment has not been determined, but in patients who have CAH along with documented arrhythmia or syncope, implantation of a defibrillator would be a prudent choice.

# ACQUIRED CORONARY ARTERY DISEASES

## Kawasaki Disease

KD, or mucocutaneous lymph node syndrome, was first described by Tomisaku Kawasaki in 1967. KD is the most common acquired coronary artery disease in children. It is an acute, febrile, multisystem vasculitis of unknown etiology that affects primarily children younger than 5 years of age, with a slight male predominance. Clinical features consist of prolonged high fever, conjunctivitis, red cracked lips, a red oral mucous membrane, a strawberry tongue, a multiform rash, cervical lymphadenopathy, and swollen hands and feet.[51] The clinical findings are self-limiting, but the main concern is the development of coronary aneurysms and thrombosis. Multiple studies have demonstrated the efficacy of treatment during the acute phase in preventing coronary artery abnormalities.

***Imaging.*** The most important complication of KD is the development of coronary artery aneurysms. Coronary artery aneurysms develop in 15% to 30% of patients who do not receive gamma globulin therapy, usually 1 to 4 weeks after disease onset. Thromboembolism of coronary artery aneurysms (Fig. 77.15) and coronary artery stenosis are the causes of myocardial ischemia,

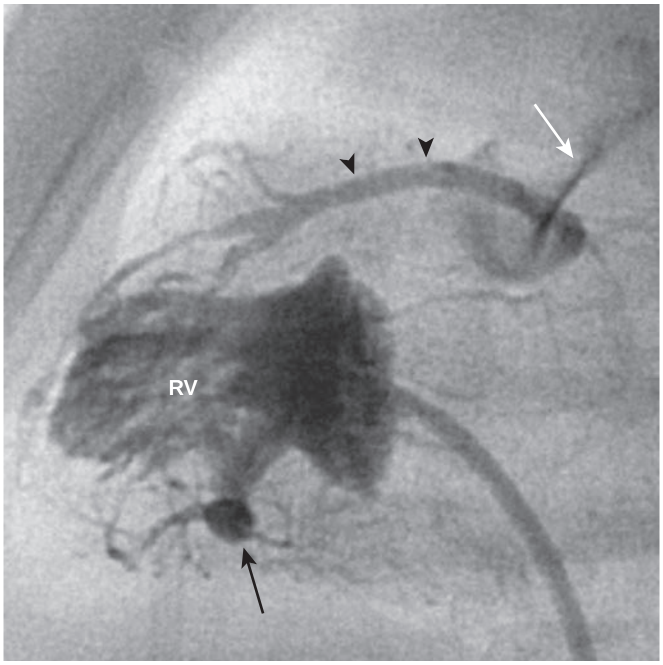

**Figure 77.13. Catheter angiography of the right ventricle of a 1-year-old boy with pulmonary atresia and an intact ventricular septum.** Contrast material injected into the right ventricle *(RV)* flows through the sinusoids *(black arrow)* into the coronary arterial system *(arrowheads)* and then flows retrograde out of the pulmonary artery *(white arrow)*. This coronary circulation is judged right-ventricular dependent.

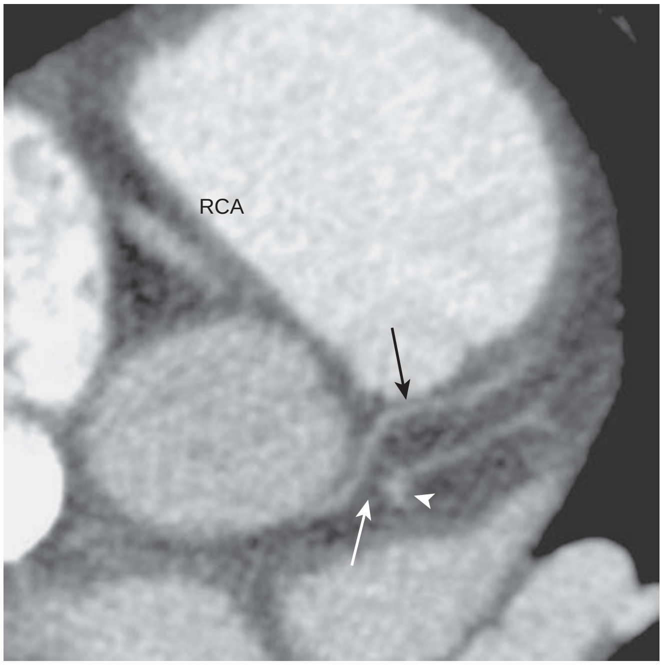

**Figure 77.14. Coronary artery hypoplasia in a 15-year-old girl with exertional angina.** Axial view from a CCTA shows diffusely small left coronary arteries compared with the right coronary artery *(RCA)*. The left circumflex artery *(arrowhead)* is occluded *(white arrow)* from the left main coronary artery *(black arrow)*.

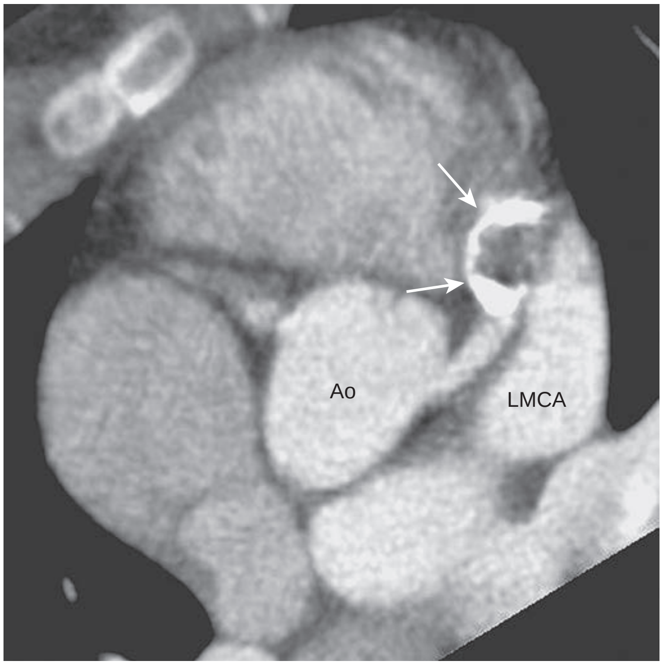

**Figure 77.15. Kawasaki disease.** Axial CCTA image shows chronic changes of Kawasaki disease, which include a calcified, thrombosed aneurysm *(arrows)* involving the left main coronary artery *(LMCA)*. *Ao,* Aorta.

infarction, heart failure, and sudden death in these patients. Expanding aneurysms may rupture. Echocardiography is the primary imaging tool in children with KD. In young children, echocardiography is quite effective in detecting coronary aneurysms. Giant aneurysms (>8 mm in diameter) are associated with increased risk of myocardial infarction and sudden death. However, the sensitivity and specificity of echocardiography for detection of thrombi is unclear. Assessment of thrombus in the infant and young child should be performed with CCTA. Although catheterization angiography can be performed, it has been associated with greater risk of adverse vascular events. Echocardiography is less effective in following older children and young adults with coronary aneurysms, and serial angiography is needed to monitor progression of aneurysms and the development of stenosis. Both CCTA and CMRA are useful noninvasive alternatives for this purpose.[52,53] In addition, CMRA is useful in the assessment of myocardial ischemia, infarction, and ventricular function.

## Trauma

***Overview.*** The most common cause of pediatric trauma is blunt trauma from motor vehicle accidents, although in urban areas, penetrating injuries from assaults and other violence occur not infrequently. Blunt injury to the coronary artery can cause an intimal tear, dissection, and acute thrombosis, leading to myocardial infarction and arrhythmia.[54,55] Both blunt and penetrating injury can cause rupture of the coronary arteries, resulting in hemorrhage, tamponade, and myocardial infarction. The infarcted or contused myocardium can become aneurysmal (e-Fig. 77.16), and if the injury to myocardium is extensive, heart failure can result. Over time, weakened or ruptured coronary vessel walls can form a pseudoaneurysm.

***Imaging and Management.*** The initial management of chest trauma focuses on more common lethal injuries such as airway compromise, pneumothorax, aortic rupture, and tamponade. Conventional non ECG-gated computed tomography angiography is routinely performed to evaluate for these findings. If signs of cardiac injury such as an abnormal ECG, hemodynamic instability, and elevated myocardial enzymes are found, echocardiography can be performed to evaluate ventricular function and pericardial effusion or blood. To assess for acute coronary injury, catheter angiography is the imaging modality of choice. Less acutely, CCTA or MRI can be used to assess structural damages in the heart, such as traumatic VSD and myocardial aneurysm. In addition, MRI is useful for the evaluation of myocardial infarction and ventricular functions.

Management of traumatic coronary artery injuries depends on the type of injury and the degree and extent of myocardial compromise. Imaging should assess for areas of dissection, intimal flap formation, and stenosis of the coronary artery, which can be treated with a stent to maintain coronary patency. Coronary aneurysms, traumatic coronary fistulae, and secondary cardiac abnormalities such as ventricular aneurysm, VSD, and injured valves require surgical repair.

## TREATMENT COMPLICATIONS INVOLVING CORONARY ARTERIES

Surgical manipulation of the coronary arteries always carries the risk of postsurgical stenosis or occlusion of the arteries. Indeed, this risk was a concern during the early surgical experience with the arterial switch operation. Other pediatric cardiac operations that affect the coronary arteries are reimplantation of an anomalous coronary artery, the Takeuchi operation for ALCAPA, surgical augmentation for supravalvular aortic stenosis, the aortic translocation or Nikaidoh procedure for TGA with a ventricular septal defect and severe pulmonary stenosis, composite valve-graft repair (the Bentall procedure) for a Marfan aortic aneurysm, and aortic valve replacement with an autologous pulmonary valve (the Ross procedure). Aneurysms of the coronary ostia after aortic root replacement can be seen in patients with connective tissue diseases, such as Marfan syndrome. Finally, radiation therapy that includes the aortic root in the radiation mantle causes accelerated atherosclerosis and stenoses of the proximal coronary arteries and the coronary ostia. Symptoms typically occur a decade or more after treatment.

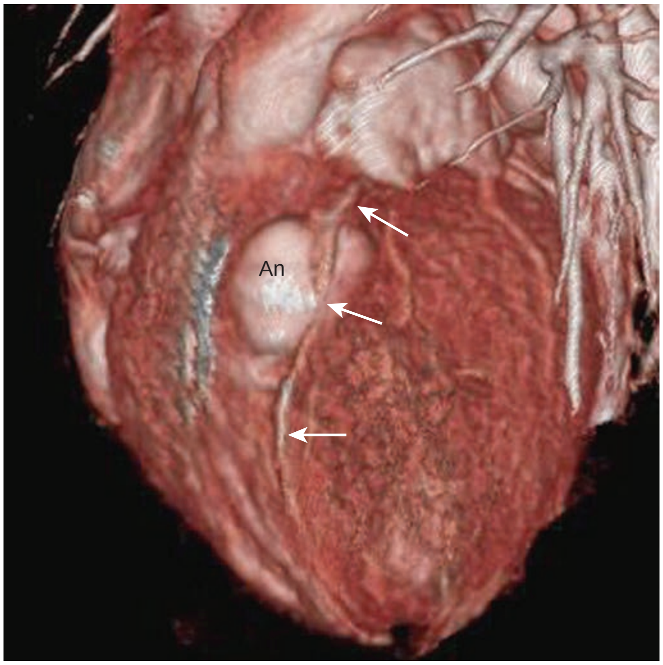
## METABOLIC DISEASES AFFECTING THE CORONARY ARTERY

### Familial Hypercholesterolemia

Familial hypercholesterolemia is an autosomal dominant disorder that causes a severe elevation in total cholesterol and low-density lipoprotein (LDL) levels. It is caused by mutations in the LDL receptor gene in chromosome 19. The prevalence of the heterozygous form of familial hypercholesterolemia is 1 in 500 people, and the prevalence of homozygous familial hypercholesterolemia is 1 in 1 million people.[56] Children with the heterozygous form usually are asymptomatic. Children with the rare but clinically much more severe homozygous form present with early atherosclerosis of the coronary arteries, leading to acute myocardial infarction and sudden death at as young as 1 to 2 years of age. These patients also experience peripheral vascular disease, cerebrovascular disease, aortic stenosis, cutaneous xanthomas, corneal arcus, and an LDL level of greater than 600 mg/dL. The role of imaging, except for echocardiography screening for aortic stenosis, has not been defined for this rare disease.

### Coronary Calcinosis

Although coronary calcification is rare in children, it can occur in children with chronic vasculitis, which is seen with KD, radiation, end-stage renal disease, and type I diabetes mellitus. Coronary calcification can be seen as part of idiopathic infantile arterial calcification, a very rare disease characterized by extensive



**e-Figure 77.16. Ventricular aneurysm *(An)* after blunt trauma to the chest of a 13-year-old boy after a motor vehicle accident.** An aneurysm developed at the anterior interventricular septum in close proximity to the left anterior descending artery *(arrows)*.

depositions of hydroxyapatite in the elastic layer of the large- and medium-sized muscular arteries, including the coronary arteries.[57] Coronary stenosis is caused by intimal proliferation, and patients with idiopathic infantile arterial calcification experience myocardial infarction in infancy. Similarly, renal artery stenosis causes hypertension, and carotid stenosis causes cerebral infarction. Patients rarely survive beyond infancy, and many die prenatally. Diagnosis is made by radiologic demonstration of diffuse arterial calcification, arterial biopsy, or prenatal ultrasound demonstrating dilated cardiac ventricles, hydrops fetalis, and hyperechogenic large vessels.

## KEY POINTS

- Patients usually are referred for coronary imaging with CT or MR for diagnosis of a coronary anomaly, confirmation and clarification of echocardiographic findings of coronary anomalies, mapping out the coronary arteries for surgical planning, and evaluation for a coronary aneurysm or stenosis.
- Evaluation of the following congenital heart diseases should include the coronary arteries: tetralogy of Fallot, preoperative; transposition of the great arteries; arterial switch procedure, postoperative; pulmonary atresia with intact ventricular septum; and Williams syndrome.

# Syndromes and Chromosomal Anomalies

*Beverley Newman, Alexander J. Towbin, and Frandics P. Chan*

A large number of syndromes, dysplasias, and chromosomal anomalies are associated with congenital or acquired cardiac and vascular disease. This chapter discusses the cardiovascular features of some of the more commonly encountered lesions. A more extensive list is provided in Tables 78.1 to 78.3 later in this chapter.

## SYNDROMES

### Situs and Cardiosplenic (Heterotaxy) Syndromes

***Overview.*** The heterotaxy syndromes, comprising right and left isomerism, feature abnormalities of visceral/atrial laterality. These syndromes have an estimated incidence of 1 in 6,000 to 1 in 20,000 live births and account for 1% to 3% of all congenital heart defects. Although heterotaxy usually occurs sporadically, familial cases have been described, particularly an X-linked form.[1] There is also an association between heterotaxy and gestational diabetes.

Body situs generally is divided into three types: solitus, inversus, and ambiguus. Situs solitus is the normal arrangement of the atria and viscera in the body (see Chapter 63). Situs inversus is the mirror image of normal; it is seen in 0.01% of the population and is associated with a slightly higher incidence of congenital heart disease (3%–5%) compared with the solitus population (0.6%–0.8%). Situs ambiguus, or heterotaxy, encompasses all other visceroatrial arrangements. By definition, in situs ambiguus, visceral malposition and dysmorphism associated with an indeterminate atrial arrangement is present.[2] Abnormal body situs occurs frequently in association with ciliary dyskinesia, as these entities are thought to be linked by underlying fetal cilial dysfunction.[3,4]

Heterotaxy syndrome with right isomerism or bilateral right-sidedness is usually, but not invariably, accompanied by asplenia.[5] The condition is more common in males and is characterized by bilateral systemic atria with broad trabeculated appendages (Fig. 78.1), bilateral trilobed lungs with bilateral minor fissures and short eparterial bronchi, a central horizontal liver, abnormal bowel rotation, and the stomach in an indeterminate position (see Fig. 78.1).[1,3,6] The abdominal aorta and inferior vena cava often are located on the same side of the spine, frequently in a posterior-anterior orientation. Other occasional anomalies include tracheoesophageal fistula, imperforate anus, absent gallbladder, pancreatic anomalies, fused adrenal glands, and genitourinary abnormalities.[3,4] The prognosis for right isomerism is often poor because of an abnormal immune status (asplenia) and the typically complex cardiac anomalies.

Cardiac anomalies are almost invariable and present with cyanosis and severe respiratory distress. The “right isomerism heart” often consists of a common atrioventricular canal, a single ventricle, a large ventricular septal defect (VSD), and a double-outlet right ventricle and/or transposition of the great vessels, along with pulmonary outflow obstruction or atresia and total anomalous pulmonary venous drainage (frequently obstructed) (see Fig. 78.1). The spectrum of cardiovascular anomalies also can include cardiac malposition (dextrocardia or mesocardia), tricuspid atresia, truncus arteriosus, right aortic arch, anomalous systemic venous return, and bilateral superior vena cavae.[5,6]

Heterotaxy syndrome with left isomerism or bilateral left-sidedness most often accompanies polysplenia. It is characterized by bilateral pulmonary atria with narrow finger-like appendages, bilateral bilobed lungs, bilateral long hyparterial bronchi, a centrally located liver, the stomach in an indeterminate position, abnormal bowel rotation, and multiclefted or multiple spleens (either right sided or left sided) (Fig. 78.2).[2,6] An interrupted inferior vena cava with azygos continuation is the most consistent abdominal finding in left isomerism (see Fig. 78.2). Left isomerism is slightly more common in females and generally has a better prognosis than right isomerism with less complex cardiovascular disease. Other associated anomalies include ciliary dyskinesia, biliary atresia, pancreatic and other gastrointestinal abnormalities, and congenital portosystemic shunts (see Fig. 78.2).[1,4,5,7]

Cardiac anomalies are seen in more than 50% of patients who have heterotaxy syndrome with left isomerism. The common cardiovascular anomalies include abnormalities of the inferior and superior vena cavae, cardiac malposition, atrial septal defect (ASD), VSD, common atrioventricular canal, double-outlet right ventricle, and anomalous pulmonary venous return (usually partial).[3,4]

***Imaging.*** Eight major structures are appraised to evaluate situs in heterotaxy syndromes[2]:

- Atrial morphology
- Cardiac apex
- Aortic position
- Stomach and bowel position
- Liver and gallbladder position
- Spleen location and morphology
- Abdominal venous drainage
- Bronchial and pulmonary anatomy

Decreased pulmonary vascularity related to pulmonary outflow obstruction or pulmonary edema as a result of pulmonary venous obstruction is the most typical pattern seen on chest radiographs in persons with right isomerism. Cardiomegaly and increased vascularity on chest radiographs as a result of left-to-right shunting is the most common appearance in persons with left isomerism (see Fig. 78.2). Other chest radiographic features of the heterotaxy syndromes are related to duplicated structures, such as fissures and bronchi, as well as abnormal cardiac and visceral situs.

Echocardiography is the main imaging modality used to evaluate disordered intracardiac anatomy associated with heterotaxy. Both magnetic resonance imaging (MRI) and computed tomography (CT) have a role in fully defining this often complex anatomy. MRI, magnetic resonance angiography (MRA), and functional MRI assessment have partially replaced catheter-based angiography in evaluating these anomalies, especially the extracardiac vascular, airway, and visceral abnormalities (see Figs. 78.1 and 78.2).[2]

Ultrasound is often the first step in evaluating the abdominal anatomy. An upper gastrointestinal study should be performed to evaluate for malrotation. A small bowel follow-through in conjunction with the upper gastrointestinal study may be helpful to determine the relative locations of the small and large bowel and to separate nonrotation from malrotation.[3]

Ultrasound, CT, MRI, or liver-spleen scans using technetium-99m sulfur colloid or p-isopropylacetanilidoimidodiacetic acid are used to evaluate the presence and location of splenic tissue, to assess other organs/anomalies, and to help diagnose biliary atresia (associated with polysplenia). Multimodality imaging may be needed to elucidate other less common anomalies associated with heterotaxy such as a congenital portosystemic shunt and a hypoplastic or

## Abstract:

This chapter highlights the cardiovascular lesions and complications associated with a broad spectrum of syndromes and chromosomal anomalies. More common or important entities are described in the text with a more comprehensive list in tabular form. Imaging features are emphasized and illustrated. Lesions covered include: heterotaxy syndromes, inherited connective tissue disorders, neurocutaneous syndromes and chromosome anomalies.

## Keywords:

cardiac
vasculopathy
syndrome
chromosome anomaly

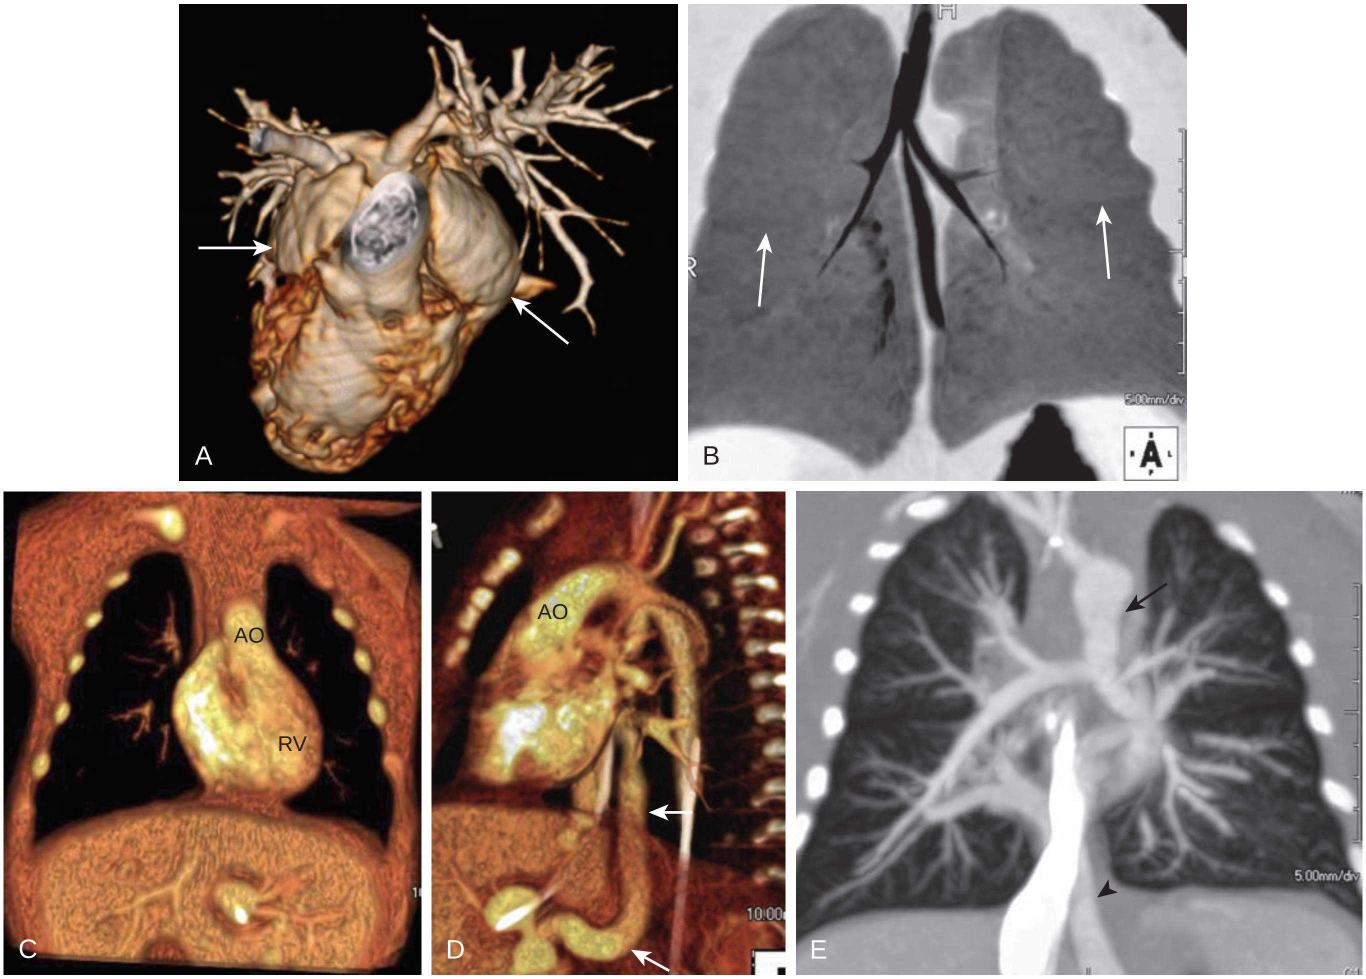

**Figure 78.1. Heterotaxy and right isomerism.** (A) Volumetric left anterior oblique, 3D CTA in a 3-year-old girl demonstrates bilateral symmetric broad atrial appendages *(arrows)* consistent with right atrial morphology. Note also the anteriorly transposed ascending aorta. (B–E) A newborn infant with complex congenital heart disease and heterotaxy with right isomerism. (B) Coronal CT minimum intensity projection reconstruction demonstrates symmetric short main-stem bronchi consistent with bilateral right-sided bronchial branching. Bilateral minor fissures also are visible *(arrows).* (C) Coronal volumetric reconstruction demonstrates a horizontal liver with no spleen. The patient has complex congenital heart disease consisting of an atrioventricular septal defect (not shown), L-transposition and pulmonary atresia, and total anomalous pulmonary venous return. On this image the left-sided ascending aorta *(AO)* is seen arising from the left-sided morphologic right ventricle *(RV).* (D) Sagittal volumetric reconstruction demonstrates the anteriorly positioned transposed ascending aorta *(AO),* absent pulmonary artery, and an anomalously draining confluence of pulmonary veins *(arrows)* extending below the diaphragm to the portal vein. (E) Coronal maximum intensity projection demonstrates a large patent ductus arteriosus *(arrow)* as the sole source of flow to the branch pulmonary arteries (the main pulmonary artery is absent). The anomalous inferiorly draining pulmonary veins *(arrowhead)* also are seen, partially obscured by dense contrast in the inferior vena cava.

absent portal vein (Abernethy malformation) with consequent hyperammonemic encephalopathy or hepatopulmonary syndrome (associated with left isomerism; see Fig. 78.2).[4,7]

## Inherited Connective Tissue Disorders

### Ehlers–Danlos Syndrome

***Overview.*** Ehlers–Danlos syndrome (EDS) is an inherited group of connective tissue disorders affecting the skin, ligaments, joints, vasculature, and visceral organs. It is characterized by joint and skin hyperextensibility, excessive bruisability, blood vessel fragility, and poor wound healing.[8] It occurs in as many as 1 in 5,000 individuals. Although EDS is incompletely understood, multiple distinct varieties of EDS have been recognized based on genetics, biochemical structure, and clinical presentation.[8,9] The vascular or arterial ecchymotic type of EDS is the most clinically severe form. Mitral valve prolapse (MVP) is the most common cardiovascular anomaly; others include a dilated aortic root, aneurysm, and aortic dissection or rupture (Fig. 78.3). Papillary muscle dysfunction or rupture and left ventricular rupture also can occur.[8]

EDS is an autosomal dominant disorder caused by heterozygous mutations in the *COL3A1* gene encoding type III collagen. More than 250 *COL3A1* mutations have been identified.[8] Patients are subject to spontaneous rupture of the bowel and other viscera. Vascular complications can occur either spontaneously or after minor trauma and include arteriovenous fistulas and aneurysms of the aorta and medium-sized arteries, with degeneration and subsequent rupture or dissection (see Fig. 78.3). The thoracic and abdominal arteries are involved in half of the cases, with extremity and head and neck vessels each contributing 25%. Neurovascular complications include carotid-cavernous fistula formation, carotid dissection, aneurysm formation, and rupture.[8-10]

***Imaging, Treatment, and Follow-up.*** Echocardiography is the mainstay for evaluation of the heart and valvular function. Ultrasound, CT, and MRI are geared toward defining areas of aneurysm, dissection, and rupture. The size and the rate of growth of each aneurysm should be quantified. Because the neurovascular system may be involved, imaging of the cerebral circulation and the carotid arteries may be necessary.

The pattern of aneurysm distribution in persons with EDS differs from that in persons with Marfan syndrome. Whereas Marfan syndrome typically results in dilation of the aortic root and the sinuses of Valsalva, EDS produces discrete, fusiform aneurysms at different locations of the aorta, the iliac arteries, the cervical arteries, and their branches. Dissection in persons with EDS often has a complex morphology (see Fig. 78.3). The abnormal vessels usually are well characterized by noninvasive computed

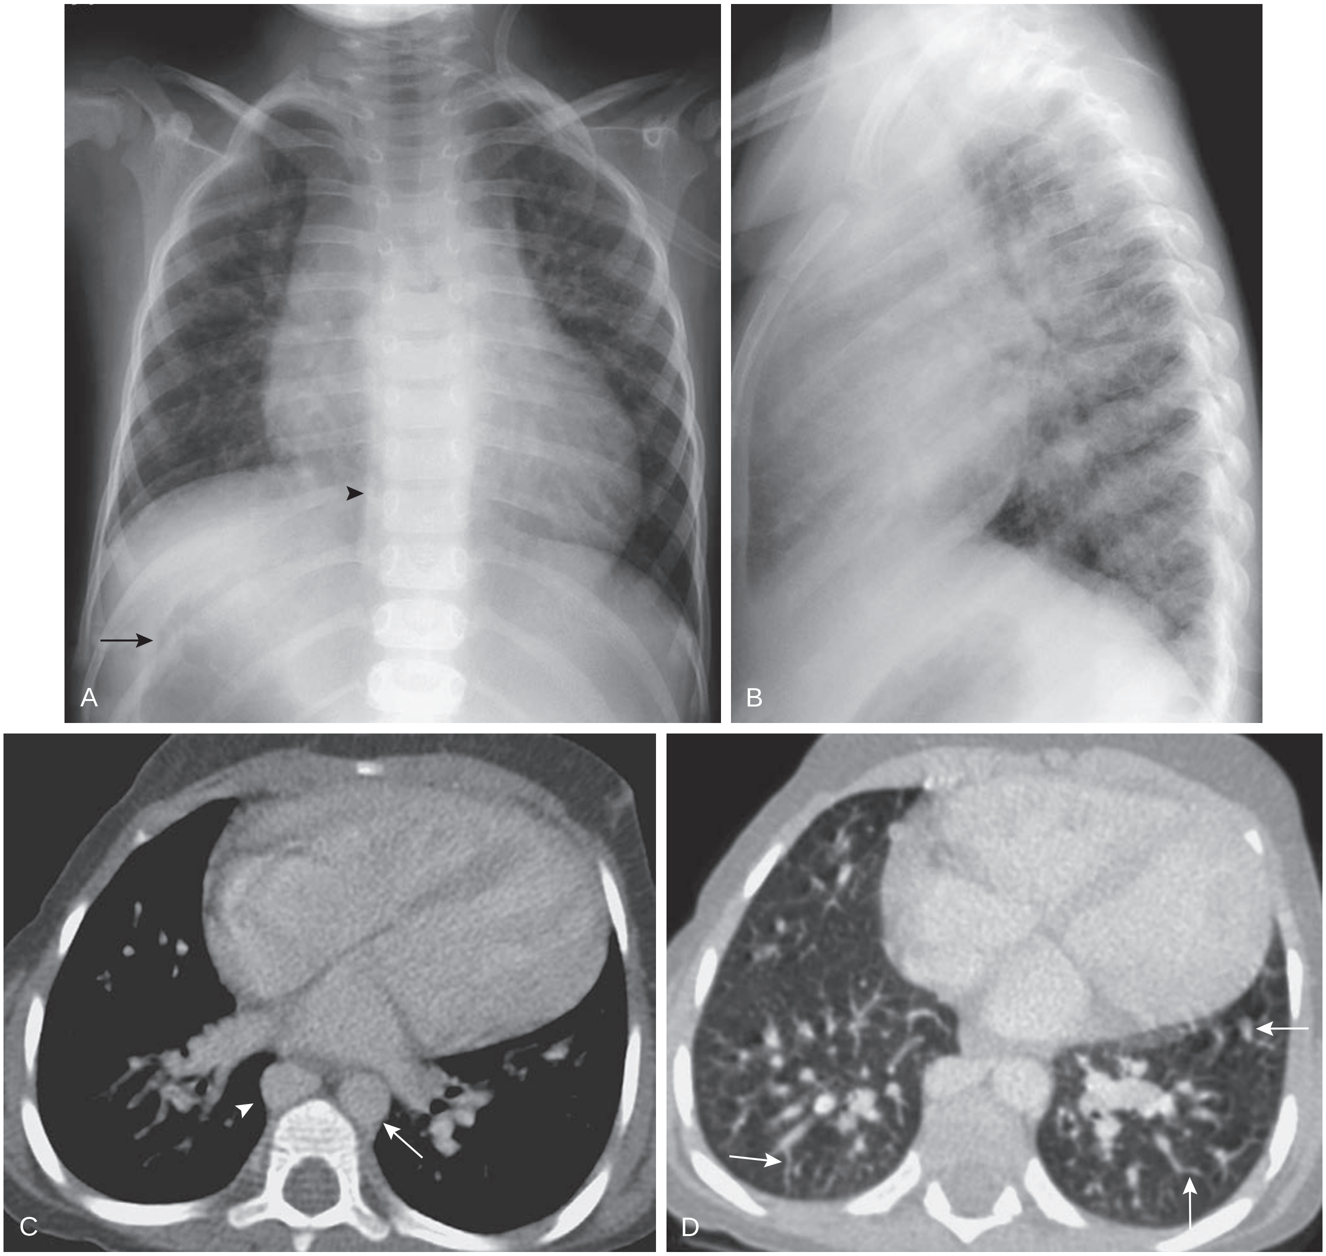

**Figure 78.2. Heterotaxy and left isomerism.** This 3-year-old girl, infant of a diabetic mother, has polysplenia and Abernethy malformation with hepatopulmonary syndrome. (A) Posteroanterior radiograph of the chest shows heterotaxy with a left-sided cardiac apex, right-sided stomach *(arrow),* and left-sided liver. Cardiomegaly and increased pulmonary vascularity (a small atrial septal defect and pulmonary arteriovenous shunting) are present. It is difficult to see the bilateral left-sided bronchi. A prominent right paraspinal line is present as a result of an enlarged azygos vein *(arrowhead).* (B) Lateral view of the chest is notable for the absence of the inferior vena cava shadow. (C) Contrast-enhanced CT of the chest shows cardiomegaly, a left-sided aorta *(arrow),* prominent pulmonary veins, and an enlarged azygos vein *(arrowhead).* (D) A contrast-enhanced CT scan of the chest displayed in the lung window shows the presence of multiple dilated peripheral pulmonary vessels *(arrows).*

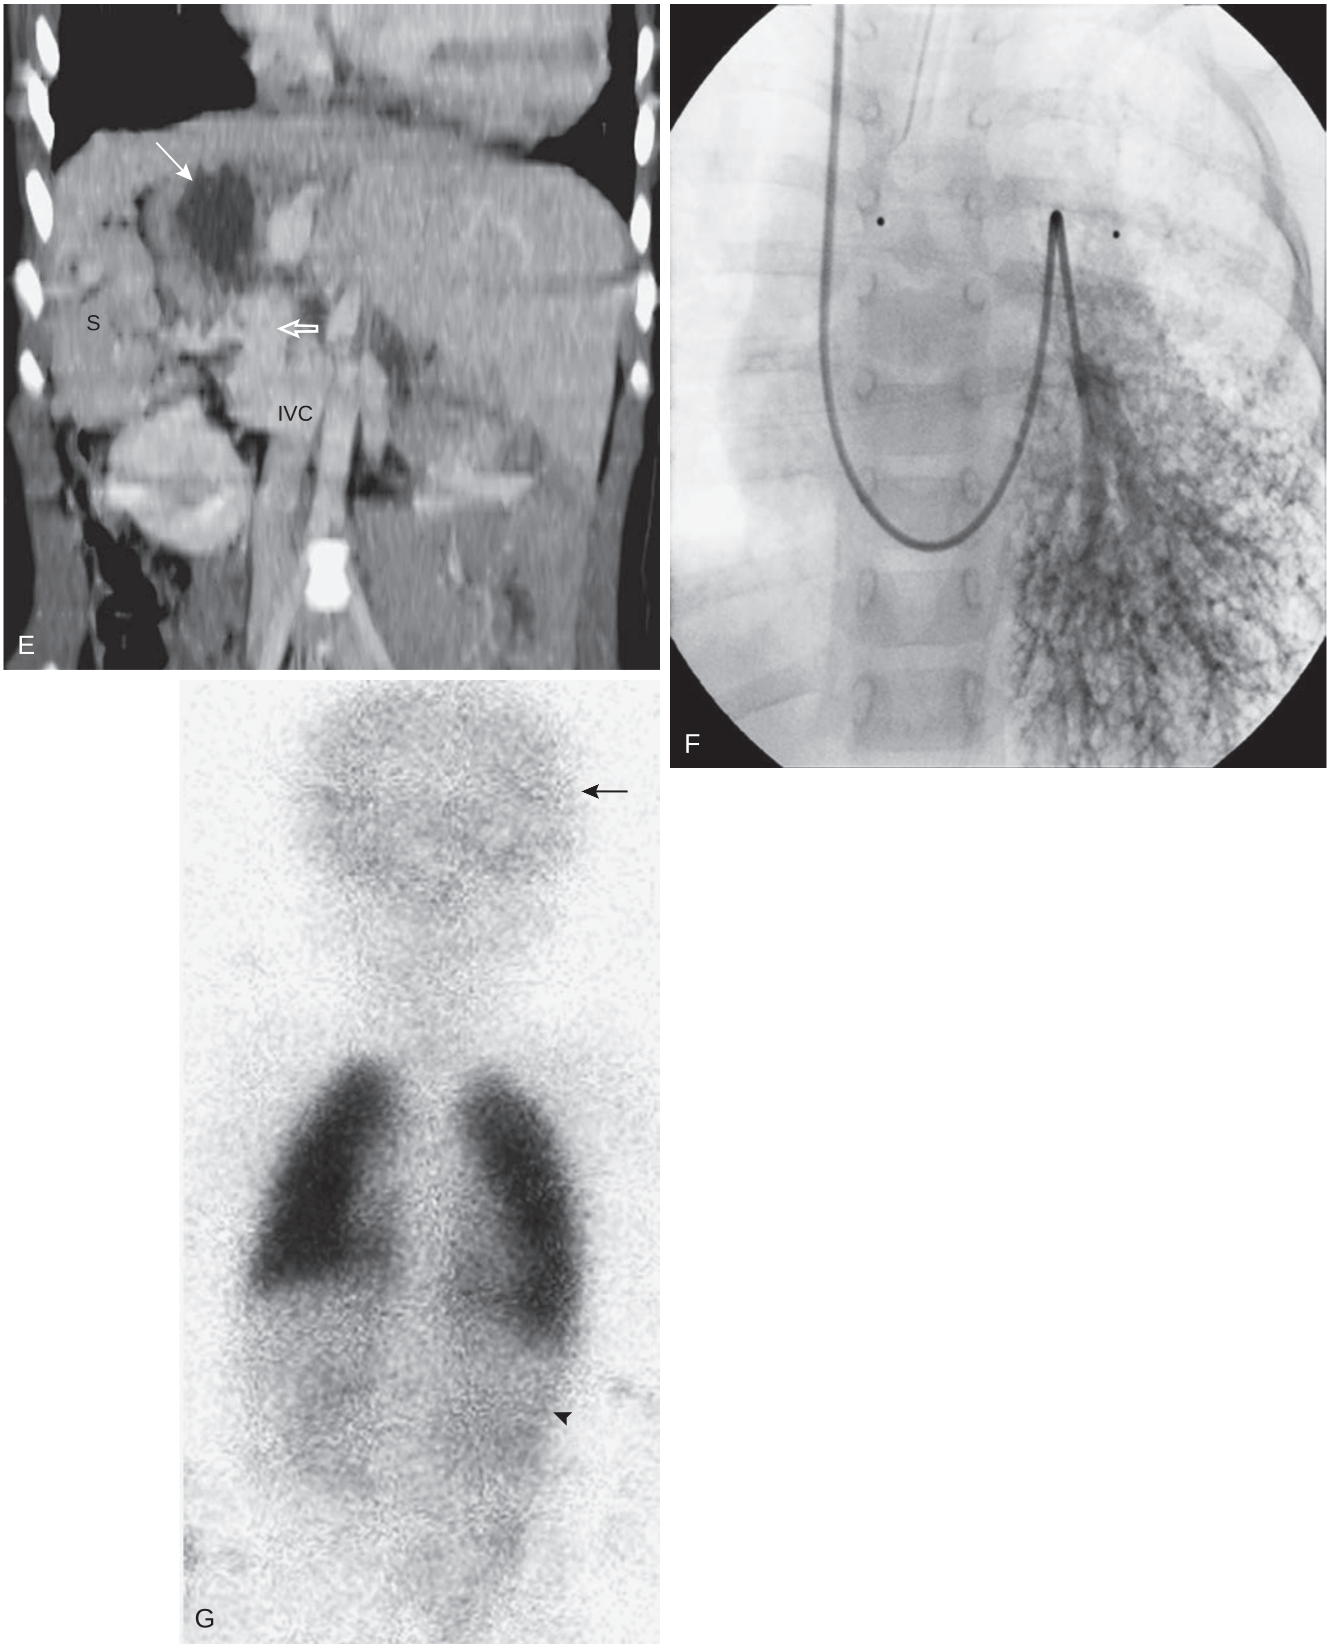

**Figure 78.2, cont'd** (E) Coronal reconstruction from a contrast-enhanced CT scan of the upper abdomen shows right-sided polysplenia *(S),* a right-sided stomach *(white arrow),* and a left-sided liver. A large right-sided portosystemic shunt (splenic vein to renal vein) is present *(open arrow).* Superiorly, there is interruption of the inferior vena cava *(IVC)* with azygos continuation (not shown). (F) Left pulmonary artery angiogram from a right jugular approach shows dilated peripheral pulmonary arteries and microarteriovenous connections, consistent with hepatopulmonary syndrome as a result of the congenital portosystemic shunt. This child does not have liver disease, and the intrahepatic portal veins are present but small (Abernethy malformation type II). (G) Perfusion portion of a ventilation-perfusion scan using technetium-99m macroaggregated albumin performed after closure of the patient's atrial septal defect shows normal perfusion of the lungs. There is abnormal radiotracer uptake within the brain *(arrow)* and kidneys *(arrowhead).* The percentage of systemic tracer uptake was calculated at 44.7%. These findings are typical of a right-to-left arteriovenous shunt and confirm the presence of hepatopulmonary syndrome.

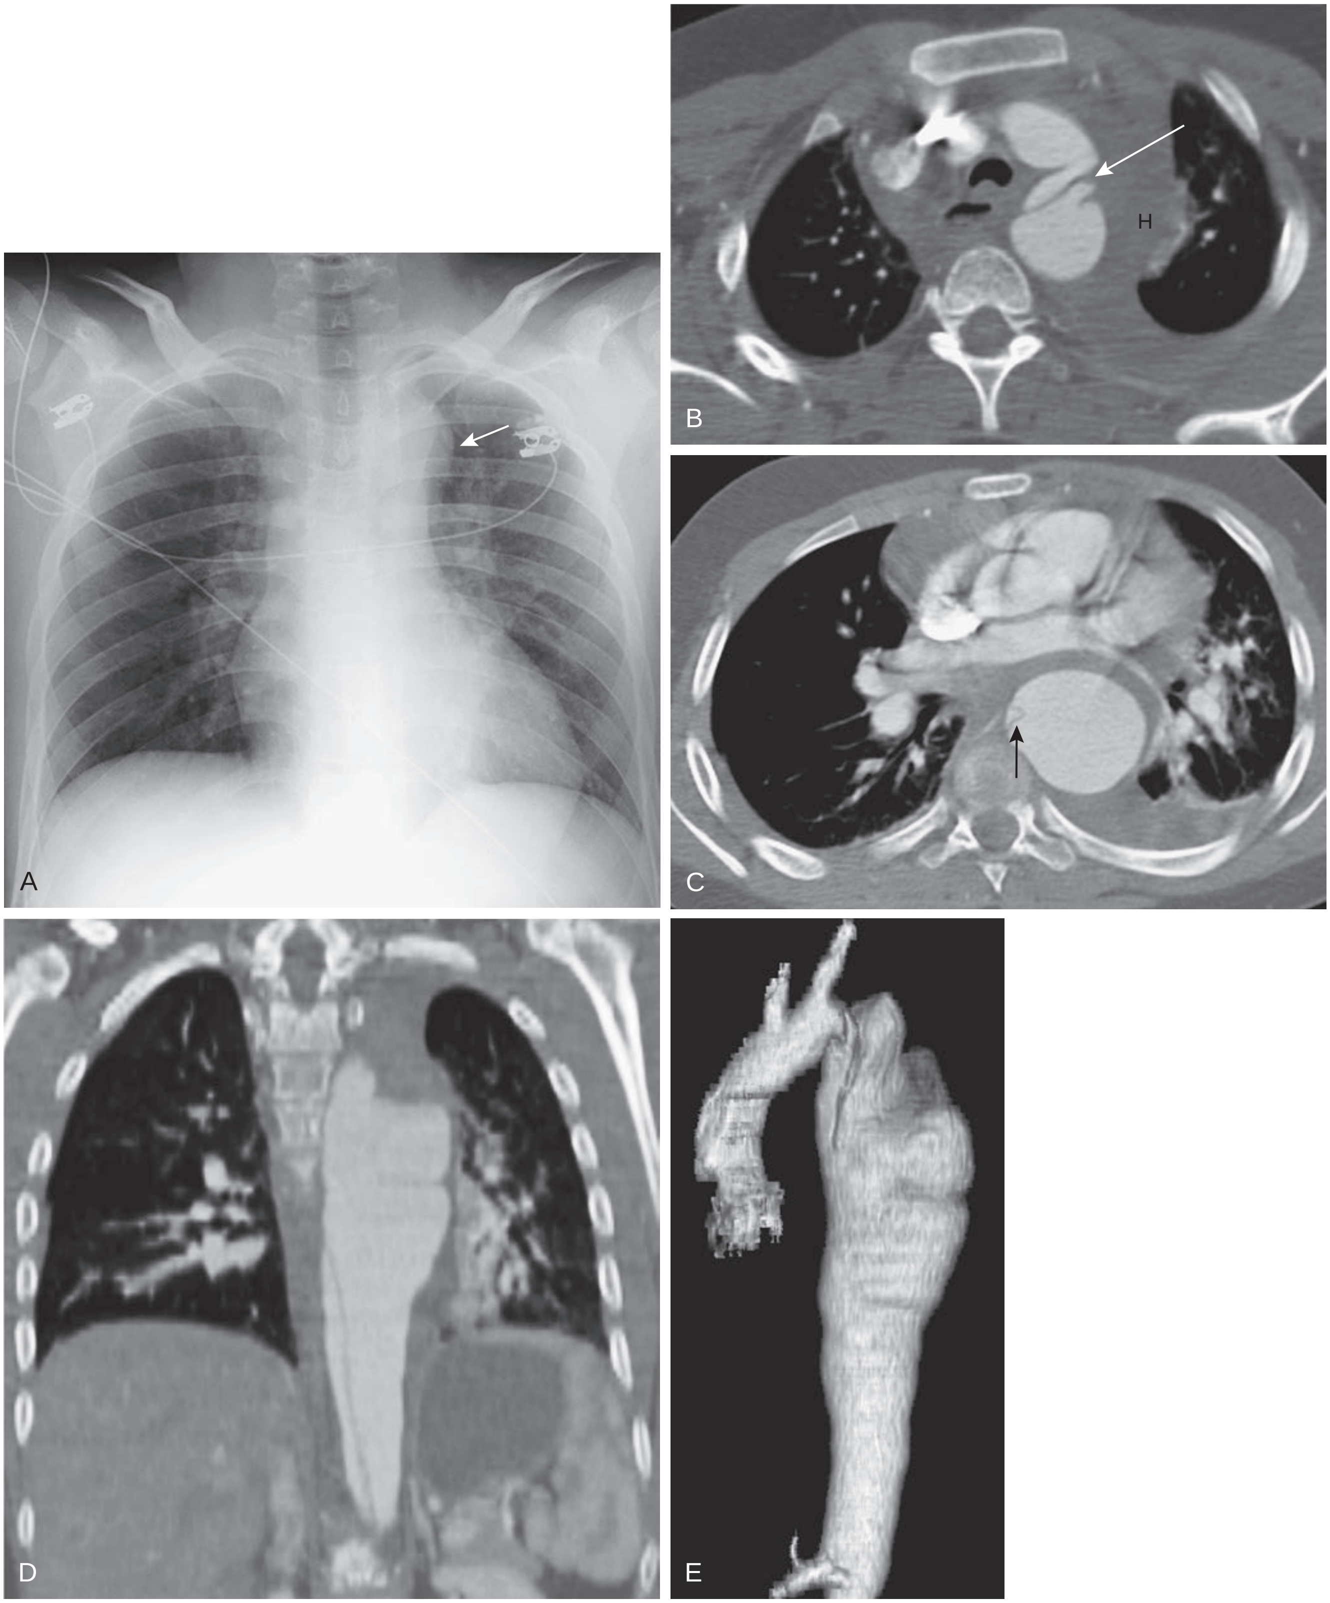

**Figure 78.3. Ehlers–Danlos syndrome.** This 14-year-old boy presented to the emergency department with chest pain and a family history of dissecting aortic aneurysm. (A) Posteroanterior radiograph of the chest shows a widened mediastinum and prominent aortic knob *(arrow).* (B) CTA of the upper chest shows an intimal flap within the aortic arch *(arrow),* representing a dissection. Other findings include a mediastinal hematoma *(H)* and a left-sided pleural effusion. (C) CTA of the chest at the level of the descending aorta shows a dilated descending aorta with a small intimal flap *(arrow),* a moderate amount of periaortic hematoma, and a small left pleural effusion. Coronal reconstruction (D) and three-dimensional reconstruction from the CTA (E) show a dissecting aortic aneurysm and an irregular severely dilated aorta.

tomography angiography (CTA) and MRA.[9,10] Catheter-based angiography carries significant hazards in these patients, with a reported complication rate of 67%.[10] Because of the fragility of the vascular wall, elective surgery is generally discouraged with conservative management favored.[8,10] Treatment with the beta-blocker celiprolol has been shown to reduce the risk of vascular events in patients with EDS.[8]

### Marfan Syndrome

***Overview.*** Marfan syndrome is an autosomal dominant disorder of connective tissue caused by mutations in the *FBN1* gene that codes for the extracellular matrix protein fibrillin-1.[11,12] Marfan syndrome is present in 1 in 3,000 to 1 in 5,000 persons and is associated with skeletal, ocular, and cardiovascular manifestations.[12] The diagnosis of Marfan syndrome is based on clinical criteria—the 2011 revised Ghent nosology.[13]

Common cardiovascular features of Marfan syndrome include mitral valve prolapse (MVP), mitral regurgitation, aortic regurgitation, aortic root dilation, and ascending aortic aneurysm (Fig. 78.4). Aortic dissection and aortic rupture are life-threatening complications.

MVP affects 35% to 100% of patients with Marfan syndrome and is more common in women and children.[14] More than 80% of children with Marfan syndrome have aortic root dilation, MVP, or both before age 18 years; aneurysms can be present even in young children.[14] Symptoms of heart failure, usually related to valvular insufficiency, can develop in childhood or young adulthood.

***Imaging.*** On chest radiographs, a pectus deformity, kyphoscoliosis, and occasionally cystic lung disease may be present in addition to cardiomegaly and a dilated ascending aorta (see Fig. 78.4). Both MRI and transthoracic echocardiography are used for initial evaluation of the heart and aorta. Both have the advantage of being relatively noninvasive without exposing the patient to ionizing radiation. In Marfan syndrome, the dilated aorta/aneurysm typically is pear shaped because the most marked area of dilation is at the level of the sinuses of Valsalva (see Fig. 78.4).

Long-term surveillance of the aortic root is performed via MRA or CTA, which have the advantage of providing a global view of the entire aorta. Reformatted and three-dimensional techniques provide excellent visualization of the anatomy and accurate long-term measurements (see Fig. 78.4).[15]

***Treatment and Follow-up.*** Measurement of the aortic root and assessment of aortic regurgitation are diagnostic criteria for Marfan syndrome. Affected individuals require long-term follow-up to identify progressive aortic root dilation and the appropriate timing for surgical intervention. In older children and adolescents, the incidence of complications such as dissection or rupture increases once the aortic root is larger than 5 cm in diameter.[14,15] Cystic medial necrosis is the underlying pathologic abnormality of the aortic wall. A composite aortic valve graft replacement or aortic graft with a surgically resuspended native aortic valve are the most common surgical procedures. The latter has the advantage of avoiding the need for anticoagulation.

It is now recognized that fibrillin-1 is involved in regulating transforming growth factor–β (TGF-β), a cytokine pathway that affects cell performance; its increased activity is thought to cause many of the manifestations of Marfan syndrome. Several other TGF-β signalopathy vascular syndromes have been identified, including Loeys–Dietz syndrome and related disorders and autosomal recessive cutis laxa.[16] Therapy using TGF-β antagonists (angiotensin receptor blockers) appears to offer promise.[11,15-17]

### Loeys–Dietz Syndrome

***Overview.*** Loeys–Dietz syndrome (LDS) is a rare connective tissue disorder associated with the dysregulation of TGF-β caused by mutations in the TGF-β receptor gene.[18] Recently, mutations in the genes coding for the ligand TGFB2 and the first downstream effector SMAD3 were also associated with an LDS-like presentation.[17] LDS is divided into two types. Type 1 patients have both craniofacial anomalies (e.g., bifid uvula, cleft palate, hypertelorism, craniosynostosis, and cervical spine instability) and widespread vascular anomalies. Type 2 patients generally have less severe manifestations; they may have a bifid uvula but usually do not have other craniofacial anomalies.[18,19]

Vascular manifestations of LDS include elongated and tortuous large arteries, aneurysm formation, and stenoses (Fig. 78.5 and Videos 78.1 and 78.2).[20] Abnormalities may be manifested in infancy. Dissection and aneurysm rupture occur commonly in persons with LDS at an earlier age and are associated with smaller-sized aneurysms than are typical for persons with Marfan syndrome.[16,18,19] Although spontaneous visceral perforation may occur in patients with LDS (similar to patients with the vascular form of EDS), both the vascular and visceral lesions tend to do well with surgical intervention (unlike in patients with EDS).[19]

## Neurocutaneous Syndromes

Neurocutaneous diseases affecting the cardiovascular system in children include neurofibromatosis type 1, tuberous sclerosis complex, and PHACES syndrome. Although not typically included in the neurocutaneous diseases, Noonan syndrome will be grouped here because of its genetic and phenotypic overlap with neurofibromatosis type 1.

### Neurofibromatosis Type 1

***Overview.*** Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder with variable multisystem involvement. The incidence is 1 in 3,500 newborns; about 50% of cases are nonfamilial.[21] The classic clinical presentation of NF1 includes café-au-lait spots, axillary freckling, dermal and plexiform neurofibromas, and learning disabilities.

NF1 is associated with a broad spectrum of heterozygous germline mutations in the NF1 gene encoding a protein called neurofibrin.[21] This is a negative regulator of the retrovirus associated DNA sequence (RAS) proto-oncogene pathway; loss of function can produce disturbances in cell development and migration and increased cellular proliferation.[21,22] RASopathies are a group of germline mutation conditions that affect the RAS/mitogen activated protein kinase (MAPK) pathway that controls cellular differentiation, migration, proliferation, and apoptosis.[23] In addition to NF1, RASopathies include Noonan, LEOPARD, Costello, and cardiofaciocutaneous syndromes.[23] These all have distinct phenotypic features with some overlap that includes craniofacial, cutaneous, and cardiovascular lesions and an increased propensity for malignant tumors.[23]

Congenital heart defects are present in 2% to 4.3% of persons with NF1. Pulmonic stenosis is the most common abnormality. Other lesions include tetralogy of Fallot (TOF), aortic stenosis, aortic coarctation, ASD, VSD, patent ductus arteriosus (PDA), MVP, and occasionally hypertrophic cardiomyopathy.[24-26] Neurofibromas can develop within the heart and obstruct blood flow by compression or invasion, or erode a vessel and cause hemorrhage.

Vascular manifestations include stenosis, aneurysms, fistulas, arteriovenous malformations, and spontaneous rupture of systemic arteries and veins (Fig. 78.6). Cerebrovascular disease is of particular concern, including stenosis, aneurysms, and moyamoya. Hypertension with or without renovascular stenosis is also common. Another vascular manifestation known as middle aortic syndrome is caused by the narrowing of the distal thoracic or abdominal aorta, leading to renal vascular hypertension and ischemia of the visceral organs and lower extremities (see Fig. 78.6).[26]

***Imaging and Treatment.*** In addition to cardiovascular findings, chest imaging in persons with NF1 can show rib deformities

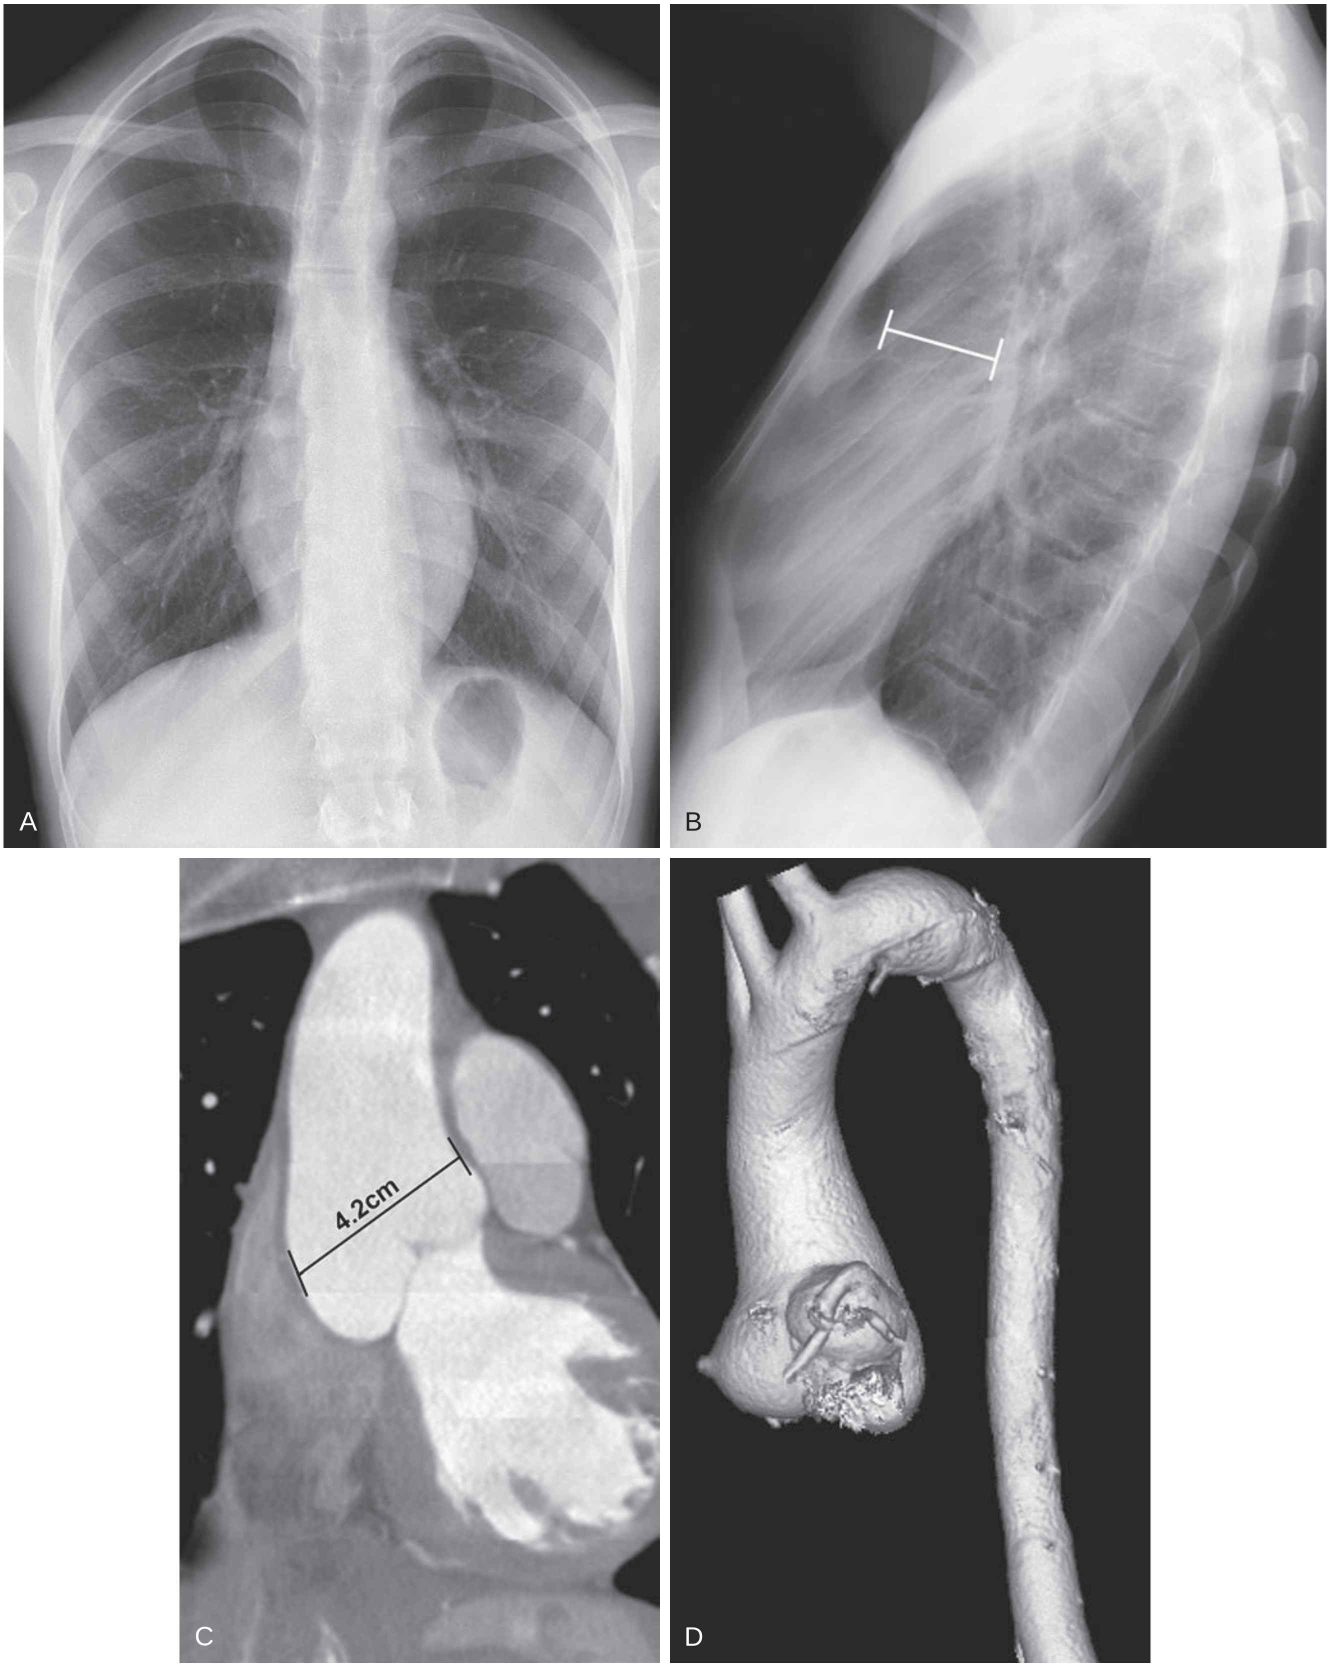

**Figure 78.4. Marfan syndrome in an 18-year-old boy.** (A) Posteroanterior chest radiograph demonstrates a marfanoid appearance, with an elongated chest and little subcutaneous tissue. The anterior ribs are vertically oriented, suggesting a pectus deformity. (B) Lateral view of the chest confirms the pectus excavatum and shows a dilated ascending aorta *(line)*. Coronal reconstruction (C) and oblique sagittal three-dimensional reconstruction (D) from CTA of the chest demonstrate the dilated aortic root, which is largest at the level of the sinuses of Valsalva (measurement in C).

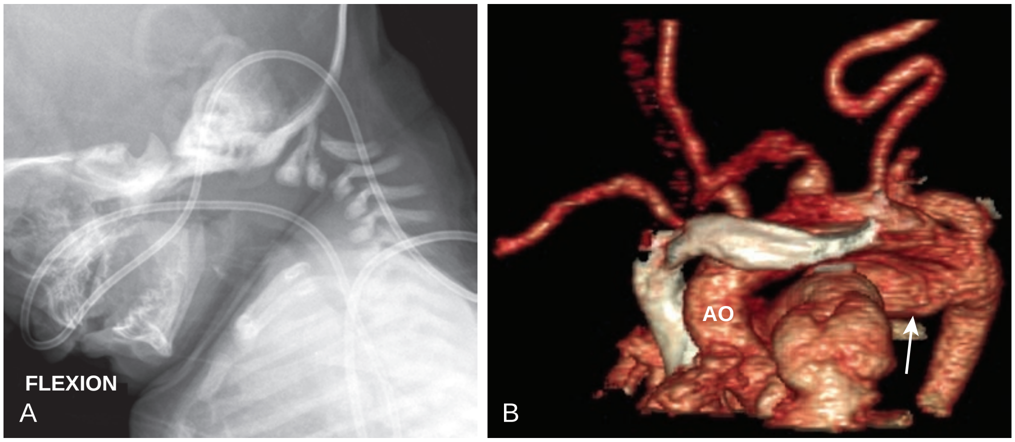

**Figure 78.5. Infant with Loeys–Dietz syndrome.** (A) Flexion lateral view of the cervical spine demonstrates instability with marked subluxation, posterior hypoplasia, and kyphosis at C2–C3. (B) Oblique coronal volumetric CTA reconstruction shows a very tortuous aortic *(AO)* arch and all cervical branches as well as an aneurysmal patent ductus arteriosus *(arrow).* See Video 78.1 for markedly tortuous aorta and iliac arteries with multiple stenoses and Video 78.2 for diffuse arterial tortuosity and multiple stenoses. *(Courtesy of Ron Cohen, Oakland Children's Hospital.)*

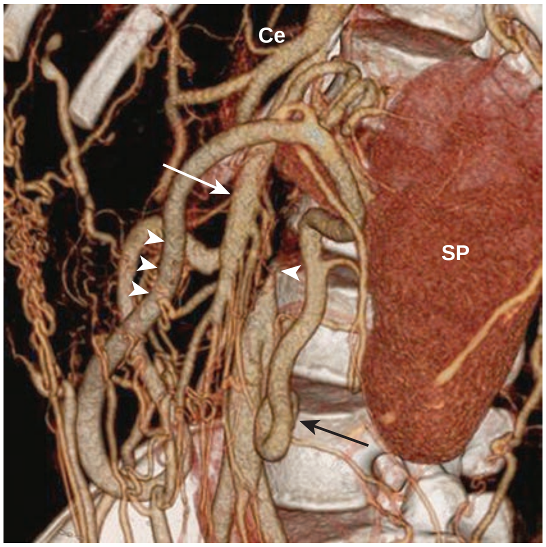

**Figure 78.6. Aortic obstruction from neurofibromatosis type 1 in a 14-year-old boy.** Volume rendering of an abdominal CTA shows a complete obstruction of the aorta beyond the origins of the celiac trunk *(Ce)* and the superior mesenteric artery *(white arrow).* The distal aorta *(single arrowhead)* is reconstituted through the superior mesenteric artery, the marginal artery of Drummond *(three arrowheads),* and the inferior mesenteric artery *(black arrow). SP,* Spleen.

("penciling" and "twisted ribbon"); enlargement of the neural foramina; intercostal, mediastinal, pleural, and soft tissue neurofibromas; and pulmonary cysts, nodules, and fibrosing alveolitis.

NF1 patients are screened with frequent blood pressure measurements and undergo arterial imaging (i.e., CTA or MRA) if hypertension or other symptoms develop.[26] Vascular lesions may be treated with drug therapy, angioplasty, or surgery. Development of additional lesions, including aneurysms, has been reported after surgery or stenting, consistent with underlying vascular fragility. Elucidation of the genetic and cellular pathophysiology of NF1 and other related diseases shows promise in the development of targeted cellular pathway therapies.[21]

## Tuberous Sclerosis

***Overview.*** Tuberous sclerosis is an autosomal dominant inherited disease occurring in 1 in 6,000 live births and is characterized by hamartomas of multiple organs, including cerebral cortical tubers, subependymal giant cell astrocytomas, and renal angiomyolipomas.[27,28] The classic clinical triad is seizures, cognitive impairment, and skin lesions.[29] The presentation and manifestations of tuberous sclerosis are quite varied, and the diagnosis can be missed for a prolonged period.[28] Mutations of *TSC1* and *TSC2*, tumor suppressor genes that encode hamartin and tuberlin proteins, have been identified as the cause of tuberous sclerosis. *TSC2* mutations tend to produce more severe clinical manifestations.[27,29]

Cardiac rhabdomyomas are the most common pediatric cardiac tumors, and 70% to 90% are associated with tuberous sclerosis (Fig. 78.7) (see Chapter 80).[29]

Other cardiovascular manifestations of tuberous sclerosis can include CNS, central and peripheral arterial aneurysms, aortic coarctation, and vascular stenotic–occlusive disease including renal artery stenosis.[30] Aneurysms may form due to medial atrophy and disruption, with abdominal aneurysms appearing at an earlier age than those in the thorax.[31]

***Imaging, Treatment, and Follow-up.*** Rhabdomyoma is the earliest finding of tuberous sclerosis in utero and can be diagnosed with ultrasound. The presence of multiple cardiac tumors in utero is sufficient to establish the diagnosis.[32] On ultrasound, rhabdomyomas appear as rounded, homogeneous, hyperechoic areas within the myocardium (see Fig. 78.7).

The signal characteristics of rhabdomyomas on MRI are variable. They often are isointense or minimally hyperintense to the myocardium on T1-weighted images (see Fig. 78.7) and hyperintense on T2-weighted images. Rhabdomyomas may be hypointense to the myocardium after administration of intravenous gadolinium contrast. They usually appear as low-density masses on contrast-enhanced CT (see Fig. 78.7).

Rhabdomyomas can cause obstruction of ventricular blood flow, arrhythmias, and loss of functional myocardium, which can lead to low cardiac output, congestive heart failure, and even myocardial infarction. Rhabdomyomas can arise anywhere in the myocardium, most commonly in the ventricles. They often are multiple and can invade the pericardium. Areas of central necrosis may be present.

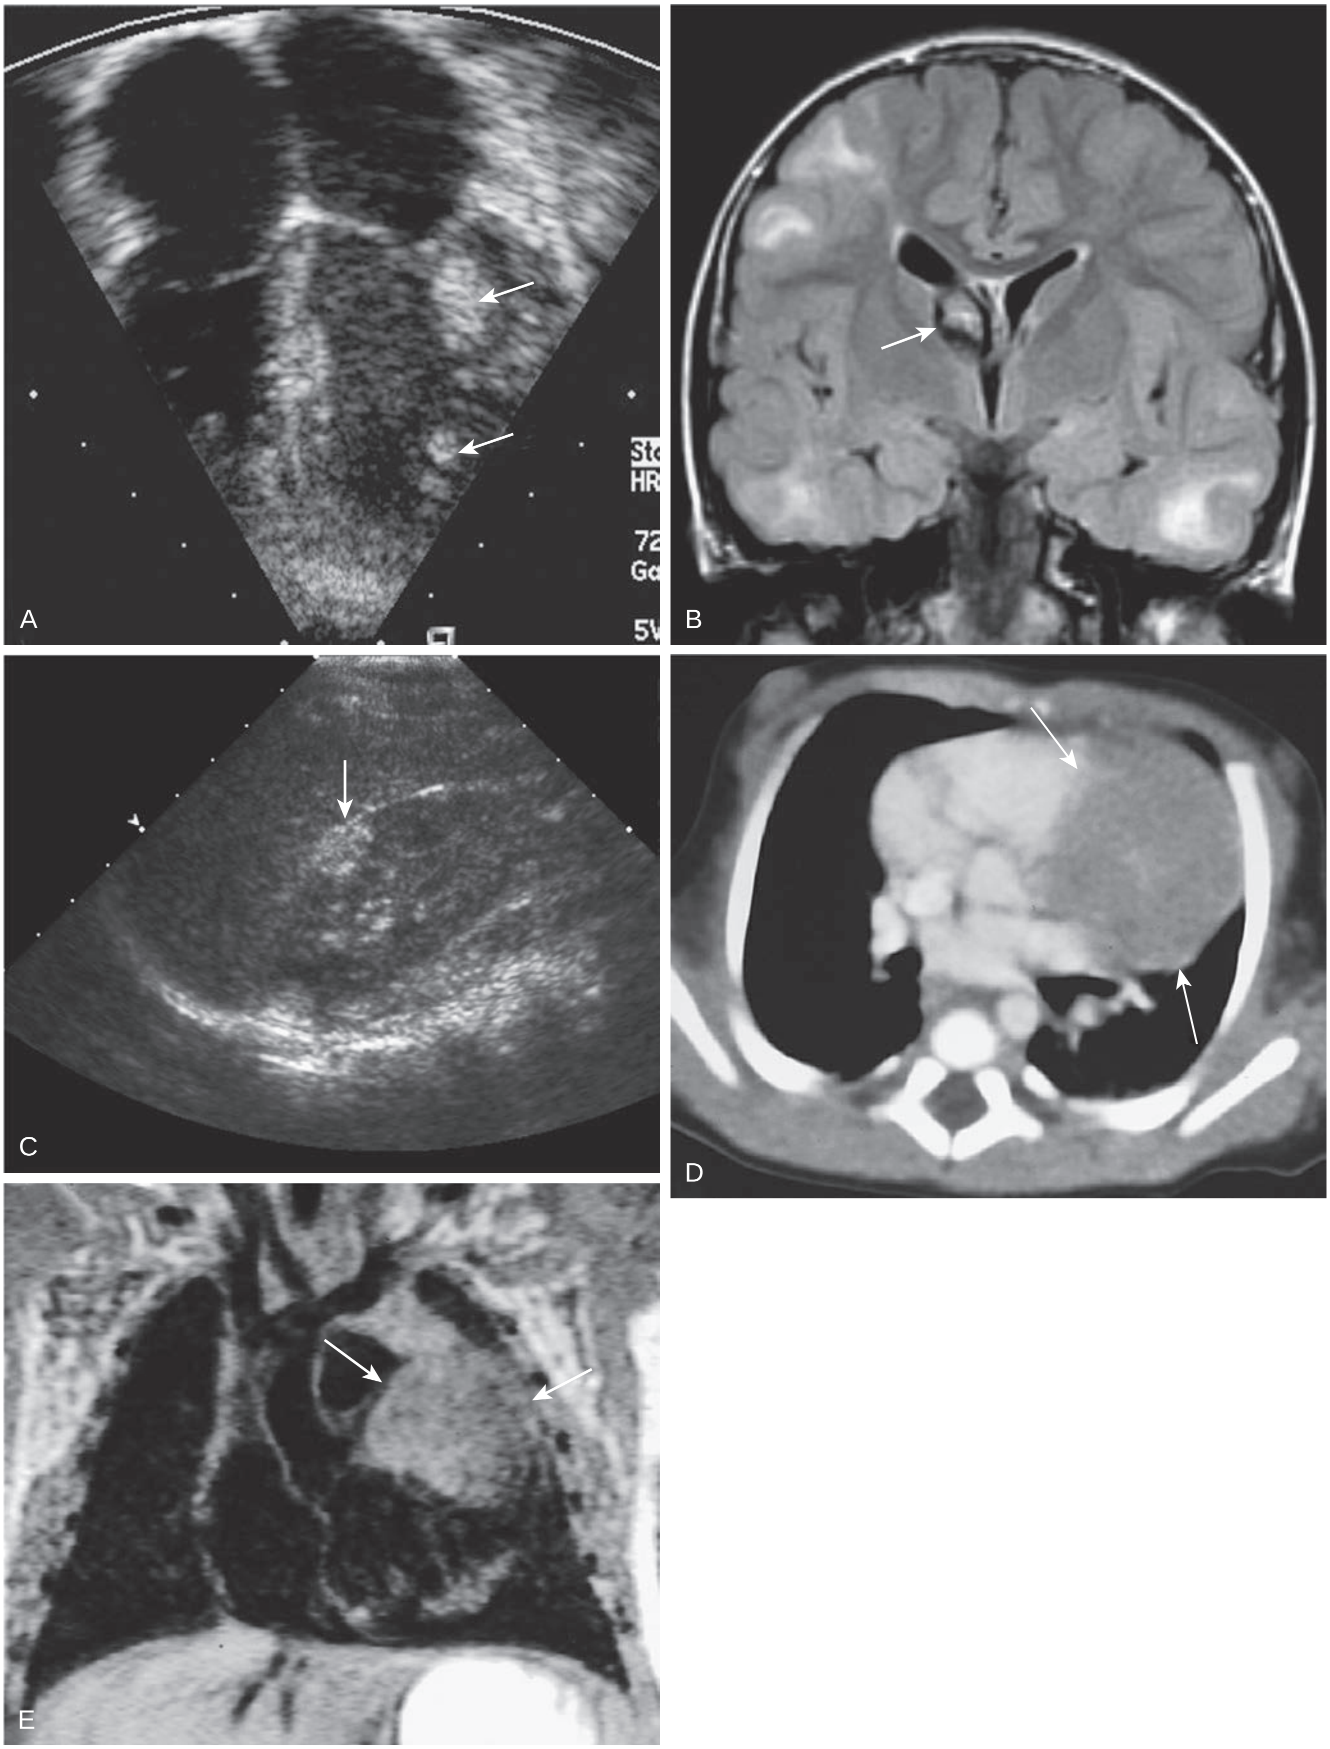

**Figure 78.7. Tuberous sclerosis.** (A) Four-chamber view from an echocardiogram shows multiple echogenic masses within the free wall of the left ventricle *(arrows).* The cardiac tumors, representing rhabdomyomas, resolved spontaneously. (B) Coronal fluid-attenuated inversion recovery MRI of the brain from the same child 2 years later shows multiple hyperintense subcortical tubers and a mixed-signal giant cell astrocytoma *(arrow)* at the foramen of Monro. (C) Sagittal ultrasonography of the right kidney shows a hyperechoic lesion in the anterior mid kidney *(arrow)* indicating an angiomyolipoma. (D and E) Different 3-day-old boy with an abnormal chest radiograph. (D) Contrast-enhanced CT demonstrates a large, hypodense, soft tissue density mass of the left ventricular wall *(arrows).* (E) Coronal T1-weighted MRI demonstrates the large, isointense-to-muscle rhabdomyoma in the left ventricular free wall *(arrows). (A, Courtesy of Lizabeth Lanford, MD, Children's Hospital, Pittsburgh, PA.)*

Rhabdomyomas tend to increase in size until 32 weeks of gestation and then progressively regress, especially during the first year of life.[32] Children can be monitored with serial echocardiograms; complete regression is observed in most patients by age 6 years and surgery is rarely required. Patients should continue to be monitored for bradyarrhythmias and tachyarrhythmias.[29]

Screening for aortic aneurysms (via ultrasound, MRA, or CTA) is recommended both at the time of diagnosis and at frequent regular intervals thereafter.[31] Open elective repair of an identified aneurysm is important because one-third of patients with tuberous sclerosis complex and aortic aneurysm present with rupture.[31]

### PHACES Syndrome

***Overview.*** PHACES syndrome, consisting of *P*osterior fossa malformations, *H*emangiomas, *A*rterial anomalies, *C*ardiac defects, *E*ye abnormalities, and *S*ternal clefting or a *S*upraumbilical raphe, is a neurocutaneous complex with a strong female predominance.[33-36] Specific major and minor criteria have been established for more accurate diagnosis of PHACES syndrome.[36,37]

The hemangioma is typically large and segmental, located on the face and/or cervical region, and behaves like an infantile hemangioma: barely visible at birth, markedly proliferating in infancy, with subsequent slow regression. It also appears to respond to propranolol therapy.[37]

Vascular lesions predominantly affect the arterial system and include dysplasia, tortuosity, dilation, narrowing, occlusion, aberrant origin or course, and persistent embryonic vessels.[36] More than 30% of patients with PHACES syndrome have coarctation of the aorta, which is often unusually complex with irregular areas of narrowing and ectasia.[36,37] Other congenital aortic abnormalities include arch interruption, atresia, aberrant subclavian origins, hypoplasia of the descending thoracic aorta, and right or double aortic arch.[34,36] Progressive abnormalities such as stenosis of and aneurysm formation in the aorta and the cervical arteries are of particular concern. Patients with PHACES syndrome are at an unusually high risk of stroke (as a result of a progressive arterial vasculopathy) and cerebrovascular abnormalities.[33,36] Currently the imaging strategy is geared toward identification of vascular lesions, treatment planning, and monitoring of disease progression.

### Noonan Syndrome

***Overview.*** Noonan syndrome is an autosomal dominant RASopathy that occurs in both male and female infants with an incidence of 1 in 1,000 to 1 in 2,000. It has been associated with advanced paternal age and linked to a large number of underlying familial or spontaneous genetic mutations; the most common, in 50% of cases, is in the *PTPN11* gene.[38] Noonan syndrome is typified by characteristic facies and a webbed neck, short stature, cardiac anomalies, deafness, motor delays, and mild cognitive impairment.

Cardiac defects are common in Noonan syndrome; the most prevalent is pulmonary stenosis (57%), frequently with a dysplastic pulmonary valve.[38,39] Hypertrophic cardiomyopathy occurs in 20% to 50% of cases, often presents in infancy, is highly associated with concomitant cardiac anomalies, and may resolve spontaneously.[39] Other abnormalities include ASD, VSD, PDA, TOF, anomalous pulmonary venous return, aortic coarctation, partial atrioventricular septal defect, mitral valve abnormalities, coronary anomalies, and electrocardiographic abnormalities.[38] Lymphatic system abnormalities are particularly common and include lymphedema, lymphangiectasia, lymphatic malformation, and chylothorax.[40] Coagulation and platelet defects with easy bruising and a propensity to develop hematologic malignancies are also notable.[23,38]

The term *neurofibromatosis–Noonan syndrome* has been used for cases of NF1 with Noonan features such as pectus excavatum, broad neck, and congenital heart disease.[6] Noonan syndrome with multiple lentigenes was formerly known as LEOPARD syndrome (lentigines, electrocardiogram abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness) (e-Fig. 78.8 and Video 78.3).[6,38]

## Other Syndromes

Other syndromes and their associated cardiovascular components are listed in Table 78.1 (e-Figs. 78.9–78.14 and Video 78.4; also see e-Fig. 78.8). The most common associated cardiac lesions are listed first, vascular lesions after. Many other rare syndromes have associated cardiac malformations; however, these syndromes are too numerous to mention specifically. Table 78.2 outlines syndromes that have cardiovascular manifestations almost exclusively (e-Figs. 78.15 and 78.16). This list is not exhaustive but includes the more common, important, and interesting entities.

# SPECIFIC CHROMOSOMAL ANOMALIES

## 22Q11 Deletion—DiGeorge Syndrome

***Overview.*** The 22q11 deletion is the most common chromosome deletion in DiGeorge syndrome, as well as the velocardiofacial syndrome.[6] DiGeorge syndrome often is remembered by the acronym CATCH 22, which refers to the major manifestations: *C*ardiac defects, *A*bnormal facies, *T*hymic hypoplasia, *C*left palate, *H*ypocalcemia (absent parathyroid), and *22*q11 chromosome deletions. The defects seen in the DiGeorge syndrome reflect field defects of the third and fourth pharyngeal pouches. The most commonly associated cardiac anomalies are truncus arteriosus (40% of truncus arteriosus cases have DiGeorge syndrome) (e-Fig. 78.17) and interruption of the aortic arch (usually type B) (see Chapter 75), as well as TOF and aberrant or isolated subclavian artery.[41]

DiGeorge syndrome is associated with other syndromes, including fetal alcohol syndrome, Noonan syndrome, and Zellweger syndrome. It also is associated with infants of diabetic mothers.[6]

The absence of the thymic shadow on radiographs in the first week of life in association with heart disease should raise strong consideration of DiGeorge syndrome. However, the thymus is not necessarily entirely absent and may just be hypoplastic.

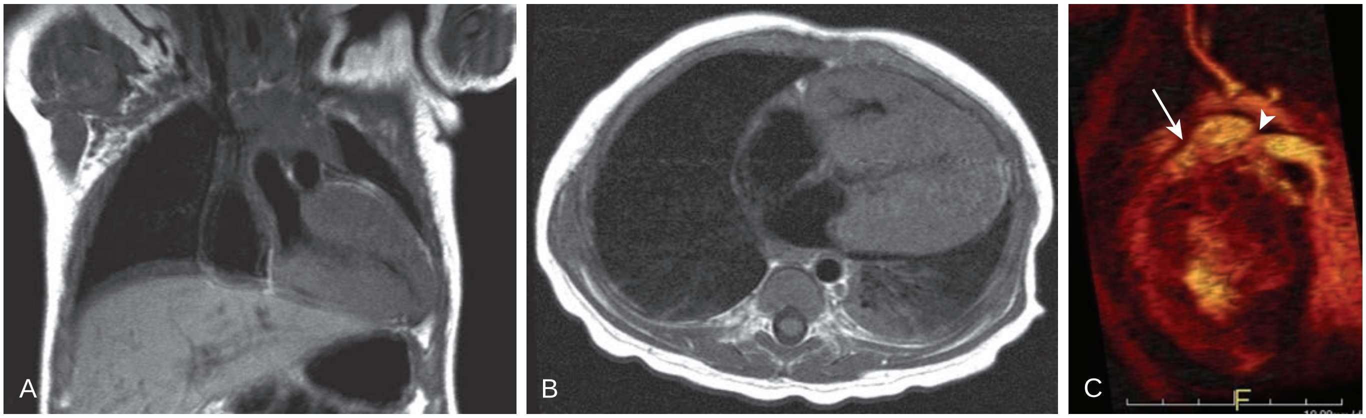
Imaging and management depends on the severity of cardiac and other anomalies. Increased susceptibility to infections, especially respiratory infections, including unusual organisms seen in immunocompromised hosts (such as acid-fast bacilli and pneumocystis), is a significant management concern.

## Fragile X Syndrome

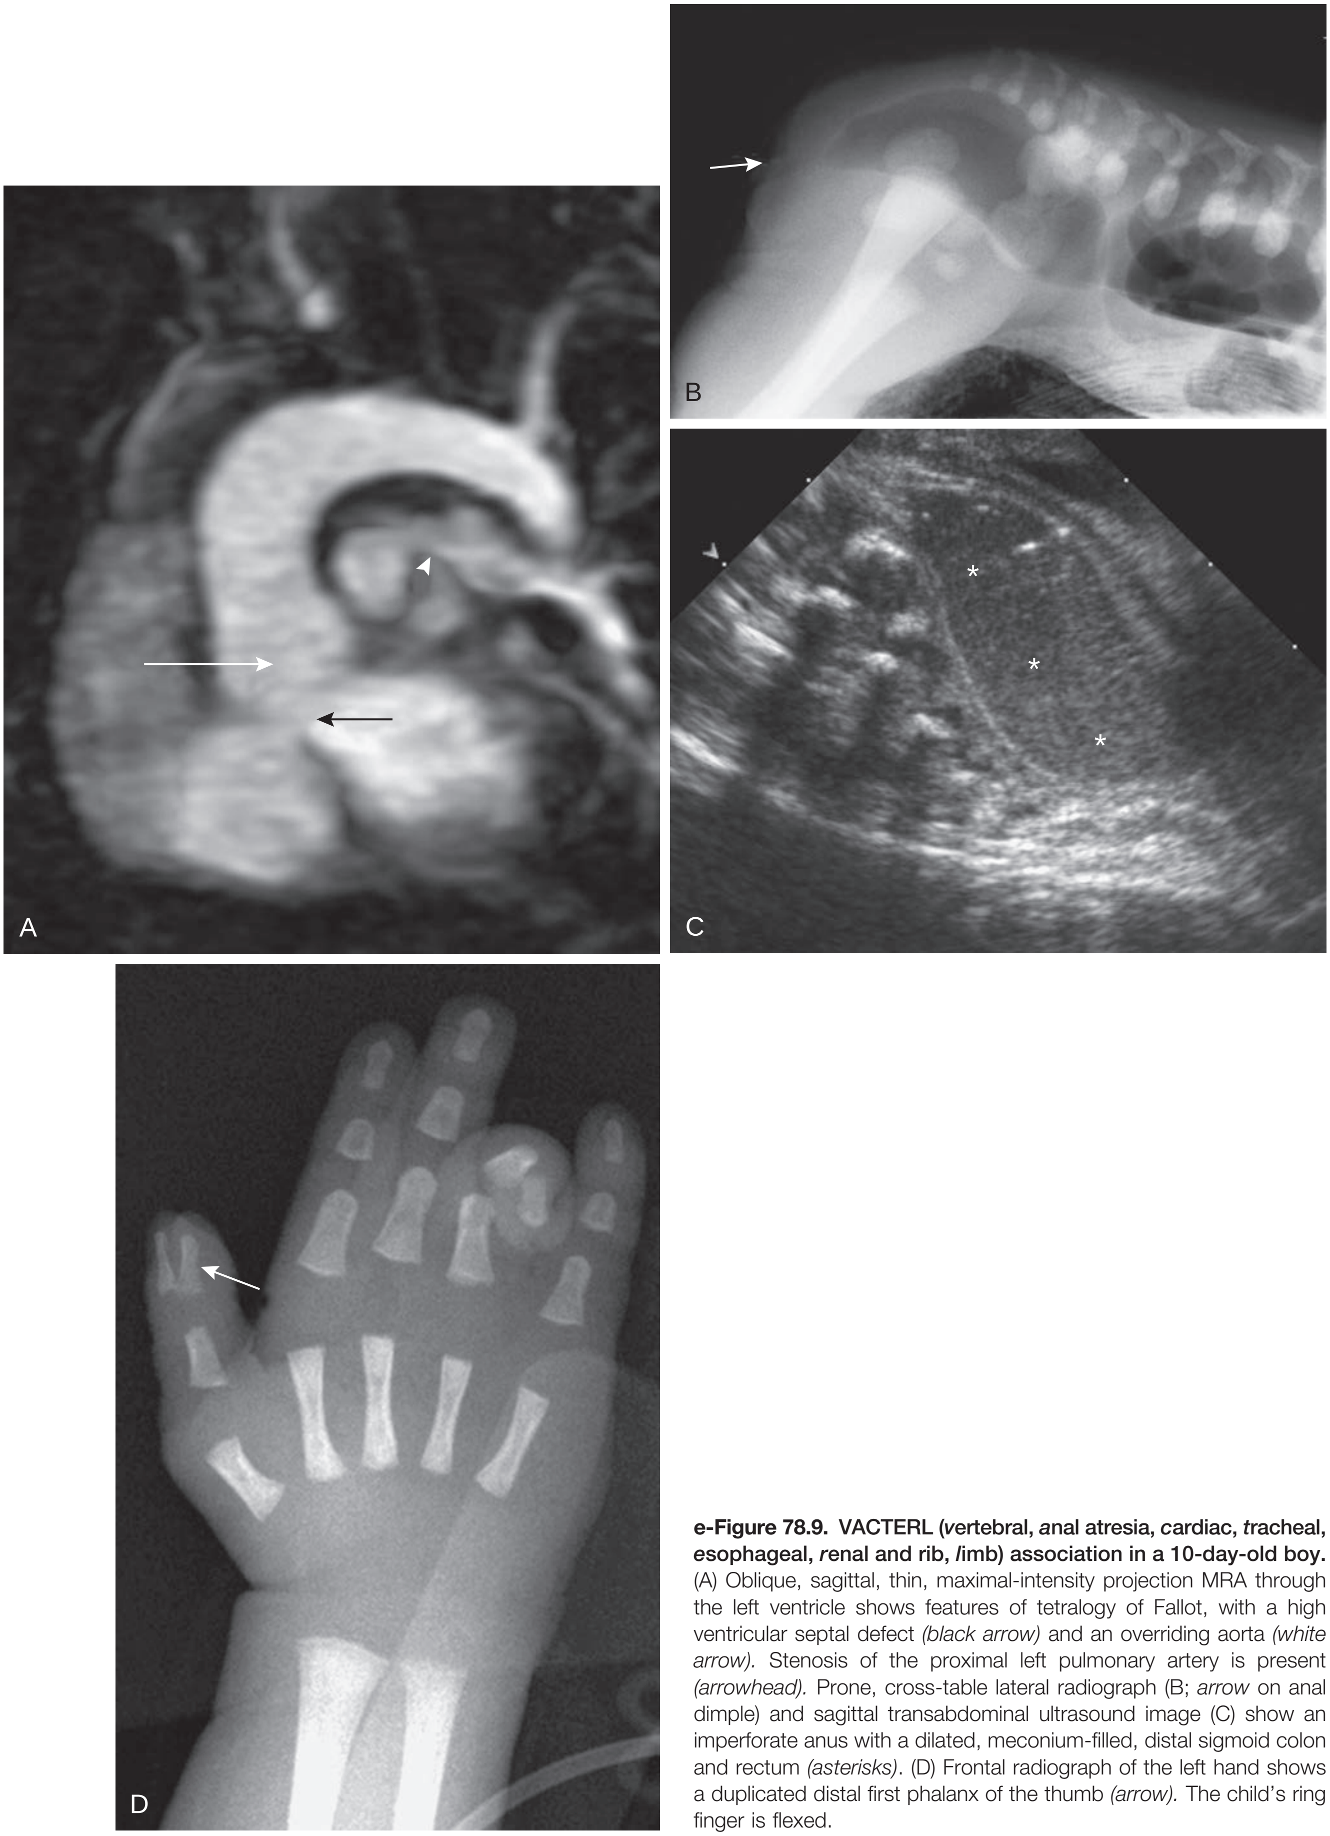
***Overview.*** Fragile X syndrome is the most common inherited form of intellectual disability. Approximately 1 in 850 people carry the gene for this X-linked disorder; however, about 20% of males with the gene are unaffected. Affected individuals may have large heads and facial abnormalities along with learning disabilities and behavioral problems. Associated cardiac abnormalities include MVP, mitral regurgitation, aortic regurgitation, tricuspid regurgitation, a dilated aortic root, and coarctation.[6]

## Trisomy 21 (Down Syndrome)

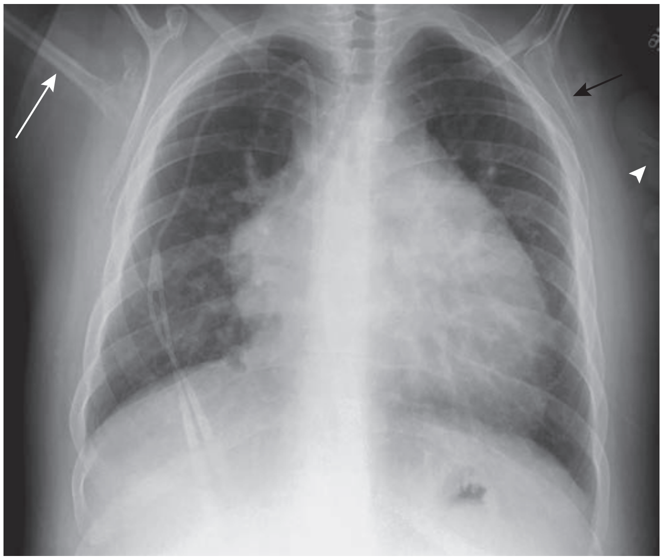
***Overview.*** Down syndrome, the most common chromosomal anomaly, is seen in 1 in 600 to 1 in 800 live births.[6a] Down syndrome is the most frequent genetic anomaly associated with congenital heart disease. Approximately 40% to 45% of patients with Down



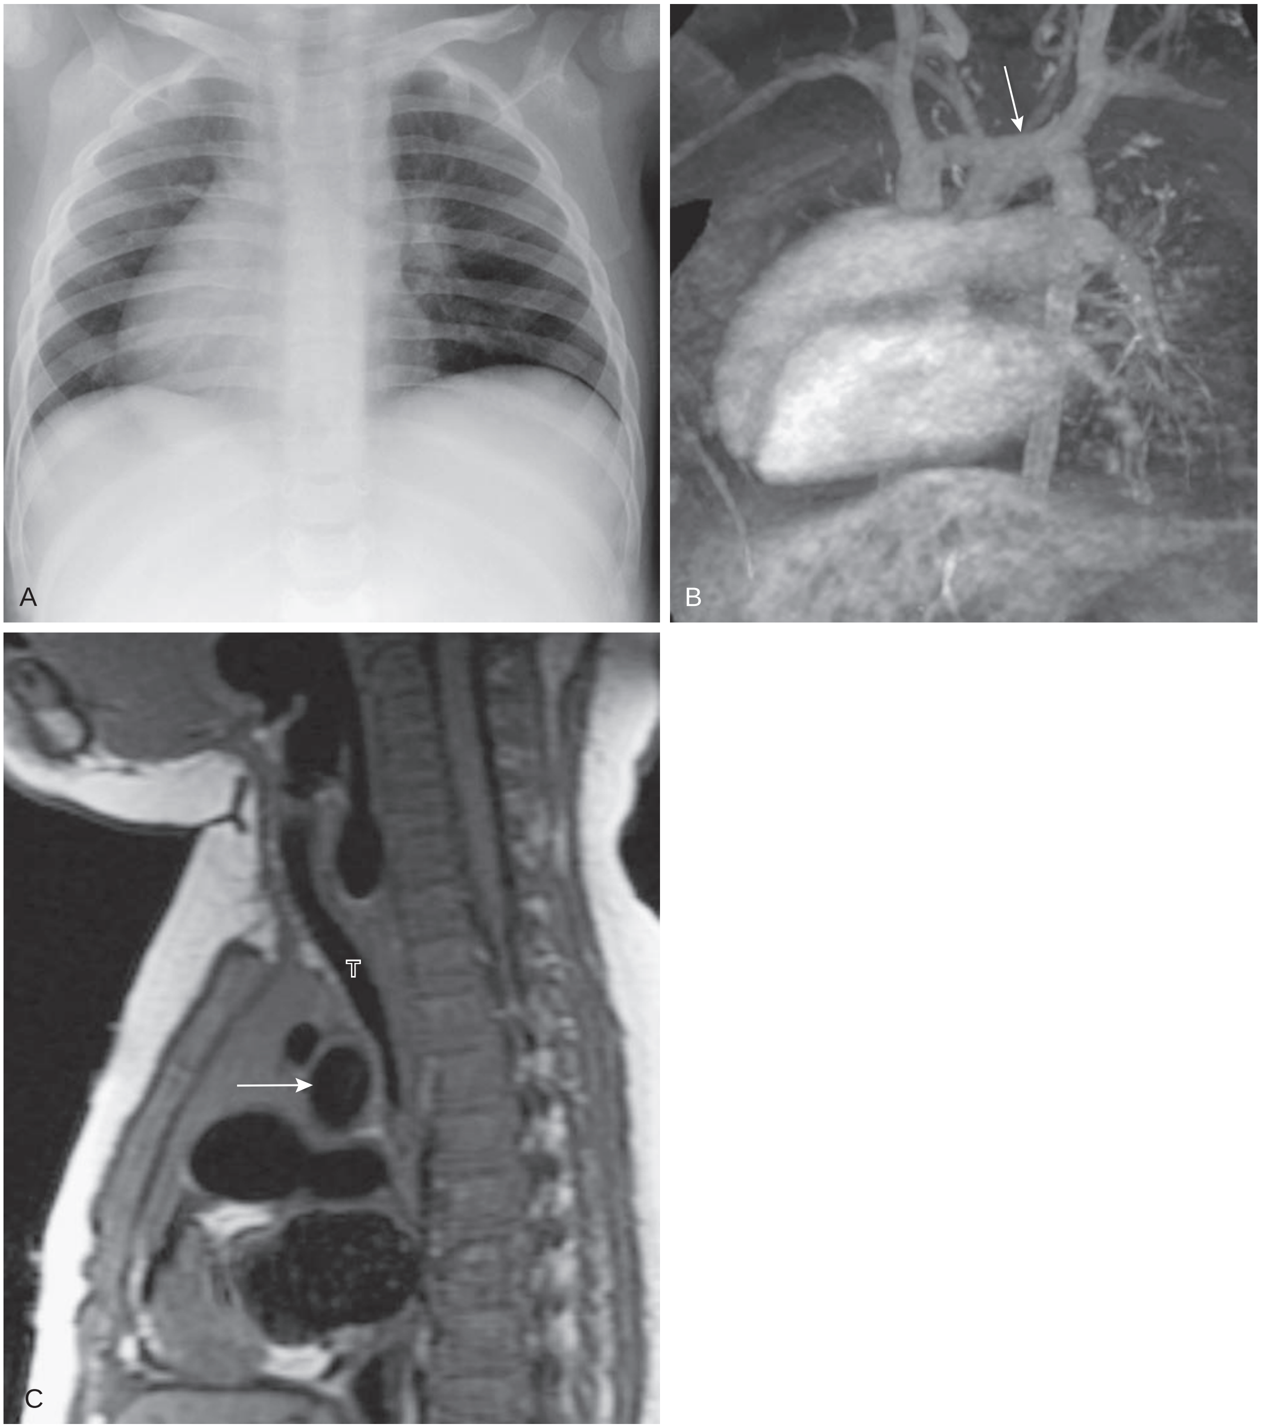
**e-Figure 78.8. A 6-month-old girl with a hypertrophic cardiomyopathy and features of LEOPARD variant of Noonan syndrome.** Coronal (A) and axial T1-weighted (B) MRI demonstrates marked thickening of the right and left ventricular myocardium with small ventricular cavities. See also Video 78.3. (C) Oblique sagittal three-dimensional MRA reconstruction demonstrates moderate pulmonic stenosis with poststenotic dilation of the pulmonary artery *(arrow)* and mild stenosis at the origin of the left pulmonary artery *(arrowhead).*



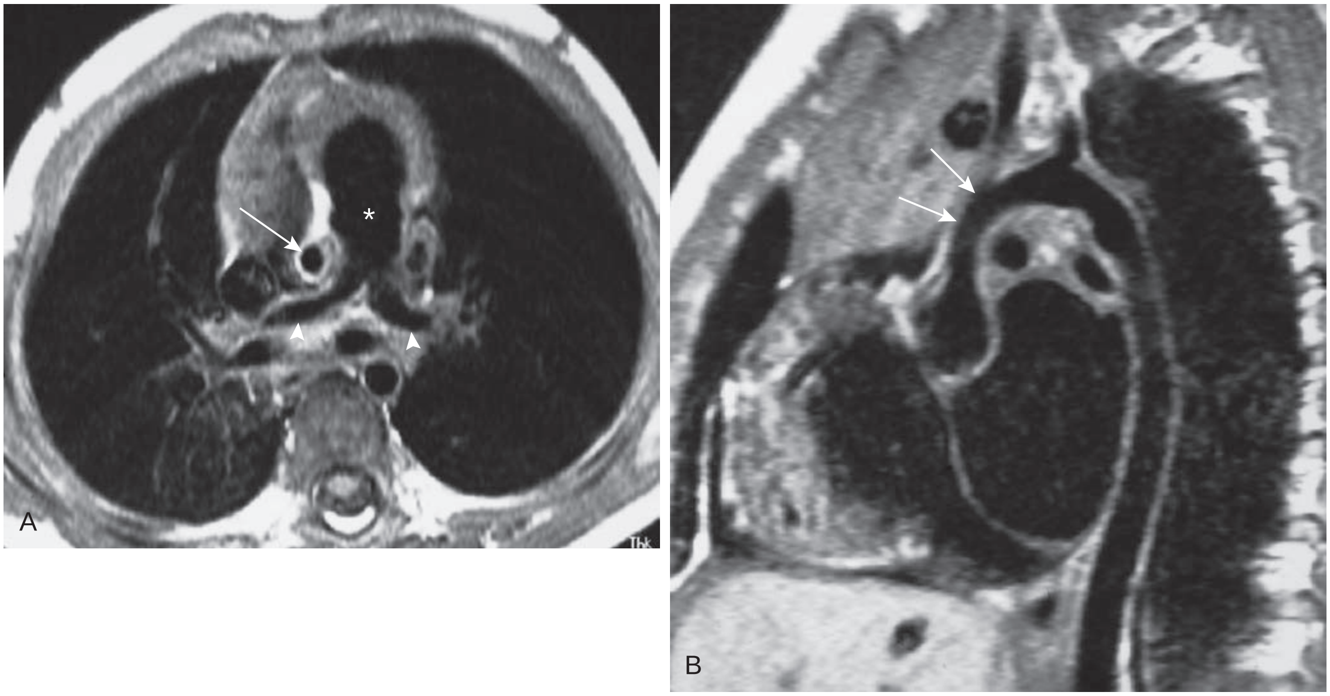
**e-Figure 78.9. VACTERL (*v*ertebral, *a*nal atresia, *c*ardiac, *t*racheal, *e*sophageal, *r*enal and rib, *l*imb) association in a 10-day-old boy.** (A) Oblique, sagittal, thin, maximal-intensity projection MRA through the left ventricle shows features of tetralogy of Fallot, with a high ventricular septal defect *(black arrow)* and an overriding aorta *(white arrow).* Stenosis of the proximal left pulmonary artery is present *(arrowhead).* Prone, cross-table lateral radiograph (B; *arrow* on anal dimple) and sagittal transabdominal ultrasound image (C) show an imperforate anus with a dilated, meconium-filled, distal sigmoid colon and rectum *(asterisks)*. (D) Frontal radiograph of the left hand shows a duplicated distal first phalanx of the thumb *(arrow).* The child's ring finger is flexed.



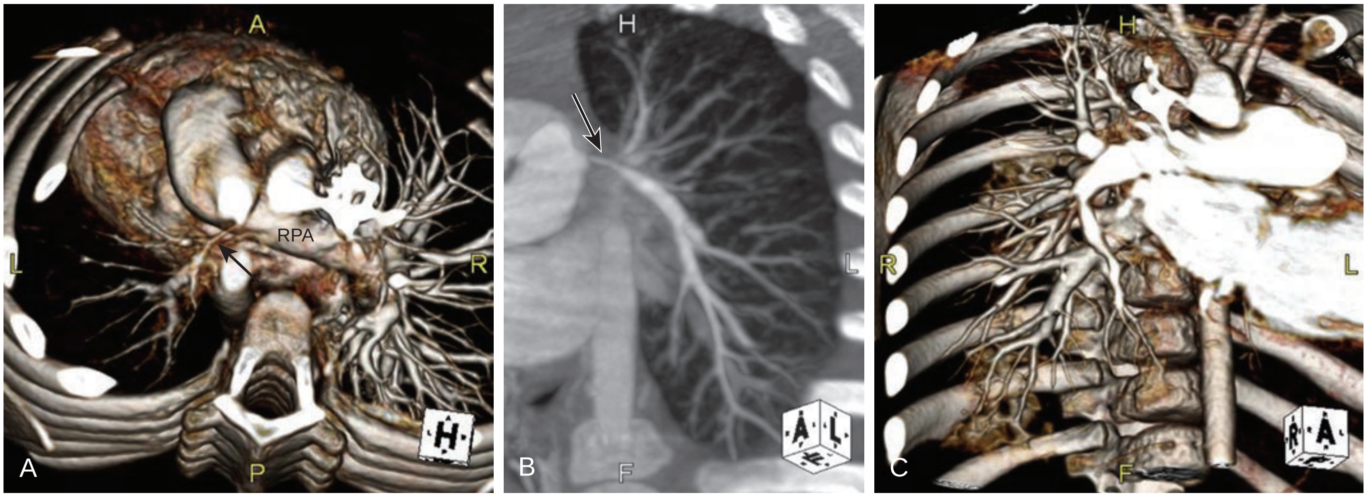
**e-Figure 78.10. Holt–Oram syndrome in a 35-year-old man with a history of atrial and ventricular septal defect repairs, as well as pulmonary arterial hypertension.** Chest radiograph shows cardiomegaly, prominent pulmonary vessels, hypoplastic scapulae (left scapula, *black arrow*), a hypoplastic right humerus *(white arrow),* and an absent left humerus with a rudimentary digit *(arrowhead).*



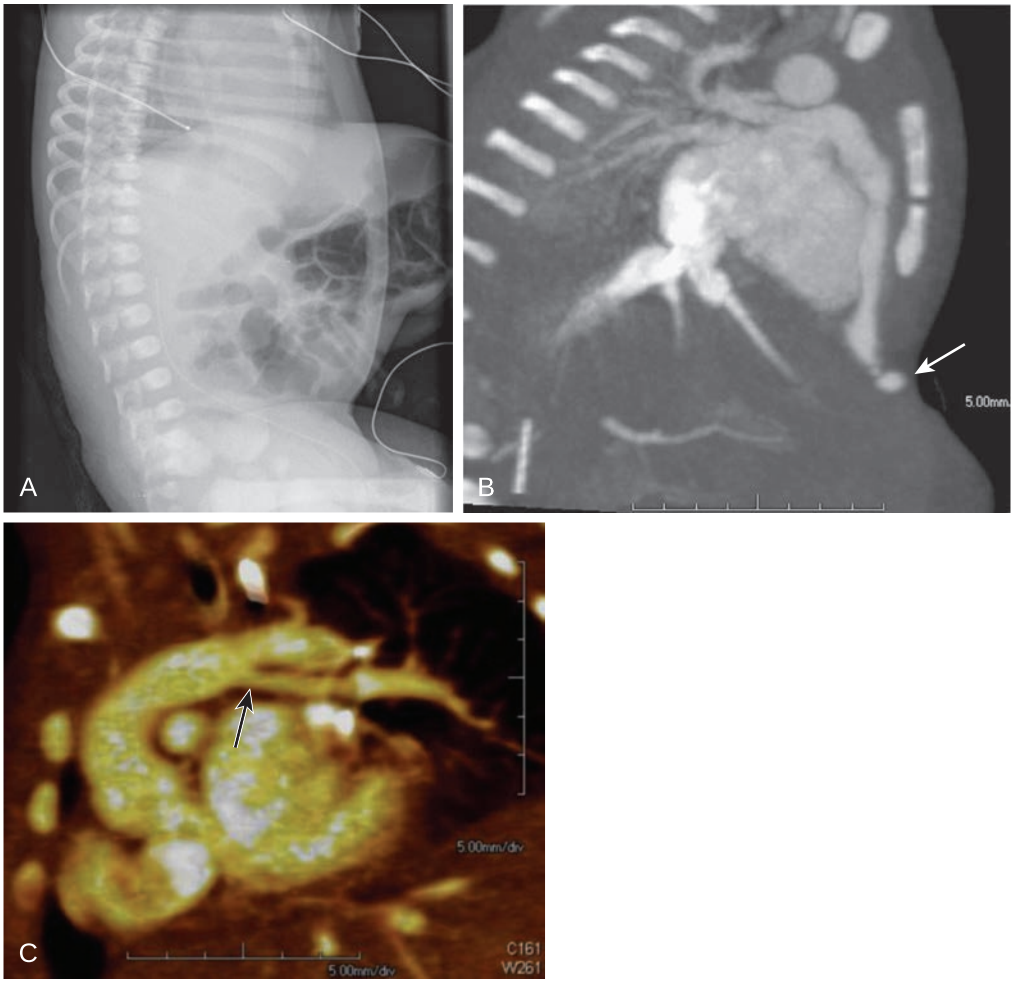
**e-Figure 78.11. A 1-year-old boy with Kartagener syndrome and stridor.** (A) Chest radiograph shows dextrocardia. The left lung is mildly hyperlucent. The abdominal situs was normal. (B) Coronal, three-dimensional, maximum-intensity projection MRA shows dextrocardia and a right-to-left course of the aorta, with a left-sided aortic arch *(arrow).* (C) Sagittal, T1-weighted MRI shows compression of the distal trachea *(T)* by the crossing aortic arch *(arrow).*



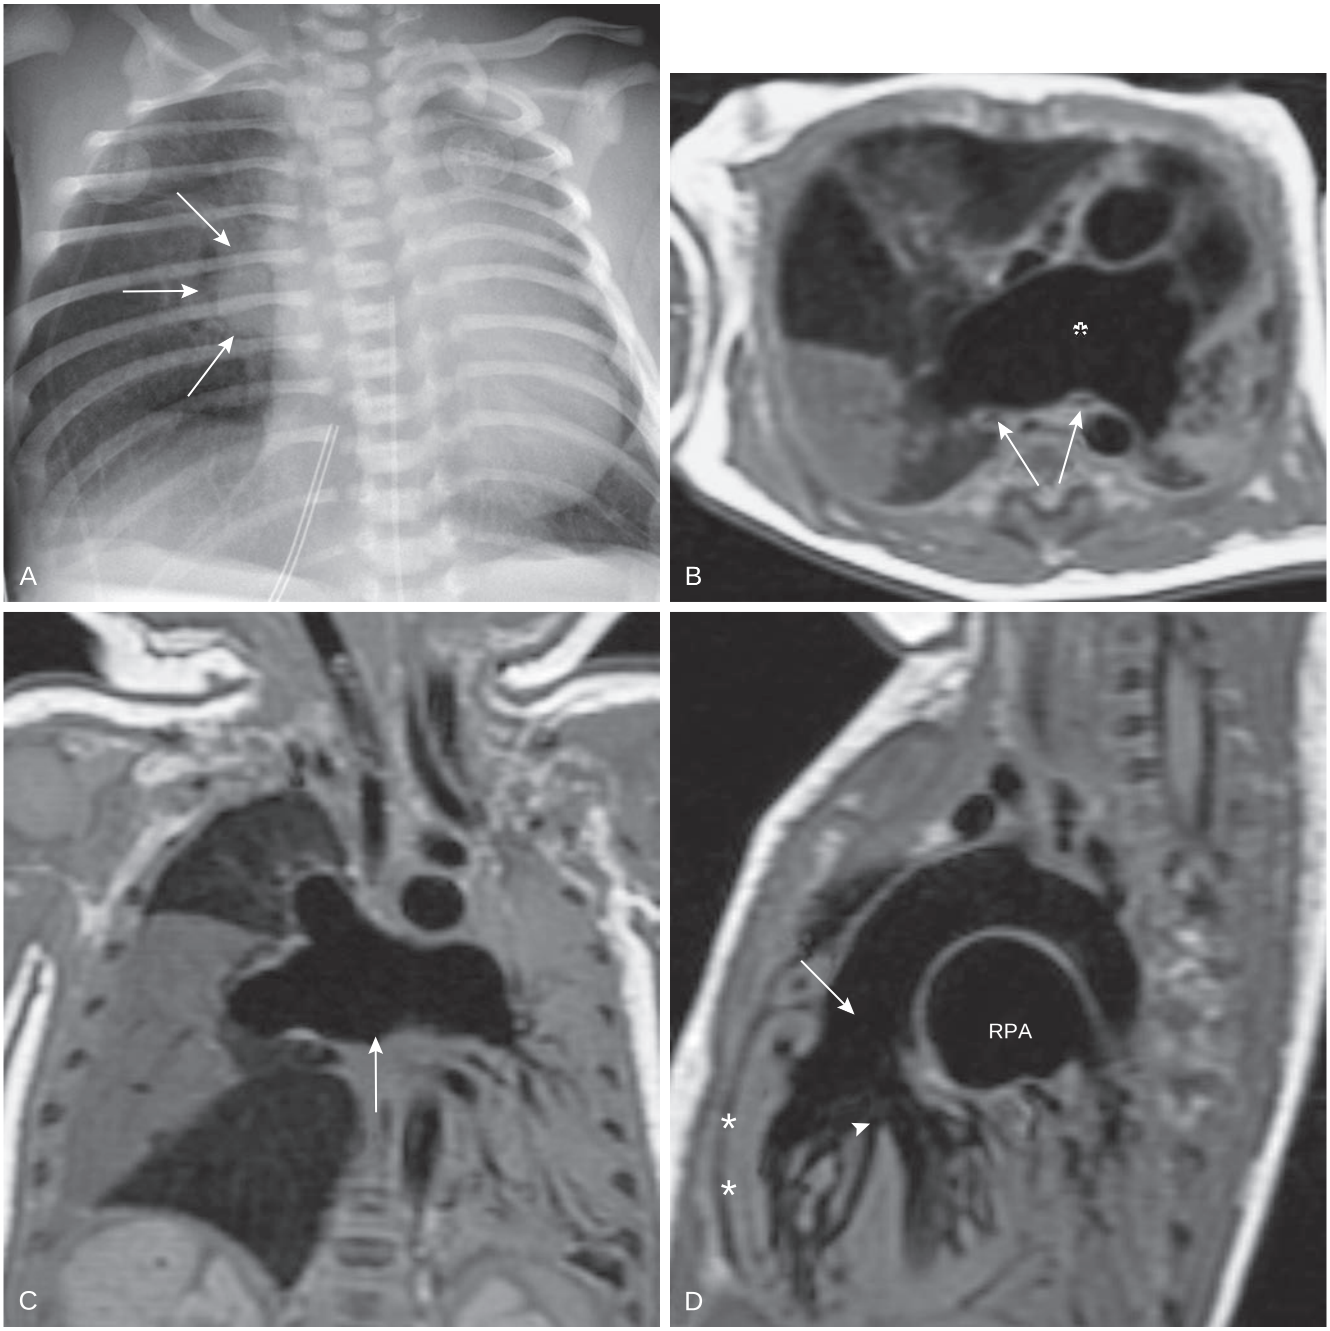
**e-Figure 78.12. Williams syndrome in a 3-year-old boy.** (A) Axial, T1-weighted MRI of the chest shows an enlarged main pulmonary artery *(asterisk),* with narrowing of the branch pulmonary arteries *(arrowheads).* Note the very small ascending aorta *(arrow).* (B) Oblique, sagittal, T1-weighted MRI shows hypoplasia of the supravalvar aorta *(arrows).*



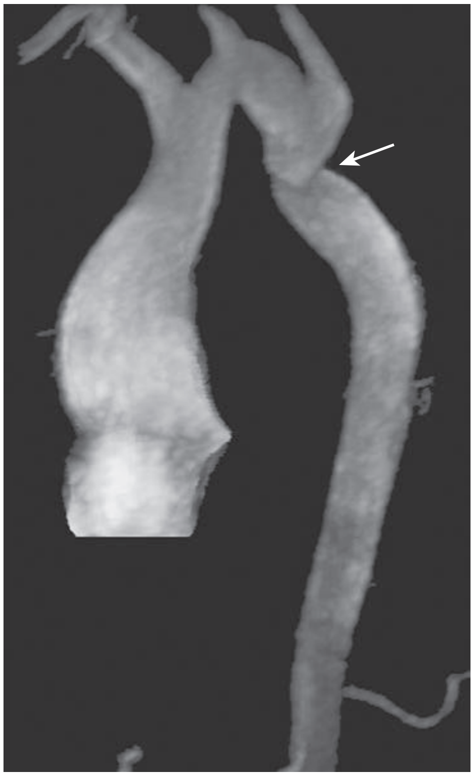
**e-Figure 78.13. Alagille syndrome (arteriohepatic dysplasia) in a 3-year-old child.** (A) Volumetric reconstruction from a CTA (viewed from above) demonstrates marked stenosis and hypoplasia of the left pulmonary artery and branches *(arrow).* The central right pulmonary artery *(RPA)* is patent, but numerous peripheral branch stenoses are present (see C). On a nuclear perfusion scan (not shown), the distribution of pulmonary flow was 86% right and 14% left. (B) Coronal maximum-intensity projection reconstruction demonstrates the very stenotic central left pulmonary artery *(arrow)* with much improved caliber more peripherally. Note additional peripheral stenosis of the origin of the left upper lobe branch. (C) Coronal volume-rendered reconstruction. Multiple peripheral RPA stenoses are present.



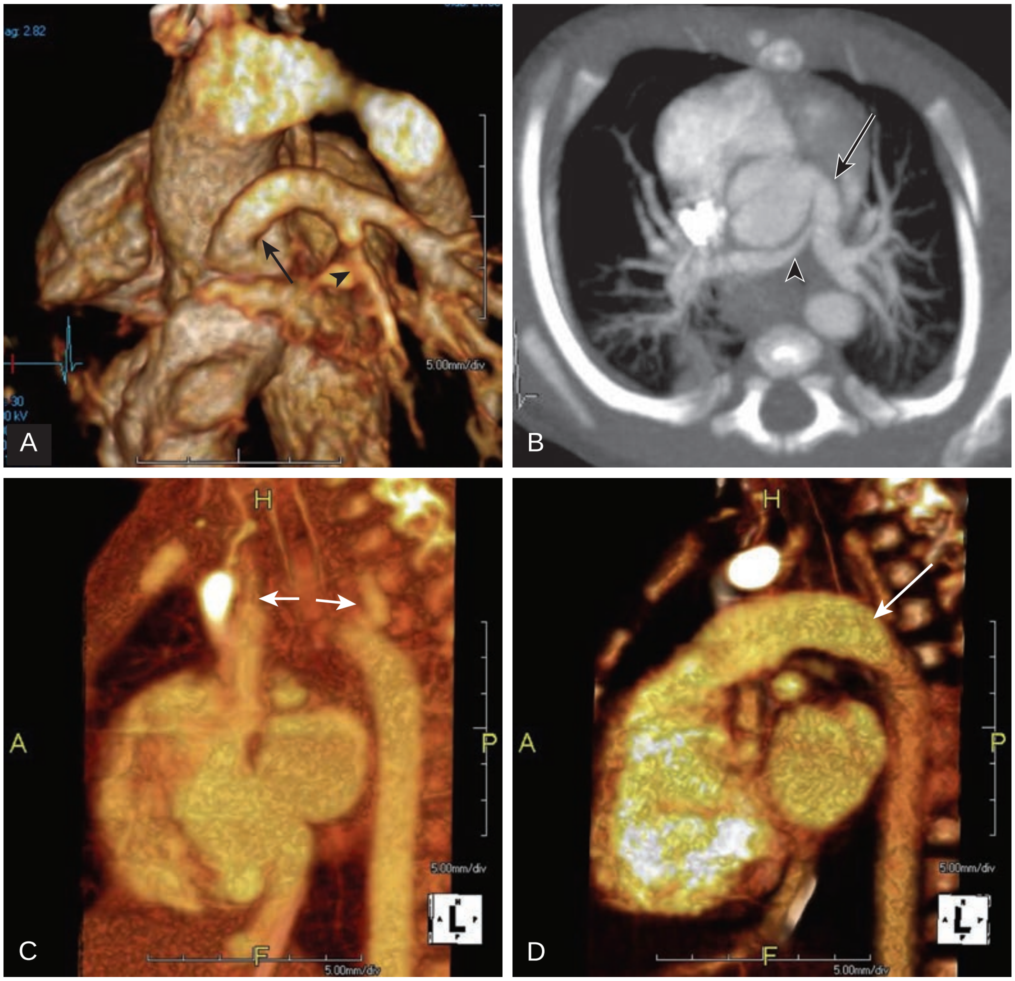
**e-Figure 78.14. Cantrell syndrome (pentalogy of Cantrell: abnormalities of the anterior abdominal wall, diaphragm sternum, pericardium, and heart) in a 2-day-old girl.** (A) Lateral chest radiograph showing a large, high omphalocele. (B) Sagittal maximum intensity projection CTA showing an absent lower sternum and hypoplastic right ventricle with an aneurysm of the right ventricular apex *(arrow)* extending into the omphalocele, probably through pericardial and diaphragmatic defects. (C) Oblique three-dimensional volumetric reconstruction shows the left pulmonary artery *(arrow)* originating from the proximal portion of the patent ductus arteriosus. The main and right pulmonary arteries were normal (not shown). Also see Video 78.4.



**e-Figure 78.15. Tetralogy of Fallot–absent pulmonary valve syndrome in a 3-day-old boy with respiratory distress.** (A) Frontal chest radiograph shows a right perihilar “mass” *(arrows)* and a hyperinflated right lung with associated leftward mediastinal shift and atelectasis. (B) Axial T1-weighted MRI obtained to evaluate the perihilar mass shows markedly dilated central pulmonary arteries *(asterisk)* compressing the bilateral bronchi *(arrows)* and causing atelectasis. (C) Coronal T1-weighted MRI shows markedly dilated central pulmonary arteries *(arrow)* with aberrant branching. There is complete atelectasis of the right middle lobe and much of the left lung. (D) Sagittal T1-weighted MRI shows features of tetralogy of Fallot with right ventricular hypertrophy *(asterisks),* a ventricular septal defect *(arrowhead),* and an overriding aorta *(arrow).* The right pulmonary artery *(RPA)* is markedly dilated.



**e-Figure 78.16. Shone syndrome with mitral and aortic valve stenosis and prior coarctation repair in a 15-year-old boy.** Oblique, sagittal, volumetric, three-dimensional MRA shows a dilated ascending aorta, tortuous cervical aortic arch, and residual aortic coarctation *(arrow).*



**e-Figure 78.17. 22q11 deletion (DiGeorge syndrome) in two newborn infants.** (A and B) Truncus arteriosus type 1. Volume-rendered, three-dimensional reconstruction, posterior oblique view (A) and axial thin maximum-intensity projection CTA (B) demonstrate a single great artery arising from the heart. The main pulmonary artery *(arrow)* arises from this vessel, which continues as the ascending aorta. Note branch pulmonary arteries with narrowing of the right pulmonary artery *(arrowhead).* (C and D) Sagittal three-dimensional volumetric CTA reconstructions show interruption of the aortic arch (type B). A marked gap exists between the ascending and descending aorta, with interruption between the left common carotid and left subclavian arteries (*arrows* in C). A large patent ductus arteriosus extends from the pulmonary artery centrally and supplies the descending aorta (*arrow* in D).

**TABLE 78.1** Syndromes, Dysplasias, and Their Associated Cardiovascular Anomalies

| Syndrome | Cardiovascular Anomalies |
|---|---|
| Achondrogenesis | PDA, ASD, VSD, COA |
| Alagille syndrome (arteriohepatic dysplasia) (see e-Fig. 78.13) | PS, PPS, ASD, VSD, TOF, PDA, PAT, PAPVR, dysplastic AV valves, COA |
| Apert syndrome (acrocephalosyndactyly) | ASD, PDA, VSD, PS, TOF, EFE, DEXTRO, COA |
| Arthrogryposis | CMY |
| Beckwith–Wiedemann syndrome (EMG syndrome) | CM, CMY, ASD, PDA, TOF, HPLH, subvalvular AS, cardiac fibromas |
| Cardioauditory syndromes | LVH, RVH |
| Cantrell syndrome (pentalogy of Cantrell) (see e-Fig. 78.14) | Combined sternal, pericardial, intracardiac, diaphragmatic, and anterior abdominal wall defects<br>Radiographic findings: sternal defect, ectopia cordis, CHD, ASD, VSD, PS, TOF, APVR, DEXTRO, ventricular diverticulum, intrapericardial herniation of abdominal organs; associated with Turner, trisomy 18, sirenomelia, and amniotic band syndromes |
| Cardiofaciocutaneous syndrome | PS, ASD, VSD, hypertrophic cardiomyopathy, heart valve abnormalities |
| Cardiosplenic (heterotaxy) syndromes (see Figs. 78.1 and 78.2) | |
| Right atrial isomerism (see Fig. 78.1) | Cardiac malposition, TAPVR, AVSD, pulmonary outflow obstruction or PAT, DORV, TGA, single atrium (R), single common ventricle, TAT, TRU (rare), AO-IVC juxtaposition, bilateral right PAs, RAA, bilateral SVC, interrupted IVC |
| Left atrial isomerism (see Fig. 78.2) | Cardiac malposition, single atrium (L), single ventricle, ASD,VSD, AVSD, DORV, APVR, interrupted IVC, bilateral left PAs, bilateral SVC |
| Cayler syndrome (cardiofacial syndrome) | ASD, PDA, VSD, AVSD, TOF, RAA, COA |
| CHARGE association | ASD, VSD, conotruncal malformations, PDA, TOF, parachute mitral valve |
| Costello syndrome | Hypertrophic cardiomyopathy, PS, Ao dilation, arrhythmia |
| Cutis laxa syndrome (autosomal recessive type) | Arteriopathy, dilation, stenosis, tortuosity, dissection |
| Degos syndrome (malignant atrophic papulosis) | MI, pericarditis, constrictive pericarditis, myocardial fibrosis, renal, cerebral, coronary, visceral and peripheral arteriopathy |
| Diamond–Blackfan syndrome (congenital red cell aplasia) | VSD, ASD, mitral valve dysplasia |
| Ehlers–Danlos syndrome (see Fig. 78.3) | MVP, dilated AO root, coronary, and aortic, carotid, and large-branch aneurysms, dissection or rupture, AS, AR, TR, PS, ASD, VSD, TOF, DEXTRO, LV rupture, arteriovenous fistula |
| Ellis–van Creveld syndrome (chondroectodermal dysplasia) | Common atrium, ASD, AVSD |
| Fryns syndrome | Septal defects, arch anomalies, TOF, cystic hygroma |
| Hallermann–Streiff syndrome (oculomandibulofacial syndrome) | PS, TOF, ASD, VSD |
| Holt–Oram syndrome (heart-hand syndrome) (see e-Fig. 78.10) | ASD, VSD, MVP, PDA, HPLH, TAPVR, TRU, conduction disorder, hypoplastic peripheral vessels |
| Jeune syndrome (asphyxiating thoracic dystrophy) | CHF |
| Kartagener syndrome (primary ciliary dyskinesia) (see e-Fig. 78.11) | DEXTRO, CHD |
| Klippel–Trénaunay–Weber syndrome (angioosteohypertrophy syndrome) | CHF, pericardial effusion, superficial varices, telangiectatic nevi, organ hemangiomas, lymphatic obstruction |
| LEOPARD syndrome (cardiomyopathic lentiginosis) aka Noonan syndrome with multiple lentigenes (see e-Fig. 78.8) | CMY, conduction defect, PS, sub-AS |
| Loeys–Dietz syndrome (see Fig. 78.5) | Congenital heart defects include PDA, bicuspid aortic valve, bicuspid pulmonary valve, MVP and ASD; arterial tortuosity, stenoses, aneurysms, dissection, diffuse arterial involvement; spontaneous rupture of viscera |
| Marfan syndrome (see Fig. 78.4) | MVP, MR, dilation of AO root, AR, CHF, aneurysms (AO, pulmonary, ductus), AO dissection, MI, arrhythmia, TR, ASD, TOF |
| MELAS syndrome | CMY, CHF, conduction abnormalities |
| Mucolipidosis III | AR |
| Mucopolysaccharidoses | |
| IH (Hurler syndrome) | Acute CMY associated with EFE, AR, MR, MS, arteriopathy (coronary, renal, AO, mesenteric) |
| IS (Scheie syndrome) | AS, MS |
| II (Hunter syndrome) | AR, CHF, valve thickening, CMY |
| III (Sanfilippo syndrome) | CMY, MR, AR |
| IV (Morquio syndrome) | AR, CMY, AS, MR, CAD |
| VI (Maroteaux–Lamy syndrome) | AS, MS, CMY |
| Neurofibromatosis type 1 (see Fig. 78.6) | PS, COA, ASD, VSD, CMY, MVP, AS, TOF, PDA, hypertrophic cardiomyopathy, vasculopathy (coronary, pulmonary, renal, systemic), cardiac neurofibroma, systemic and intracranial vascular stenosis, aneurysms, arteriovenous fistula, spontaneous vascular rupture, lymphatic abnormality |

**TABLE 78.1** Syndromes, Dysplasias, and Their Associated Cardiovascular Anomalies—cont'd

| Syndrome | Cardiovascular Anomalies |
|---|---|
| Noonan syndrome (Turner phenotype with normal karyotype) | PS, dysplastic pulmonic valve, hypertrophic CMY, lymphatic abnormalities, PDA, ASD, VSD, AVSD, TOF, COA, mitral valve abnormalities, AS, pericarditis, APVR, coronary anomalies, arrhythmias, coagulopathy, platelet defects |
| Oculoauriculovertebral dysplasia (Goldenhar syndrome) | TOF, VSD, DORV, PAT, TAPVR, RAA, COA, asplenia |
| PHACES | Large segmental facial/cervical hemangioma, COA, aortic arch atresia/ interruption, aberrant subclavian origins, hypoplasia of the descending thoracic aorta, RAA, double aortic arch, COA arterial tortuosity, stenosis, occlusion, and aneurysm, aberrant origin/course formation of the aorta and the cervical, intracranial arteries, stroke |
| Progeria (Hutchinson–Gilford syndrome) | Accelerated atherosclerosis, CM, MI, CHF, stroke |
| Proteus syndrome | CHD, CMY, myocardial mass, conduction abnormality, venous dilation, hemangioma, lymphangioma |
| Ravitch syndrome (thoracoabdominal wall defect) | Ectopia cordis, pentalogy of Cantrell, TGA, PDA, ASD, VSD, PS, TOF |
| Robinow syndrome (fetal face syndrome) | CHD (right-sided heart lesions) |
| Rubinstein–Taybi syndrome | ASD, VSD, PDA, COA, PS, bicuspid AO valve |
| Silver–Russell syndrome | CHD |
| Smith–Lemli–Opitz syndrome | ASD, complex cardiac anomalies |
| Thrombocytopenia–absent radius (TAR) syndrome | COA, ASD, VSD, PDA, AVSD, TOF |
| Tuberous sclerosis (Bourneville–Pringle syndrome) (see Fig. 78.7) | Rhabdomyoma, other hamartoma, CHF, CMY, COA, arrhythmia, arterial aneurysm and stenosis (AO, cerebral, renal, peripheral) |
| VATER/VACTERL association (see e-Fig. 78.9) | VSD, ASD, PDA, TOF, TGA, COA, DEXTRO, single ventricle; associated with infants of diabetic mothers and trisomy 18 |
| Velocardiofacial syndrome (Shprintzen syndrome) | TOF, TRU, PA, VSD, absent pulmonary valve, TGA, AS, interrupted AO arch, RAA |
| Williams syndrome (see e-Fig. 78.12) | Supravalvar AS, PPS, MR, ASD, VSD, TOF, MI, COA, interrupted arch, hypoplastic AO, aneurysm or stenosis (AO, systemic, coronary, renal, cerebral arteries) |
| Zellweger syndrome (cerebrohepatorenal syndrome) | CHD, PDA, VSD, DiGeorge |

*AO,* Aorta or aortic; *APVR,* anomalous pulmonary venous return; *AR,* aortic regurgitation; *AS,* aortic stenosis; *ASD,* atrial septal defect; *AV,* atrioventricular; *AVSD,* atrioventricular septal defect; *CAD,* coronary artery disease; *CHARGE,* coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, ear abnormalities; *CHD,* congenital heart disease; *CHF,* congestive heart failure; *CM,* cardiomegaly; *CMY,* cardiomyopathy; *COA,* coarctation of the aorta; *DEXTRO,* dextrocardia; *DORV,* double-outlet right ventricle; *EFE,* endocardial fibroelastosis; *EMG,* exomphalos, macroglossia, gigantism; *HPLH,* hypoplastic left heart; *IVC,* inferior vena cava; *L,* left; *LEOPARD,* lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, deafness; *LV,* left ventricle; *LVH,* left ventricular hypertrophy; *MELAS,* mitochondrial myopathy, encephalopathy, lactic acidosis, stroke; *MI,* myocardial infarction; *MR,* mitral regurgitation; *MS,* mitral stenosis; *MVP,* mitral valve prolapse; *PA,* pulmonary artery; *PAPVR,* partial anomalous pulmonary venous return; *PAT,* pulmonary atresia; *PDA,* patent ductus arteriosus; *PHACES,* posterior fossa brain malformations, hemangiomas of the face, arterial anomalies, cardiac anomalies, eye abnormalities, sternal clefting or supraumbilical raphe; *PPS,* peripheral pulmonary stenosis; *PS,* pulmonary stenosis; *R,* right; *RAA,* right aortic arch; *RVH,* right ventricular hypertrophy; *SVC,* superior vena cava; *TAPVR,* total anomalous pulmonary venous return; *TAT,* tricuspid atresia; *TGA,* transposition of the great arteries; *TOF,* tetralogy of Fallot; *TR,* tricuspid regurgitation; *TRU,* truncus arteriosus; *VACTERL,* vertebral, anal atresia, cardiac, tracheal, esophageal, renal, limb; *VATER,* vertebral defects, VSD, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia; *VSD,* ventricular septal defect.

syndrome have congenital cardiac malformations, which represent the leading cause of death in the first 2 years of life.[42]

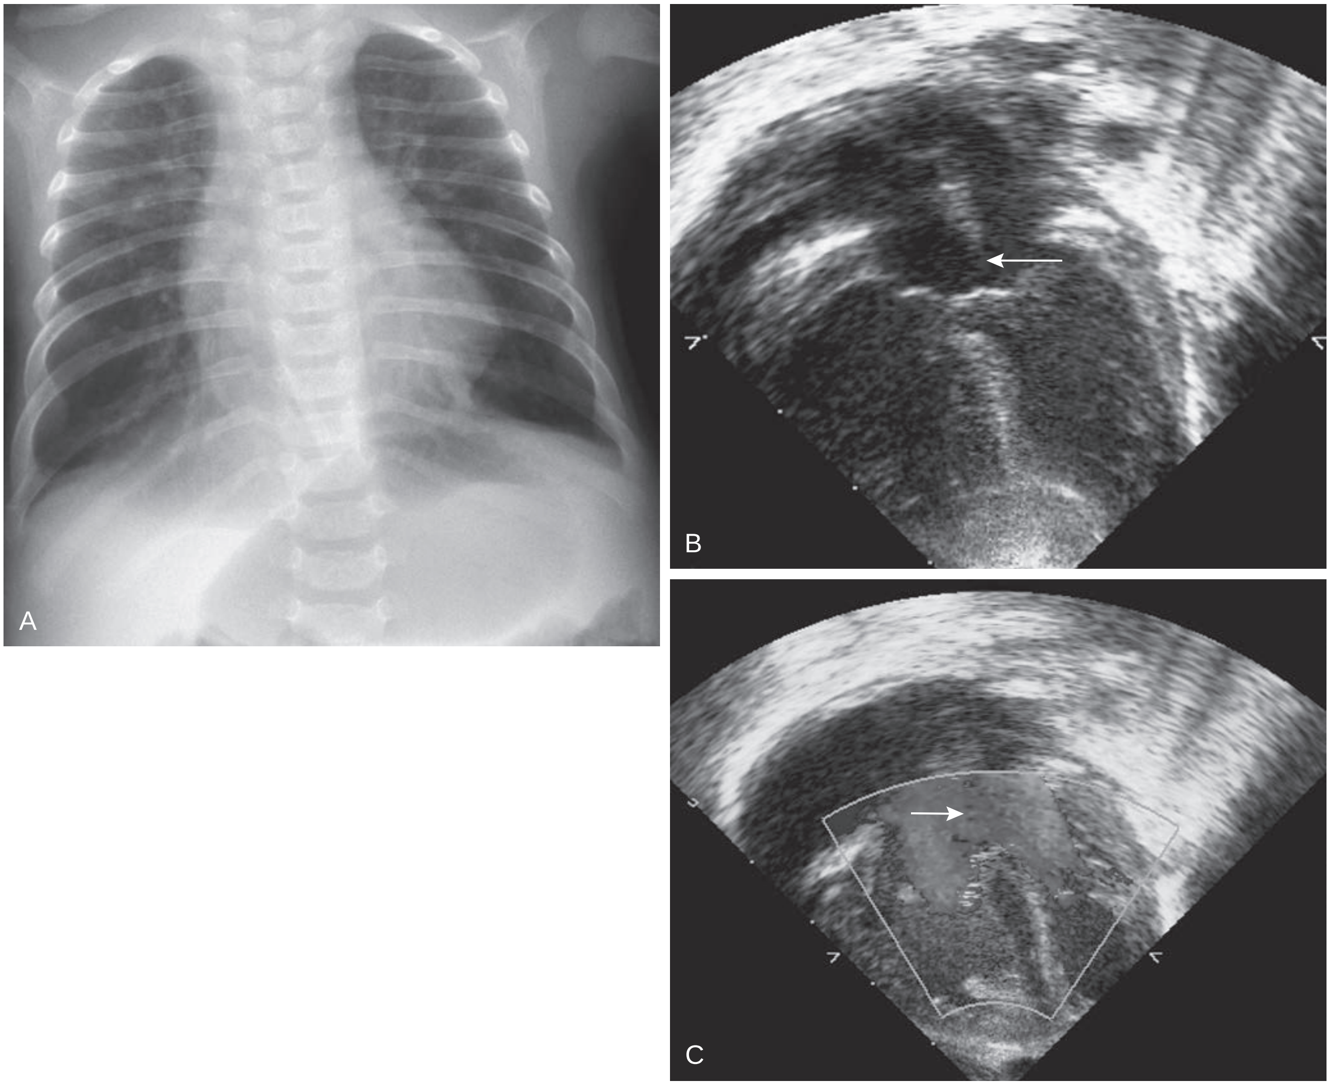
The most characteristic abnormality in Down syndrome is an atrioventricular septal defect (AVSD), also known as a common atrioventricular canal or endocardial cushion defect (e-Fig. 78.18) (see Chapter 72). Almost 70% of AVSDs are associated with Down syndrome. Other common cardiac defects include VSD, PDA, TOF, and pulmonary stenosis.[6,42] Arterial and lymphatic abnormalities also occur, the latter especially in utero.[6] Because persons with Down syndrome have decreased muscular tone, a relatively large tongue, a small pharynx, and laryngotracheomalacia, chronic upper airway obstruction may be a significant clinical problem and can result in congestive heart failure.

***Imaging.*** A combination of plain chest radiographs, ultrasound, and CT or MRI is used most often to evaluate and manage cardiovascular lesions in persons with Down syndrome, supplemented by catheter angiography as needed (see Chapter 72 and e-Fig. 78.18).

Noncardiac chest imaging findings include the presence of 11 ribs and hypersegmentation of the manubrium, as well as multiple small peripheral and parafissural cysts thought to represent hypoplastic/dysplastic lung changes. Recurrent infection, follicular bronchiolitis, and increased tumor propensity, especially leukemia and lymphoma, are additional features related to immune dysfunction in persons with Down syndrome. Abdominal findings include a characteristic configuration of the pelvis (flattened acetabula and flared iliac wings), duodenal stenosis or atresia, annular pancreas, and Hirschsprung disease.[6a]

## Trisomy 13 (Patau Syndrome)

***Overview.*** Trisomy 13 is the least common and the most severe of the viable trisomies. It occurs in 1 in 29,000 live births.



**e-Figure 78.18. Down syndrome and an atrioventricular septal defect in a 3-month-old girl.** (A) Frontal chest radiograph shows increased vascularity, mild congestion, and accompanying hyperinflation of the lungs. Eleven ribs are present bilaterally. (B) Four-chamber view from an echocardiogram shows a large atrioventricular septal defect *(arrow).* (C) Left-to-right Doppler flow is shown across the atrial defect *(arrow). (*B *and* C, *Courtesy of Lizabeth Lanford, MD, Children's Hospital, Pittsburgh, PA.)*

**TABLE 78.2** Syndromes That Predominantly Affect the Cardiovascular System

| Syndrome | Cardiovascular Defects |
|---|---|
| Absent pulmonary valve leaflet syndrome (see e-Fig. 78.15) | Maldeveloped nodular myxoid pulmonary valve cusps with aneurysmal dilation of central PAs associated with TOF, airway compression, lobar emphysema and abnormal PA branching, CM, RAA, ASD, VSD, PDA, DORV, AVSD, Marfan syndrome, 18q deletion |
| Berry syndrome | Distal AP window with AO origin of the right PA and arch interruption |
| Bland–White–Garland syndrome | Anomalous origin of left coronary artery from PA |
| Congenital cardiomyopathy: hypertrophic cardiomyopathy | Asymmetric septal hypertrophy, systolic anterior motion of mitral valve, LVOT obstruction, myocardial scar, arrhythmias |
| Arrhythmogenic right ventricular dysplasia | Fibrofatty infiltration of right ventricular myocardium, RV dyskinesia/aneurysms, arrhythmias |
| Eisenmenger syndrome | Pulmonary hypertension with bidirectional or reversed shunt at atrial, ventricular, or AP level; cyanosis; dyspnea; sudden death; peripartum CMY radiographic findings: dilated central PAs with tapering, PA calcification |
| Floppy valve syndrome | MVP, prolapse of other valves, CAD, congestive or hypertrophic CMY, ASD, MR, AR, papillary muscle or chordae tendineae rupture |
| Hypoplastic left heart syndrome | Combined mitral and AO obstruction (stenosis or atresia), underdeveloped LA and LV, hypoplastic ascending AO ± COA or AO interruption; may be associated with right diaphragmatic hernia, omphalocele, brain anomalies; radiographic findings: CM and pulmonary edema |
| Lutembacher syndrome | ASD associated with MS |
| Postmyocardial infarction syndrome (Dressler syndrome) | Chest pain, fever, polyserositis—several weeks postinfarction; radiographic findings: pericardial or pleural effusion, noncardiogenic edema |
| Postpericardiotomy syndrome | Chest pain, fever, joint pain—weeks or months after closed or open heart surgery; radiographic findings: pericardial or pleural effusion, noncardiogenic pulmonary edema, constrictive pericarditis |
| Romano–Ward syndrome | Familial Q-T prolongation, arrhythmias, syncope |
| Shone syndrome (or complex) (see e-Fig. 78.16) | Complex of multiple left-sided obstructions, parachute mitral valve, supravalvar ring of LA, sub-AS, COA |
| Sick sinus syndrome | Arrhythmias |
| Tetralogy of Fallot (see e-Figs. 78.9 and 78.15) | Combination of VSD, overriding AO, RVH, RV outflow obstruction; may be PS and PPS |
| Trilogy of Fallot | PS, ASD (or PFO), right-to-left shunting |
| Uhl syndrome (anomaly) | Congenital aplasia of RV myocardium, RV CMY |
| Wolff–Parkinson–White syndrome | Aberrant intracardiac ECG pathway producing arrhythmias; associated with Ebstein anomaly, IHSS, levo-TGA, giant RA diverticulum |

*AO,* Aorta or aortic; *AP,* aorticopulmonary; *AR,* aortic regurgitation; *AS,* aortic stenosis; *ASD,* atrial septal defect; *AVSD,* atrioventricular septal defect; *CAD,* coronary artery disease; *CM,* cardiomegaly; *CMY,* cardiomyopathy; *COA,* coarctation of the aorta; *DORV,* double-outlet right ventricle; *ECG,* electrocardiogram; *IHSS,* idiopathic hypertrophic subaortic stenosis; *LA,* left atrium; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *MR,* mitral regurgitation; *MS,* mitral stenosis; *MVP,* mitral valve prolapse; *PA,* pulmonary artery; *PDA,* patent ductus arteriosus; *PFO,* patent foramen ovale; *PPS,* peripheral pulmonary stenosis; *PS,* pulmonary stenosis; *RA,* right atrium; *RAA*, right aortic arch; *RV,* right ventricle; *RVH,* right ventricular hypertrophy; *TGA,* transposition of the great arteries; *TOF,* tetralogy of Fallot; *VSD,* ventricular septal defect.

Eighty-two percent of patients die within the first month of life. Congenital heart defects are seen in approximately 80% of patients. The most common defects include ASD, VSD, PDA, dextrocardia, and a double-outlet right ventricle.[6,43]

## Trisomy 18 (Edwards Syndrome)

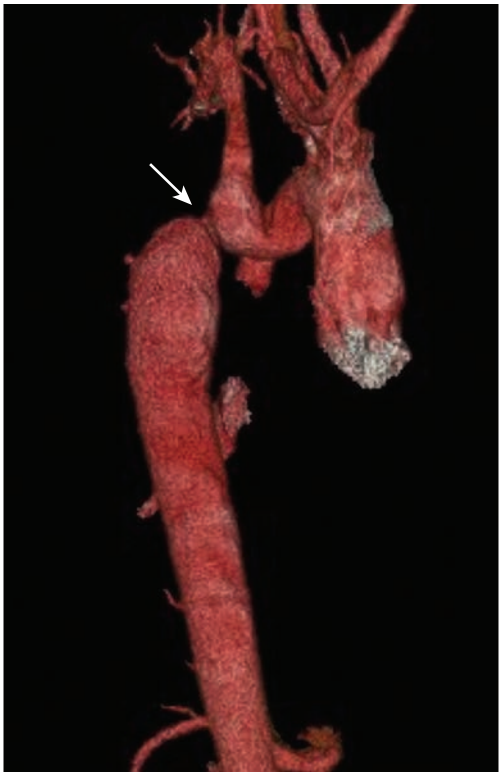
***Overview.*** Trisomy 18 is the second most common autosomal trisomy, with prevalence at birth of about 1 in 7,000. It is characterized by severe psychomotor and growth retardation, microcephaly, microphthalmia, micrognathia or retrognathia, microstomia, malformed ears, distinctively clenched fingers, and other congenital malformations.

Cardiac anomalies are seen in 90% to 100% of cases. The most common cardiac anomalies are VSD and valvular heart disease.[6] The pulmonary and aortic valves usually are affected. Other cardiac anomalies include ASD, PDA, aortic coarctation, TOF, transposition of the great arteries, and a hypoplastic left heart. Anomalies of the VACTERL spectrum also are associated with trisomy 18.

## Turner Syndrome

***Overview.*** Turner syndrome (XO, monosomy X) is one of the most frequent chromosomal aberrations in females. It affects approximately 1 in 2,000 live female births, but it has been estimated that only 1% of fetuses survive to term and that as many as 10% of spontaneous miscarriages have the 45,XO karyotype.[44] The characteristic clinical findings include a webbed neck, a shield chest with widely spaced nipples, short stature, gonadal insufficiency, and infertility.[45]

A congenital heart defect occurs in 20% to 40% of patients with Turner syndrome. The most common are coarctation of the aorta (30%) (e-Fig. 78.19) and bicuspid aortic valve (30%–50%) (see Chapter 73). Dilation of the aortic root is not as common (3%–8%) but can have devastating consequences such as dissection and rupture.[44] Other less common malformations include MVP, aortic stenosis, aortic regurgitation, partial anomalous pulmonary venous drainage, and hypoplastic left heart syndrome. Lymphangiectasia, lymphedema, hemangiomas, and systemic venous anomalies also can occur.[45]



**e-Figure 78.19. Turner syndrome in a 10-year-old girl.** This sagittal oblique three-dimensional volumetric reconstruction of the aortic arch demonstrates marked tortuosity of the transverse arch along with focal coarctation immediately distal to the left subclavian artery *(arrow).*

**TABLE 78.3** Chromosomal Anomalies and Their Associated Cardiovascular Defects

| Chromosomal Anomaly | Cardiovascular Defects |
|---|---|
| Fragile X | MVP, MR, AR, TR, dilated AO root, COA |
| Trisomy 13 (Patau syndrome) | PDA, VSD, ASD, DEXTRO, capillary hemangioma, cervical cystic hygroma |
| Trisomy 18 (Edwards syndrome) | VSD, polyvalvular heart disease (pulmonary and AO valves), ASD, PDA, COA, TOF, TGA, HPLH, VACTERL, pentalogy of Cantrell |
| Trisomy 21 (Down syndrome) (see e-Fig. 78.18) | AVSD, VSD, ASD, TOF, PDA, PS, MVP, aberrant right SCA, intimal arterial fibrodysplasia, lymphatic abnormality, upper airway obstruction and CHF |
| Cat-eye syndrome (trisomy or tetrasomy 22) | TAPVR, TOF |
| Monosomy X, XO (Turner syndrome) (see e-Fig. 78.19) | COA, bicuspid AO valve, AO aneurysm, dissection, septal defects, abnormal mitral valve, sub-AS, PS, APVR, HPLH, pentalogy of Cantrell, DEXTRO, RAA, hemangioma, lymphangiectasia, venous anomalies |
| XXY (Klinefelter syndrome) | MVP, Takayasu arteritis, cerebral aneurysms, varicose veins |
| **DELETION SYNDROMES** | |
| Monosomy 1p36 syndrome | Dilated CMY, PDA |
| 22q11 (predominantly DiGeorge syndrome (CATCH 22), also velocardiofacial syndrome) (see e-Fig. 78.17) | Type B interrupted arch, RAA, VSD, TOF, TRU, COA, aberrant right SCA, isolated SCA |
| 5p: Cri du chat syndrome | CHD |
| 4p: Wolf–Hirschhorn syndrome | ASD, VSD, valve anomalies, complex CHD, persistent left SVC |
| 17p: Miller–Dieker syndrome (lissencephaly type 1) | ASD, CHD, conduction abnormalities |
| 18q syndrome | Absent pulmonary valve, PDA, AS, dilated ascending AO |

*AO,* Aorta or aortic; *APVR,* anomalous pulmonary venous return; *AR,* aortic regurgitation; *AS,* aortic stenosis; *ASD*, atrial septal defect; *AVSD,* atrioventricular septal defect; *CATCH 22,* cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, 22q11 deletions; *CHD,* congenital heart disease; *CHF,* congestive heart failure; *CMY,* cardiomyopathy; *COA,* coarctation of the aorta; *DEXTRO,* dextrocardia; *HPLH,* hypoplastic left heart; *L,* left; *MR,* mitral regurgitation; *MVP,* mitral valve prolapse; *PDA,* patent ductus arteriosus; *PS,* pulmonary stenosis; *RAA,* right aortic arch; *SCA,* subclavian artery; *SVC,* superior vena cava; *TAPVR,* total anomalous pulmonary venous return; *TGA,* transposition of the great arteries; *TOF,* tetralogy of Fallot; *TR,* tricuspid regurgitation; *TRU,* truncus arteriosus; *VACTERL,* vertebral, anal atresia, cardiac, tracheal fistula, esophageal atresia, renal, limb; *VSD,* ventricular septal defect.

***Imaging.*** The approach to imaging of the cardiovascular system in Turner syndrome varies with the clinical scenario and is similar to other diseases with widespread cardiovascular manifestations.

## Klinefelter Syndrome

***Overview.*** Klinefelter (47,XXY) syndrome is present in 1 in 500 to 1 in 1,000 live male births.[46] The clinical findings of Klinefelter syndrome include infertility, gynecomastia, hypogonadotropic hypogonadism, cognitive impairment, and predisposition to malignancy.[46]

MVP, the most common cardiac anomaly, occurs in 55% of patients. Other uncommon defects include TOF, ASD, VSD, tricuspid atresia, and aortic coarctation. Vascular abnormalities include cerebral aneurysms, varicose veins, venous thromboemboli, and arteritis.[47]

## Other Chromosomal Anomalies

Less common chromosomal anomalies and their associated cardiovascular lesions are listed in Table 78.3. The most commonly associated defects are listed first, and cardiac lesions generally are listed before vascular malformations.

### KEY POINTS

- The typical right atrial isomerism often includes AVSD, single ventricle, DORV or TGA with pulmonary atresia, and TAPVR (often obstructed).
- Left atrial isomerism is more commonly associated with less complex CHD. The most consistent vascular anomaly is absence of the intrahepatic inferior vena cava with azygos continuation.
- Conservative management is favored where possible in the vasculopathy associated with Ehlers–Danlos syndrome. Marked vascular fragility makes both catheter and surgical interventions hazardous.
- Elucidation of the genetic and cellular pathophysiology of many of the syndromes discussed in this chapter has shed new light on the spectrum of related disorders and shows promise in the development of targeted cellular pathway therapies.
- Several hereditary vascular lesions have been linked to altered regulation of TGF-β, a cytokine pathway that affects cell performance. These TGF-β signalopathies include Marfan syndrome, Loeys–Dietz syndrome, and autosomal recessive cutis laxa. Treatment with TGF-β antagonists appears to be promising.
- RASopathies are a group of lesions with germline mutations that affect the RAS/MAPK pathway, which controls cell development, growth, and proliferation. These include NF1 and Noonan, Costello, and cardiofaciocutaneous syndromes. These lesions have distinct but overlapping features with craniofacial, cutaneous, and cardiovascular lesions and an increased propensity for malignant tumors.
- Truncus arteriosus and type B interruption of the aortic arch are often associated with a 22q11 deletion (DiGeorge syndrome).
- Trisomy 21 (Down syndrome) is the most common chromosomal disorder associated with congenital heart disease; atrioventricular septal defect is especially common.
- Monosomy X (Turners syndrome) is most strongly associated with bicuspid aortic valve and aortic coarctation. There is also a specific association with ascending aortic aneurysm and venolymphatic abnormalities.

# Myocardial, Endocardial, and Pericardial Diseases

*Randolph Otto, A. Luana Stanescu, and Mark Ferguson*

## MYOCARDIAL DISEASES

Cardiomyopathies include various diseases of the myocardium, often chronic or progressive, and associated with cardiac dysfunction. These are rare but serious disorders; only 25% of children survive more than 5 years after the onset of symptoms. Although our understanding of the causes of pediatric cardiomyopathy has advanced, the prognosis has not changed considerably in the past 30 years and is the same in developing and industrialized nations.[1,2]

Cardiomyopathies may be classified according to the dominant pathophysiology (e-Box 79.1). Four major physiologic forms of cardiomyopathy are described: dilated, hypertrophic, restrictive, and arrhythmogenic. While often discussed as distinct entities, occasionally there is considerable overlap in pathophysiologic features. Dilated and hypertrophic cardiomyopathies are the most common forms in children.[2]

Cardiomyopathy may also be classified according to etiology. Inflammatory and isolated familial cardiomyopathies account for the majority of pediatric cases with a known cause.[3] Other specific cardiomyopathies that are less common in the pediatric population include those resulting from metabolic disorders, general systemic diseases, muscular dystrophies, neuromuscular disorders, and sensitivity or toxic reactions (e.g., radiation and chemotherapy). In two-thirds of children with cardiomyopathy, no specific etiology is found.[2,3]

Because of its availability, lack of radiation use, and portability, echocardiography is the most common method used to classify cardiomyopathy and evaluate cardiac function. With improvements in technology, cardiovascular magnetic resonance imaging (MRI) has become an increasingly powerful tool.[4,5] With the multiple techniques available, cardiac MRI can be used to assess myocardial morphology and function (cine sequences), with expanding techniques for myocardial tissue characterization, including perfusion, delayed myocardial enhancement, and T1 mapping.[4]

### Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiovascular disease and has autosomal dominant inheritance. HCM demonstrates quite variable penetrance and expression, but significant disability and even sudden death can occur at any age.[6]

The cellular myocardial architecture in HCM is disorganized, while the characteristic gross morphologic feature is that of hypertrophy. Myocardial wall thickening most commonly manifests in an asymmetric distribution involving the anterior septum, but some patients show symmetric (concentric) involvement of the left ventricle (Video 79.1). Furthermore, there can be associated obstruction of the left ventricular outflow tract secondary to septal hypertrophy and systolic anterior motion of the mitral valve.[6,7]

Echocardiography is the primary imaging study used to diagnose and characterize HCM. MRI can provide a more comprehensive evaluation of regions of wall thickening as well as offer more advanced techniques such as assessing for late myocardial enhancement within regions of scarring (Fig. 79.1), perform native T1 mapping of the myocardium, and even analyze cardiac strain parameters.[7–9]

### Dilated Cardiomyopathy

Dilated cardiomyopathy is the most common form of cardiomyopathy and currently the most frequent indication for heart transplantation.[1] Characterized by dilation and impaired systolic function of the left or occasionally both ventricles, patients typically present with progressive heart failure (Fig. 79.2), up to 75% succumbing or undergoing transplantation within 5 years.[1] While the majority of pediatric cases (66%) are idiopathic, common specific etiologies may include infectious myocarditis, familial disease, and neuromuscular disorders (most commonly Duchenne and Becker muscular dystrophies).[10] Although a frequent cause of dilated cardiomyopathy in adults, coronary artery disease is uncommon in childhood. Children with sickle cell disease may develop ischemic cardiomyopathy related to “sludging microinfarctions” with resulting focal myocardial fibrosis.[11] Most children with dilated cardiomyopathy are diagnosed in the first year of life. Late presentation in childhood, reduced left ventricular shortening fraction or ejection fraction, severe mitral regurgitation, right ventricular failure, and mural thrombus were found to be associated with a worsened prognosis, while those with infectious myocarditis generally fare better.[12]

Cardiac MRI can be helpful in characterizing the presence of myocardial edema, late enhancement, ventricular function, myocardial mass, and valvular regurgitation.[13,14]

### Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is the most arrhythmogenic form of human heart disease,[15] characterized by progressive fibrofatty replacement of myocardium, most commonly involving the right ventricle (RV). Approximately 50% of affected individuals have one or more identified mutations encoding desmosomal proteins,[16] with substantial variation in genetic penetrance and clinical manifestations. ARVC is also related to the rare autosomal recessive cardiocutaneous disorders Naxos disease and Carvajal syndrome. Remodeling of intercellular gap junctions is found diffusely in ARVC, including areas not exhibiting myocyte degeneration and fibrofatty replacement. These changes may play a role in the onset of ventricular arrhythmias and sudden death, with symptoms often manifesting earlier in athletic adolescents and young adults.[17] Fibrofatty myocardial infiltration and wall thinning of ARVC can be visualized on T1-weighted spin echo magnetic resonance (MR) sequences but has low sensitivity and specificity compared with right ventricular volumes and function.[18] Additional reliable MR findings include abnormal right ventricular regional or global wall motion and aneurysms, most frequently involving the RV free wall, inflow, and outflow tracts.[19] Late gadolinium enhancement may also be present.[20–22] Biventricular involvement has been identified on MRI in more than half of ARVC cases, and while less common, left dominant forms of the disease are increasingly recognized, with involvement of the left ventricle

**e-BOX 79.1** Classification of Cardiomyopathies According to the World Health Organization

**DILATED CARDIOMYOPATHY**

- Congestive cardiomyopathy

**HYPERTROPHIC CARDIOMYOPATHY**

- Hypertrophic obstructive cardiomyopathy
- Idiopathic hypertrophic subaortic stenosis
- Asymmetrical septal hypertrophy
- Nonobstructive hypertrophic cardiomyopathy

**RESTRICTIVE CARDIOMYOPATHY**

- Arrhythmogenic right ventricular cardiomyopathy
- Arrhythmogenic right ventricular dysplasia
- Right ventricular dysplasia
- Right ventricular cardiomyopathy

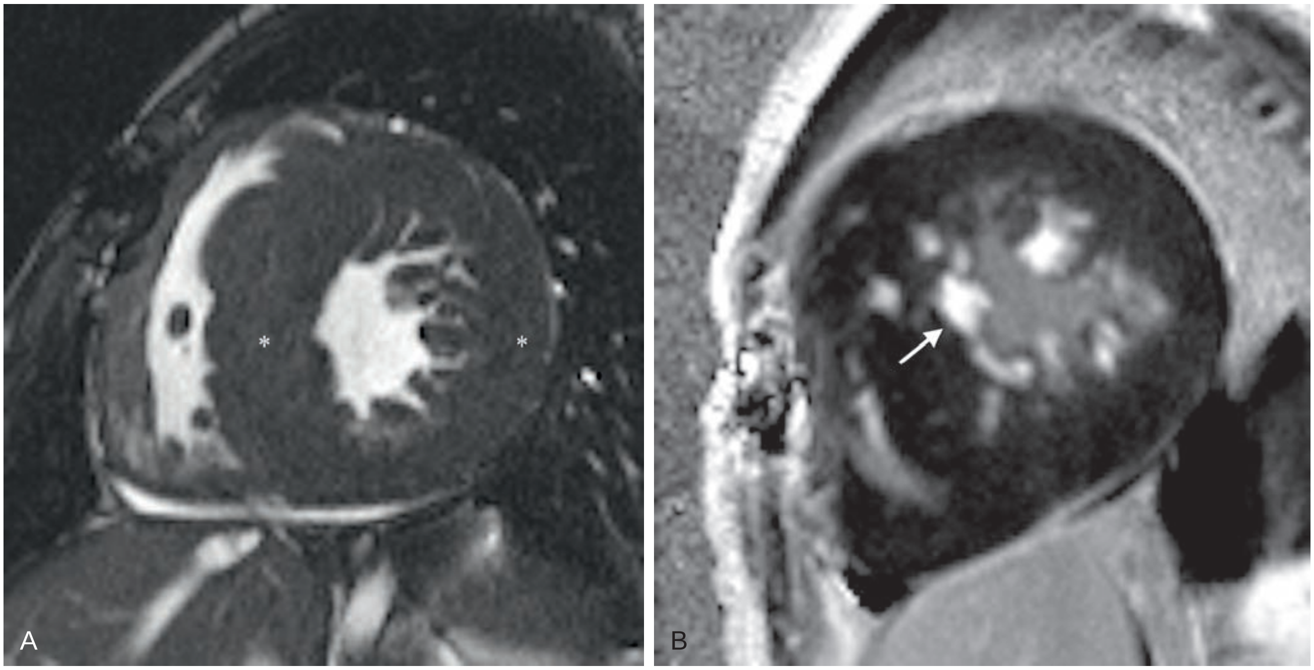

**Figure 79.1. Hypertrophic cardiomyopathy.** (A) Bright blood short axis MR image at end-diastole shows marked concentric LV wall thickening *(asterisk)*. (B) Postcontrast short axis MR image at end-diastole shows patchy late gadolinium enhancement in the LV myocardium including some trabeculations *(arrow)*.

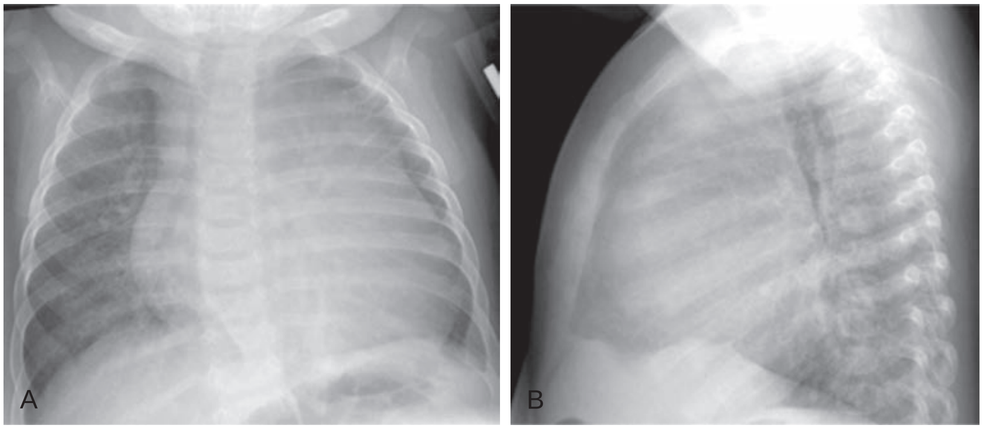

**Figure 79.2. Dilated cardiomyopathy.** (A) Antero-posterior (AP) and (B) lateral chest radiographs in an 11-month-old infant with dilated cardiomyopathy and glutamic aciduria type II show moderate enlargement of the cardiothymic silhouette.

(LV) posterolateral wall most frequent, where the changes can be potentially mistaken for myocarditis.

## Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM) is the least common pediatric cardiomyopathy[3] and continues to carry the worst prognosis and transplant-free survival despite advances in therapy.[23,24] RCM is characterized by increased myocardial or endomyocardial stiffness leading to incomplete ventricular relaxation with decreased diastolic filling, while preserving normal or near-normal systolic function.[25,26] Endomyocardial fibrosis is one of the most common etiologies of restrictive cardiomyopathy in children and adolescents. A wide variety of genetic or acquired causes of infiltrative as well as noninfiltrative myocardial diseases may also be involved in restrictive cardiomyopathy pathogenesis. However, the majority of pediatric cases remain idiopathic.[23] Marked atrial dilation contrasting with the normal or small-sized ventricles is pathognomonic on imaging. Chest radiographs demonstrate cardiomegaly with pulmonary venous congestion in up to 90% of the cases.[23] Cardiac MRI will reflect the same anatomic findings, while additionally allowing real-time evaluation of regional and global ventricular function, calculation of ventricular volumes, and quantitative assessment of blood flow across the atrioventricular valves.

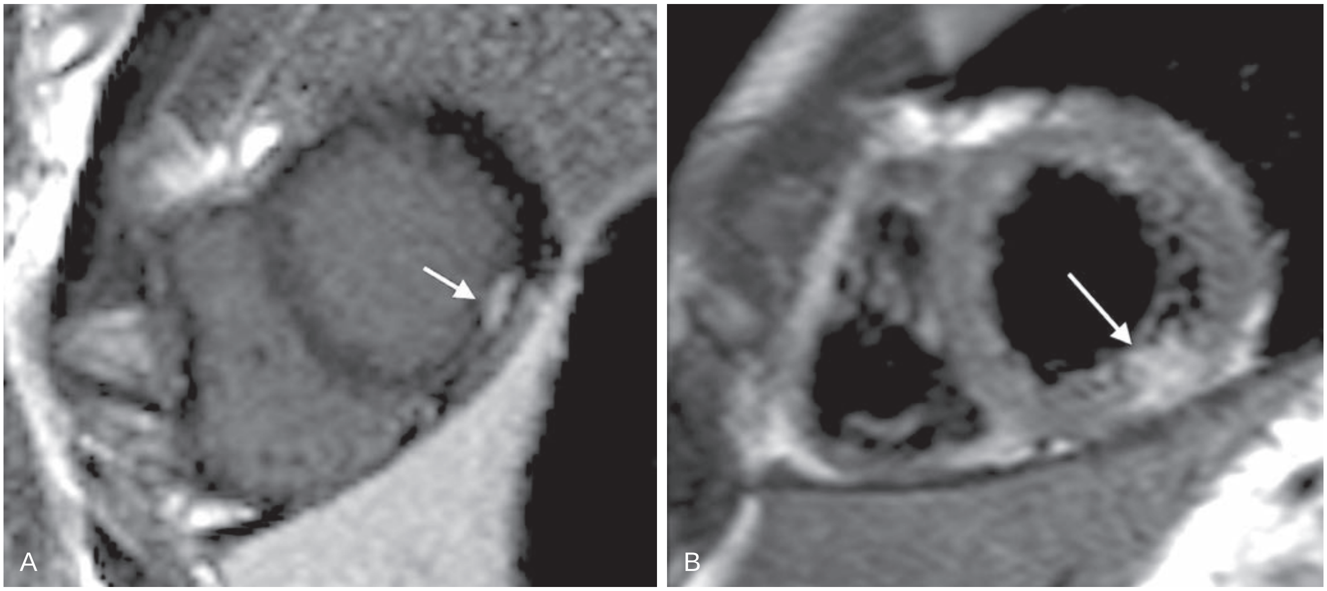

**Figure 79.3. Inflammatory cardiomyopathy.** (A) T2-weighted short axis MR image at end-diastole shows a focal region of hyperintense signal *(arrow)* within the LV inferolateral wall. (B) Postcontrast short axis MR image shows focal late gadolinium enhancement at the same site *(arrow)*. Findings are consistent with viral myocarditis.

Structural myocardial abnormalities, usually fibrosis, can be detected on delayed postcontrast inversion recovery MRI or T1 mapping. A variable degree of increased LV myocardial thickness is present in up to 34% of patients indicating a "mixed" restrictive/hypertrophic phenotype, which has been found to be associated with a better prognosis than "pure" restrictive cardiomyopathy.[24]

Constrictive pericarditis presents with similar restrictive physiology and should be differentiated from restrictive cardiomyopathy given the different management and prognosis. Increased pericardial thickness (>4 mm) with calcifications with or without contrast enhancement on computed tomography (CT) or MRI as well as a tubular configuration of the compressed ventricles are usually present in constrictive pericarditis, in contradistinction to restrictive cardiomyopathy.

## SPECIFIC CARDIOMYOPATHIES

### Inflammatory Cardiomyopathy

Inflammatory cardiomyopathy (myocarditis) is primarily caused by infectious agents, but can also be secondary to autoimmune diseases, hypersensitivity reactions, and toxic insults. While the infectious agent can be bacterial, fungal, or parasitic, in developed countries the most common etiology is viral (enterovirus, adenovirus, parvovirus, herpesvirus, etc.).[27]

Myocarditis can present with diverse manifestations ranging from nonspecific systemic symptoms (exertional dyspnea, fever, myalgia, etc.) to hemodynamic collapse and death.[28] Myocarditis has been involved in 8.6% to 12% of cases of sudden death in young adults.[29]

Echocardiography remains the initial imaging modality of choice and may demonstrate dilated cardiomyopathy, reduced ejection fraction, wall motion abnormalities, and even transient left ventricular hypertrophy.[30] However, MRI can provide a more complete and extensive evaluation of both cardiac function and myocardial tissue characterization (Fig. 79.3). The Lake Louise Criteria for diagnosing myocarditis by MRI include: hyperintense T2 signal (myocardial edema), early gadolinium enhancement of myocardium (hyperemia), and late gadolinium enhancement (fibrosis). If two of the three findings are present, the diagnostic accuracy is 78%.[31] Furthermore, T1 mapping may provide for greater diagnostic accuracy, perhaps even without the need for an intravenous contrast agent.[32,33]

### Neuromuscular Cardiomyopathy

Neuromuscular cardiomyopathy occurs in a variety of inherited neuromuscular disorders. Duchenne muscular dystrophy (DMD) is the most common of the muscular dystrophies and is caused by a defective gene on the X chromosome responsible for dystrophin production. Cardiac involvement by DMD results in myocardial fibrosis, degeneration, and fatty infiltration with associated compromise of left ventricular function.[34]

While changes associated with DMD related cardiomyopathy can be appreciated by electrocardiography and echocardiography, MRI is the superior modality for assessment.[35] Specifically, MRI offers the most comprehensive and accurate assessment of cardiac function as well as the ability to detect regions of myocardial fibrosis with late gadolinium enhancement (typically in the inferolateral wall, Fig. 79.4) and to evaluate myocardial strain metrics.[36,37] T1 mapping of the myocardium has the potential for additional quantitative assessment and detection of cardiac involvement in DMD.[38]

Becker muscular dystrophy (BMD) is another X-linked disorder that involves the dystrophin gene. While the overall clinical manifestations demonstrate a later onset and slower progression than those of DMD, the cardiac involvement in BMD can be more severe.[39]

Friedreich ataxia is an autosomal recessive trait related to mutations in the frataxin gene characterized by progressive ataxia and musculoskeletal abnormalities. The specific cardiac manifestations include hypertrophic cardiomyopathy (HCM) with systolic function impairment and associated arrhythmic complications. Heart failure is the primary cause of death in about 60% of patients.[40]

Cardiomyopathy related to BMD and Friederich ataxia can be best assessed by MRI similar to DMD.

### Metabolic Cardiomyopathy

Inborn errors of metabolism account for approximately 5% to 26% of cases of pediatric cardiomyopathy. There is a wide spectrum

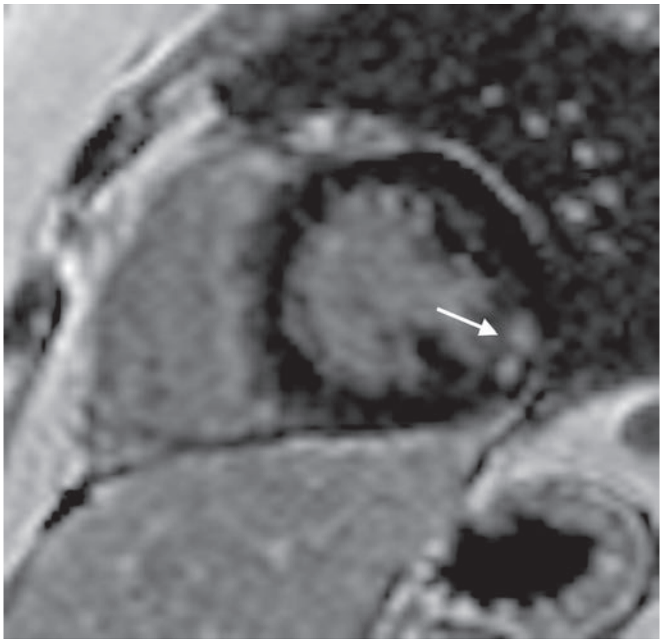

**Figure 79.4. Duchenne muscular dystrophy.** Postcontrast short axis MR image at end-diastole shows patchy late gadolinium enhancement within the LV inferolateral wall *(arrow)*.

of underlying pathophysiologies most commonly including storage disorders, fatty acid oxidation disorders, and organic acidurias, but mitochondrial and glycosylation disorders have also been implicated.[41,42]

Lysosomal storage disorders are characterized by accumulation of waste material within lysosomes. The mucopolysaccharidoses (Hurler syndrome and Hunter syndrome) are the most well known to be associated with cardiovascular disease with manifestations including thickened valves with shortened/thickened chordae tendineae resulting in valvular dysfunction as well as rigid and thickened coronary arteries. Fabry disease, a deficiency of lysosomal α-galactosidase A, can result in myocardial hypertrophy and dilation as well as conduction abnormalities and valvular dysfunction.[43]

Glycogen storage diseases are caused by deficiencies in glycogen metabolism. Types II (Pompe disease), III, and IV are the most common to involve the heart.[43]

Glycogen storage disease II is secondary to a deficiency in acid α-glucosidase and presents with two traditionally described phenotypes: classic infantile onset (<1 year of age) and late onset. Infantile onset disease classically manifests with cardiomegaly, HCM, and heart failure, with 75% of patients dying before 12 months of age.[44] However, some cases of early onset disease without cardiomyopathy have been described. Later onset disease (juvenile or adult) is often more mild in nature.[43] Cardiomyopathy tends to be rare in glycogen storage disease III; however, electrophysiologic evidence of heart dysfunction is typical. Patients with glycogen storage disease IV often die of liver disease before their cardiomyopathy becomes clinically evident.[43]

## Myocardial Iron Overload

Hemochromatosis is a disease in which there is abnormal iron deposition (iron overload) within multiple organs and can be classified as primary or secondary. Primary disease results from abnormal regulation of iron absorption. Secondary hemochromatosis is secondary to another disorder typically requiring chronic red blood cell transfusions.

Neonatal hemochromatosis is a condition in which severe liver disease is also accompanied by extrahepatic siderosis. Gestational alloimmune liver disease is typically the underlying process in which maternal antibodies bind to fetal liver antigens and result in hepatocyte injury and death.[45] While iron deposition is most notable in the liver, extrahepatic siderosis involves the heart, pancreas, exocrine and endocrine organs, and intestines, as well as the gastric and salivary glands. The reticuloendothelial elements are typically spared.[46]

Juvenile hereditary hemochromatosis is a characterized by severe iron overload occurring in the first to third decade of life. Two underlying gene mutations have been identified, *HJV* and *HAMP*. Typical clinical features include liver fibrosis/cirrhosis, hypogonadotropic hypogonadism, cardiomyopathy, and arthropathy. The primary cause of death is cardiac disease.[47]

Transfusion-related iron overload (a form of secondary hemochromatosis) is the most frequently encountered type of hemochromatosis in pediatric patients referred for imaging. Patients with refractory anemias, such as thalassemia, sickle cell anemia, myelodysplastic syndrome, or aplastic anemia, receive chronic transfusions resulting in overload of total body iron. While the liver remains the primary organ affected by iron deposition, cardiotoxicity related to iron deposition is largely accountable for patient's morbidity and mortality. Chelation therapy is critical and is guided by assessment of total body iron.

MRI has proven to be an effective method to determine total body iron (via liver assessment) as well as more specifically cardiac iron deposition. Increasing tissue iron concentrations result in an accelerated loss of T2 and T2* signal on multi-echo imaging from which tissue values can be derived (Fig. 79.5). The liver and heart can be routinely directly evaluated. However, assessment of pancreatic iron concentration has also been proposed as a simple stratification method to determine which patients are at risk for cardiac iron overload.[48]

## Toxic Cardiomyopathy

Survival rates for childhood cancers have significantly improved over the past few decades, often related to the use of anthracycline chemotherapeutic agents. However, the leading noncancer-related cause of morbidity and mortality amongst these cancer survivors is cardiovascular related disease. Anthracyclines, such as doxorubicin, are the underlying cause of many of these cardiovascular complications including decreased left ventricular mass, wall thickness, and contractility with associated heart failure.[49]

Conventional cardiac MRI offers a comprehensive evaluation of the cardiac function, whereas advanced MRI techniques include quantitative assessment of myocardial strain parameters as well as tissue characterization with T1 mapping.[50,51]

## Left Ventricular Noncompaction

Left ventricular noncompaction, also known as persistence of the spongy myocardium or left ventricular hypertrabeculation, is characterized by prominent left ventricular trabeculae, a thin compacted myocardial layer, and deep intertrabecular recesses. This appearance may be observed in healthy subjects with normal ventricular size and function, can be acquired, and can even be reversible. With more than 30 known associated genetic mutations, it remains uncertain if these features represent a distinct entity or merely a phenotypic manifestation of various cardiomyopathies. Patients with this condition may be at risk for systolic and diastolic dysfunction, arrhythmias, and embolic events.[52] Echocardiography and MRI can be useful in the identification of the thickened left ventricular trabeculae, bilayered myocardium, and deep recesses within the myocardial wall. The areas of left ventricular noncompaction may be focal or diffuse, and the diagnosis is suggested on CT or MRI by a noncompacted to compacted wall ratio of greater than 2.3 in diastole (Fig. 79.6).[53] Delayed contrast enhancement is associated with more advanced disease and is rare in infants and young children.

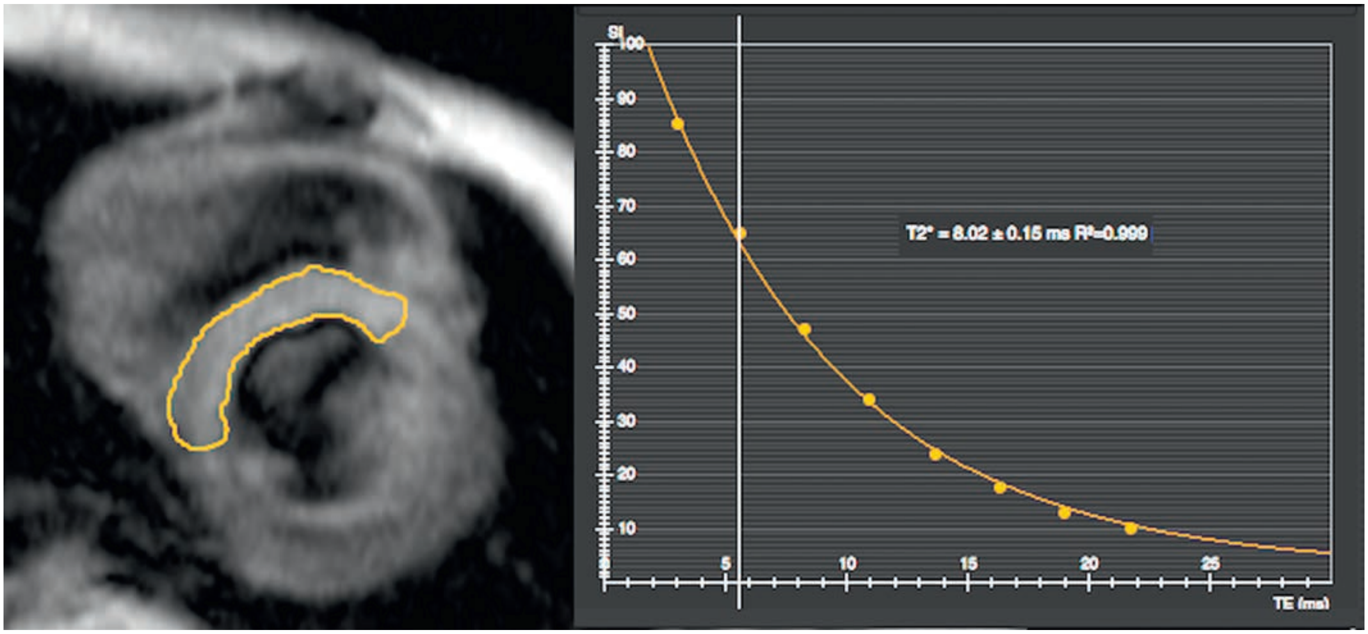

**Figure 79.5. Iron overload.** Representative image from a multiecho gradient echo MR acquisition in short axis orientation with a region of interest drawn to include the interventricular septum. Corresponding signal intensity curve over progressively increasing echo times with calculated T2* value is shown on right (Created in CVI42).

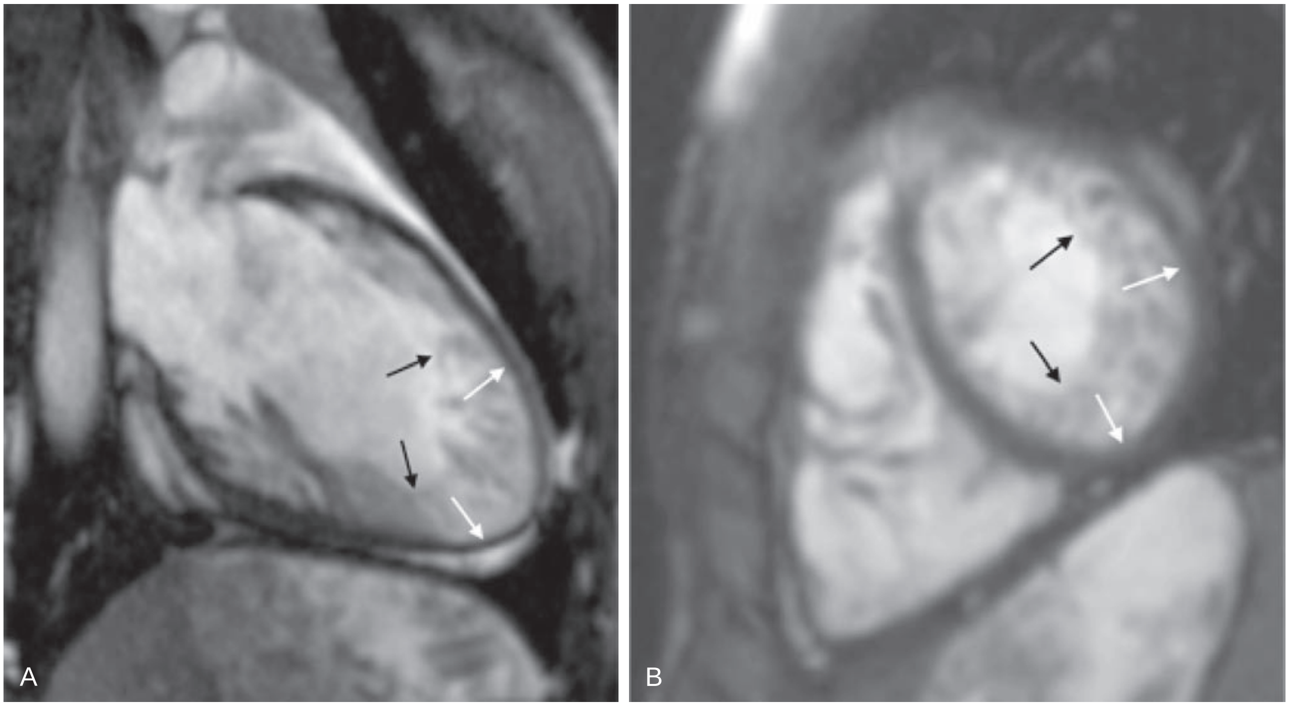

**Figure 79.6. Left ventricular noncompaction.** Left ventricular vertical long axis (A) and short axis (B) end-diastolic steady state free precession (SSFP) MR images demonstrate thickening of noncompacted myocardium *(black arrows),* compacted myocardium *(white arrows),* with noncompacted to compacted ratio greater than 2.3.

## VALVES

### Infectious Endocarditis

Before 1970, infectious endocarditis was common in children with underlying rheumatic heart disease. In the current era, endocarditis is most commonly associated with underlying congenital heart disease, whether untreated or after palliative or corrective surgery, where prosthetic patches, conduits, and valves can increase this risk. The incidence of catheter-associated infectious endocarditis involving the right heart has also risen among neonates and children receiving intensive care.[54] In recent years, an increase in infectious endocarditis in children without preexisting congenital heart disease has also been described. These cases are believed to be a result of valve infection from *Staphylococcus bacteremia*.[55,56]

Although children with infectious endocarditis may present acutely with high spiking fevers, the presentation typically is more indolent, with prolonged low-grade fever and nonspecific complaints including lethargy, weakness, arthralgia, myalgia, and weight loss.[56] In neonates, the symptoms may be more difficult to recognize and may include feeding difficulties and neurologic signs and symptoms, including seizures, hemiparesis, and apnea. Over the past 80 years, the leading bacteriologic agent responsible for infectious endocarditis has changed from viridans streptococci to staphylococci.[57]

The diagnosis of infectious endocarditis is based on the modified Duke criteria.[58] These criteria involve a combination of major criteria, including positive blood cultures or evidence of endocardial or valve involvement by echocardiography (e.g., vegetations and valve dysfunction), and minor criteria, including fever, predisposing factors (e.g., a heart condition or intravenous drug use), and evidence of embolic disease (e.g., septic pulmonary emboli, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions).[58]

Radiographic findings of infectious endocarditis may include cardiomegaly and congestive heart failure. In the setting of right heart involvement, septic emboli may result in poorly marginated, cavitary, and nodular pulmonary parenchymal opacities with a basilar predilection. Diagnostic imaging also is beneficial in assessing for sequelae of endocarditis. Mycotic aneurysms may develop when infections involve the great arteries or a patent ductus arteriosus. Prompt diagnosis of these life-threatening aneurysms by echocardiography, CT, MRI (Fig. 79.7), or angiography is critical. The valves themselves are best assessed with echocardiography from both a morphologic and a functional standpoint.

Clinical settings increasing the risk for complications include prosthetic valves, left-sided endocarditis, infection with *Staphylococcus aureus* or fungal organisms, recurrent or prolonged course, cyanotic heart disease, and systemic to pulmonary shunts. Surgery is indicated in patients with recurrent systemic embolization, unresponsive congestive heart failure, acute valvular insufficiency, conduction abnormalities such as complete heart block, or persistent sepsis despite adequate antibiotic therapy. Surgery may also be useful in patients with fungal endocarditis, large or enlarging abscesses, mycotic aneurysms, or fistulous tracts (into the pericardium, between the cardiac chambers or vascular structures).[59]

### Rheumatic Fever

Rheumatic heart disease was once the leading cause of childhood-acquired heart disease in the United States and remains preeminent within disadvantaged populations across the globe. Rheumatic heart disease is the most serious manifestation of rheumatic fever, an autoimmune disease seen after pharyngitis with group A beta-hemolytic Streptococcus. The incidence of rheumatic fever and rheumatic heart disease has decreased dramatically with improved living conditions and the prompt use of antibiotics in the developed world.[60]

Diagnosis of rheumatic fever is based on the Jones criteria.[61] Rheumatic fever is diagnosed if the child has two major criteria or one major and two minor criteria, plus evidence of recent streptococcal infection. Major criteria include migratory arthritis, carditis, Sydenham chorea, erythema marginatum, and subcutaneous nodules. Minor criteria for diagnosis include aseptic arthralgias or monoarthritis, fever, elevated erythrocyte sedimentation rate, presence of C-reactive protein, prolonged PR interval on the electrocardiogram, and leukocytosis.[62]

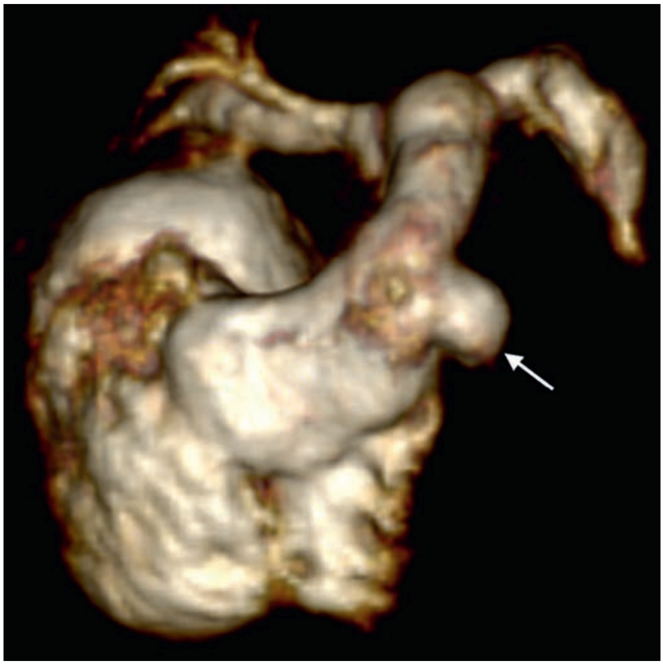

**Figure 79.7. Infectious endocarditis.** Contrast-enhanced MR angiography of the right heart and pulmonary arteries in a 3-year-old child with palliated complex congenital heart disease. Volume rendered image demonstrates a saccular mycotic pseudoaneurysm arising at the proximal right ventricle to pulmonary artery conduit anastomosis *(arrow)*.

Although all four cardiac valves may be affected by rheumatic heart disease, it is predominantly the mitral valve that is involved.[60] Acute valvular insufficiency develops, which, if severe, can result in congestive heart failure and death.[60] Noninfectious vegetations can be present on the valve leaflets, and the diagnosis of subclinical carditis is increasing with the use of echocardiography.[62] Other abnormalities that can be seen in patients with rheumatic heart disease include pericardial effusion and left atrial enlargement, characteristically involving the atrial appendage (Fig. 79.8). In chronic disease, affected valves may become stenotic in addition to the regurgitation that develops acutely.

## PERICARDIUM

### Normal Pericardium

The pericardium is a thin double-layered serous and fibrous structure that covers the heart and the origin of the great vessels.[63] The pericardial cavity is delineated by the visceral and parietal components of the inner serosal layer. Up to 50 mL of physiologic serous fluid can fill the pericardial cavity in adults. The pericardial fluid usually accumulates in the two main pericardial sinuses, transverse and oblique, and their multiple recesses (Fig. 79.9), which may be confused on CT with mediastinal lymphadenopathy, bronchogenic cysts or aortic dissection.[64,65]

Given that normal pericardial thickness measures less than 2 mm, radiologic visualization is possible only when facilitated by adjacent epicardial fat (more prominent along the right ventricle), mediastinal fat, and/or pericardial fluid.[65] Limited visualization

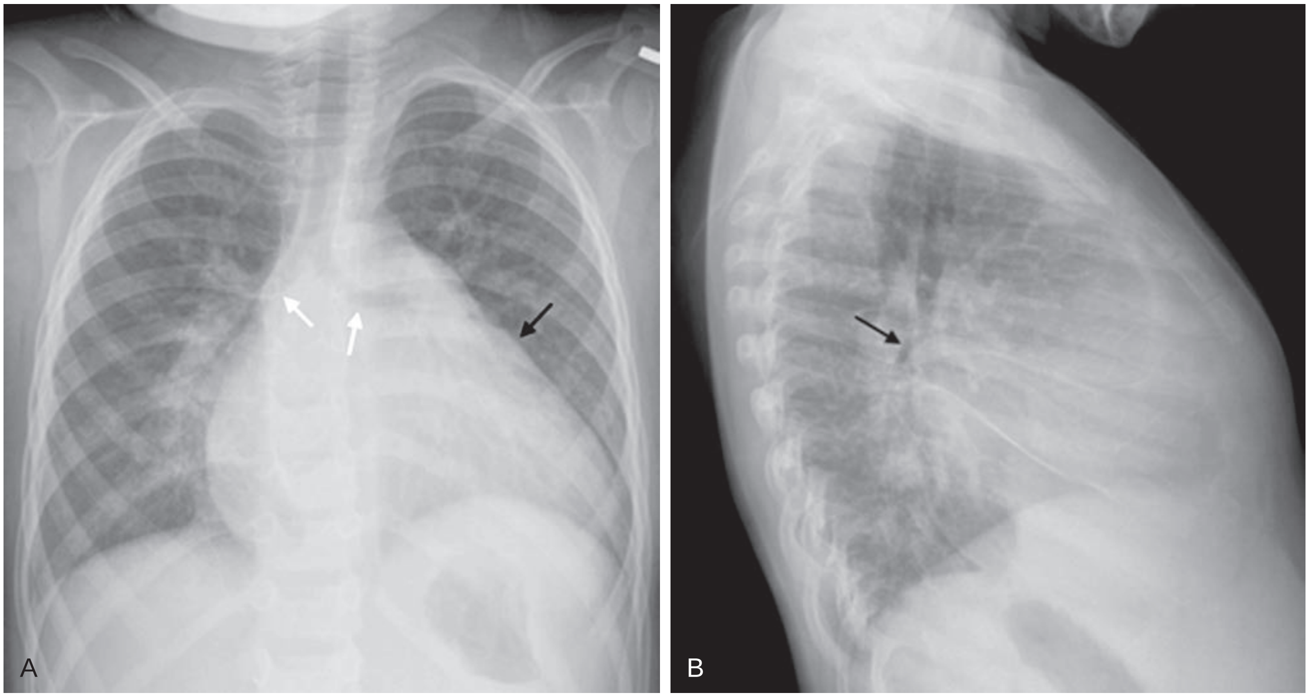

**Figure 79.8. Rheumatic heart disease.** PA (A) and lateral (B) chest radiographs demonstrating typical findings of generalized cardiac enlargement, with splaying of the carina *(white arrows)* and posterior displacement of the left lower lobe bronchus *(black arrow)* on (B) as evidence of left atrial enlargement, with prominent left atrial appendage *(black arrow)* on (A). Interstitial pulmonary edema and pleural fluid reflect elevated pulmonary venous pressure.

of the pericardium along the left ventricular wall due to minimal epicardial fat should not be confused with a pericardial defect in the absence of additional imaging signs.

Similar to adults, echocardiography has an important initial role in evaluating pericardial disease in pediatric patients, but is limited at times by difficulties in detecting mildly increased pericardial thickness or loculated pericardial effusions.[65,66] MR and CT provide a more complete evaluation of the pericardium and can be utilized as problem-solving tools in complicated cases.[65] MR is becoming the imaging modality of choice in children, allowing morphologic as well as functional cardiac evaluation with a large field of view, high soft tissue contrast, and characterization of inflammatory pericardial disease with late gadolinium enhancement.[13]

Normal pericardium is indirectly visualized as an echogenic line on echocardiography. On CT, the pericardium is best appreciated in systole as a hyperdense linear structure outlined by adjacent fat, while on MRI, the normal pericardium is characterized by intermediate to low signal on both T1 and T2 sequences given the fibrous composition.[67]

## Congenital Absence of the Pericardium

Pericardial defects are rare, found in less than 1/10,000 autopsies, and can be partial or complete.[67]

Partial pericardial defects involve the left heart in the majority of cases.[68] Partial pericardial defects, particularly the so-called foramen types, were found to cause herniation of cardiac structures that may lead to left atrial appendage strangulation or coronary artery compression with acute myocardial necrosis.[66,67,69] A focal bulge is typically present along the left heart border on imaging, corresponding to the herniated region.[67]

Complete absence of the pericardium usually involves the left side more frequently than the right, or may be bilateral. Complete pericardial absence is usually asymptomatic. Incidental imaging findings in complete bilateral as well as left-sided pericardial absence include levorotation of the heart with effacement of the right heart border and abnormal lucent bands on radiographs and CT due to lung tissue interposition in the aortopulmonary window and between the heart base and the diaphragm.[67,70] Excessive apical mobility may be present on cardiovascular magnetic resonance (CMR) imaging.[71]

## Pneumopericardium

In infants and neonates, pneumopericardium associated with other air leaks can occur in the setting of resuscitation or severe lung disease requiring utilization of positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP).[72] In older children with obstructive airway disease like asthma, pneumopericardium may present with pneumomediastinum and subcutaneous emphysema as part of air leak syndrome.[73]

On chest radiographs and CT, the hallmark of pneumopericardium is a lucent band that surrounds the cardiac silhouette up to the origin of the great vessels (Fig. 79.10). Pneumopericardium should be differentiated from pneumomediastinum that may also surround the heart but usually extends more superiorly in the upper thorax above the great vessels root, potentially dissecting into the cervical region soft tissues. Tension pneumopericardium in neonates is associated with high mortality and should be recognized and treated promptly.[74,75]

## Infectious/Inflammatory Pericarditis

In children, pericarditis most often occurs after cardiac surgery. In the absence of a surgical history, idiopathic or viral pericarditis accounts for up to 68% of cases, while bacterial etiology is found

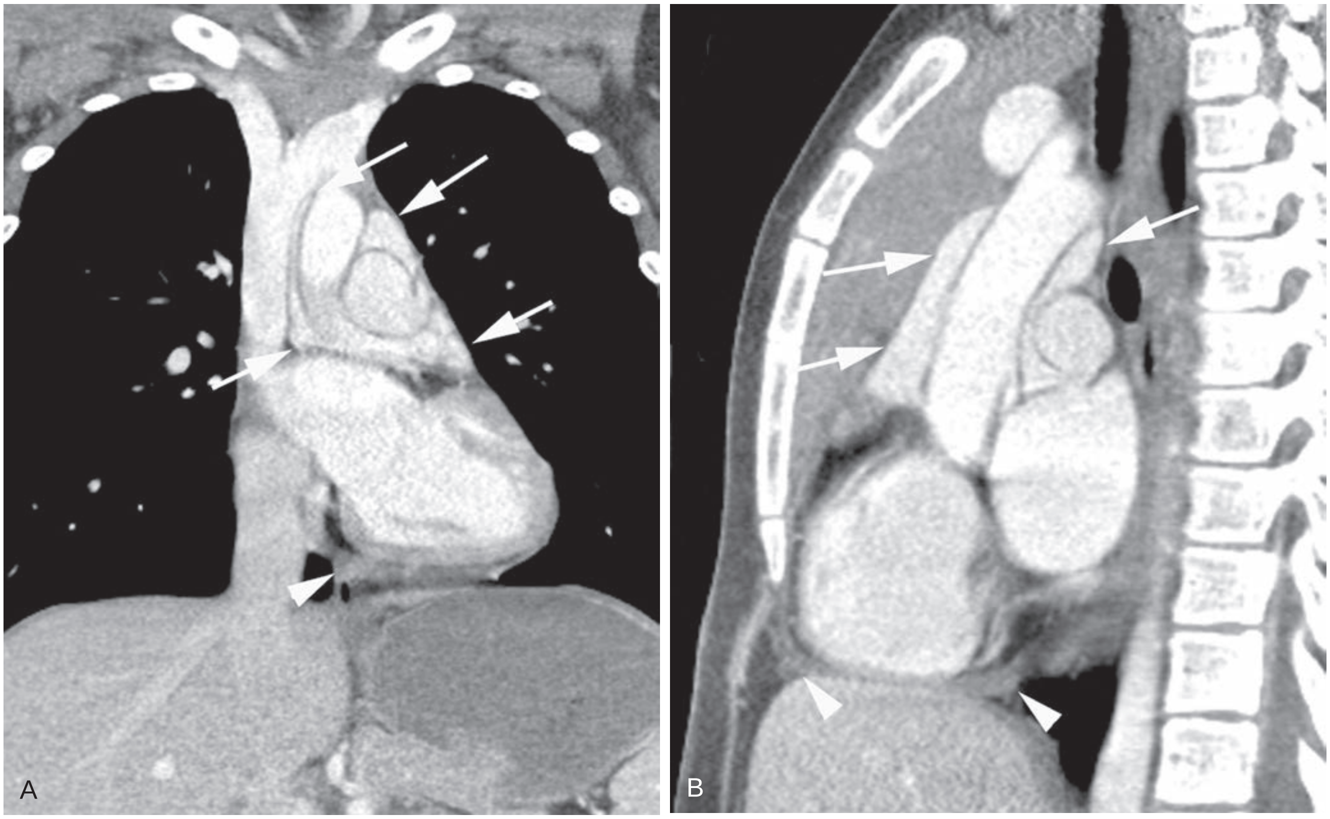

**Figure 79.9. Hemorrhagic pericarditis.** Coronal (A) and sagittal (B) contrast-enhanced chest CT images in an 11-year old with recurrent hemorrhagic pericarditis show active extravasation within the antero-superior aspect of the transverse pericardial sinus *(arrows)*. No hemorrhagic source was clearly identified. Slightly hyperdense pericardial fluid is also noted along the inferior aspect of the ventricles *(arrowheads)*. The patient was eventually diagnosed with pulmonary capillaritis and familial factor X deficiency.

in approximately 5% of cases (Fig. 79.11).[76,77] Chest trauma or connective tissue disorders such as lupus may also cause pericarditis in pediatric patients.

Cardiac MR plays an increasing role in the diagnosis and management of pericarditis in children, similar to adults. In the acute phase, inflammatory changes will cause pericardial thickening greater than 4 mm, with effusion and focal or diffuse pericardial enhancement on late gadolinium enhancement sequences (see Fig. 79.11).[13] Chronic inflammatory pericarditis is characterized by irregular thickening of the pericardium with variable contrast enhancement and occasionally increased adjacent epicardial fat.[66] In constrictive pericarditis, the fibrotic and/or calcified pericardium will demonstrate low signal on all MR sequences. Pericardial calcifications are best depicted on CT. The presence of late gadolinium enhancement may indicate potential reversibility with medical therapy.[78] Functional MRI will demonstrate diastolic interventricular septal flattening while phase contrast imaging of the tricuspid valve will show a restrictive filling pattern.[79]

## Pericardial Effusion

The etiologic spectrum of pericardial effusions in children has dramatically changed over the last decades. Neoplastic disease has become the leading cause, since the use of vaccines and antibiotic therapy has significantly decreased the incidence of pericardial effusion associated with bacterial pericarditis.[80] Idiopathic or viral pericardial effusions are more common in adolescents, particularly males.[77]

Accumulation of pericardial fluid follows a sequential pattern, with early collection seen along the posterolateral left or inferolateral right ventricular walls, followed by filling of the superior pericardial recess. Moderate to large pericardial effusions eventually accumulate anterior to the right ventricle and right atrium (Fig. 79.12).[66,79] Echocardiography remains the first-line imaging method of choice. CT and MRI can help differentiate pericardial effusion from pericardial thickening as well as characterize the pericardial fluid based on attenuation values (CT) and signal intensity (MRI). Chest radiographs have a limited utility in the diagnosis of pericardial effusion.[65,79]

Cardiac tamponade is the result of rapid accumulation of a relatively small amount of pericardial fluid or air (150–200 mL) that causes increased pericardial pressure, limiting the ventricular filling and cardiac output and eventually leading to cardiogenic shock and cardiac arrest.[79,81] Although the diagnosis is mostly clinical, if patients are evaluated with CT or MRI the imaging signs would include a large pericardial effusion with dilation of the superior vena cava (SVC), inferior vena cava (IVC), and hepatic veins, as well as flattening or inversion of the anterior right atrial and right ventricle walls during early systole and diastole.[66,79]

Pericardial tamponade in neonates after central venous catheter placement with vessel wall perforation is rare but associated with high mortality. A recent study suggests that this may be prevented if the tip of the catheter remains above the superior pericardial reflection, projected on chest radiographs just below the posterior right third intercostal space.[82]

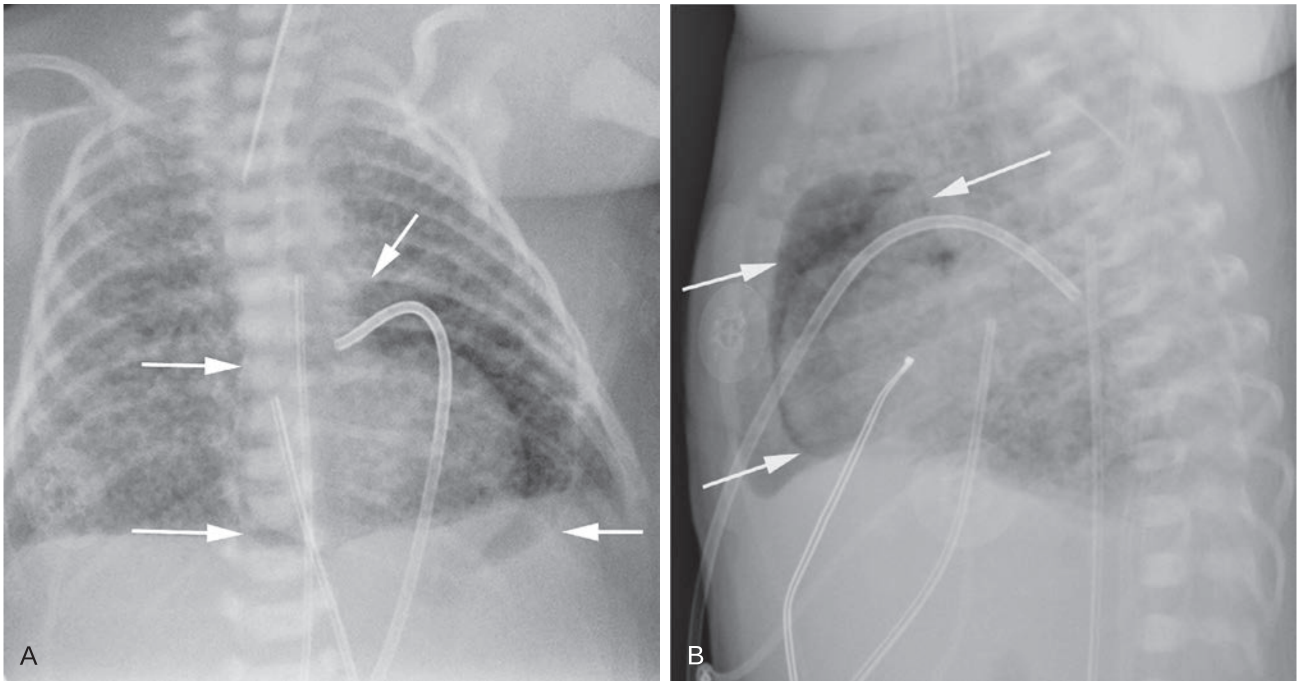

**Figure 79.10. Pneumopericardium.** Frontal (A) and lateral (B) chest radiographs in a ventilated premature newborn female with a large neck mass demonstrate air outlining the cardiac silhouette and the origin of the great vessels *(arrows)*. Diffuse granular and patchy pulmonary opacities are also noted consistent with infantile respiratory distress syndrome.

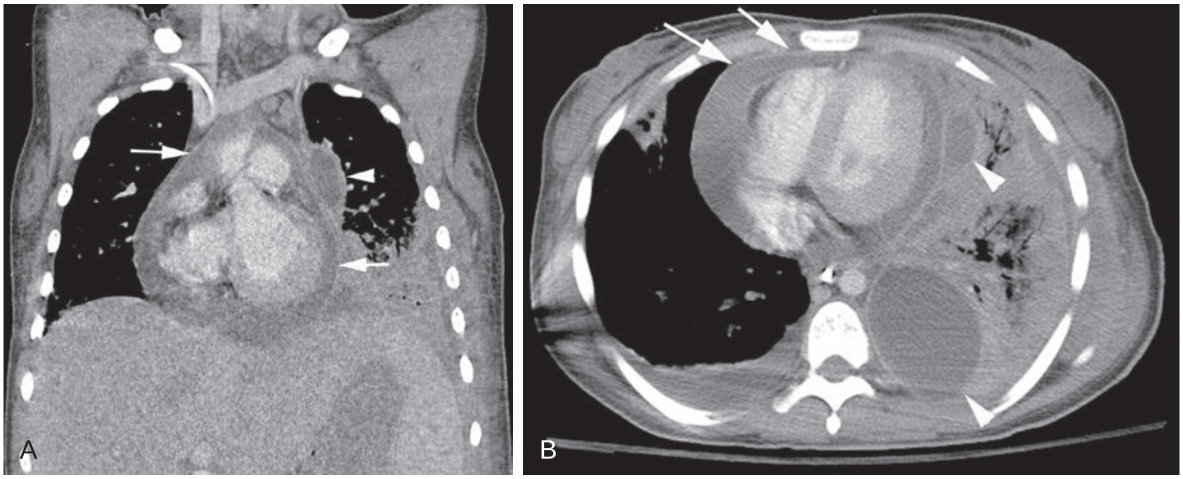

**Figure 79.11. Infectious pericarditis.** Contrast-enhanced coronal (A) and axial (B) CT images of the chest show a large pericardial effusion with pericardial enhancement *(arrows)* suggestive of pericarditis in this 16-year-old with severe pneumonia. Loculated left empyema *(arrowheads)* is also noted.

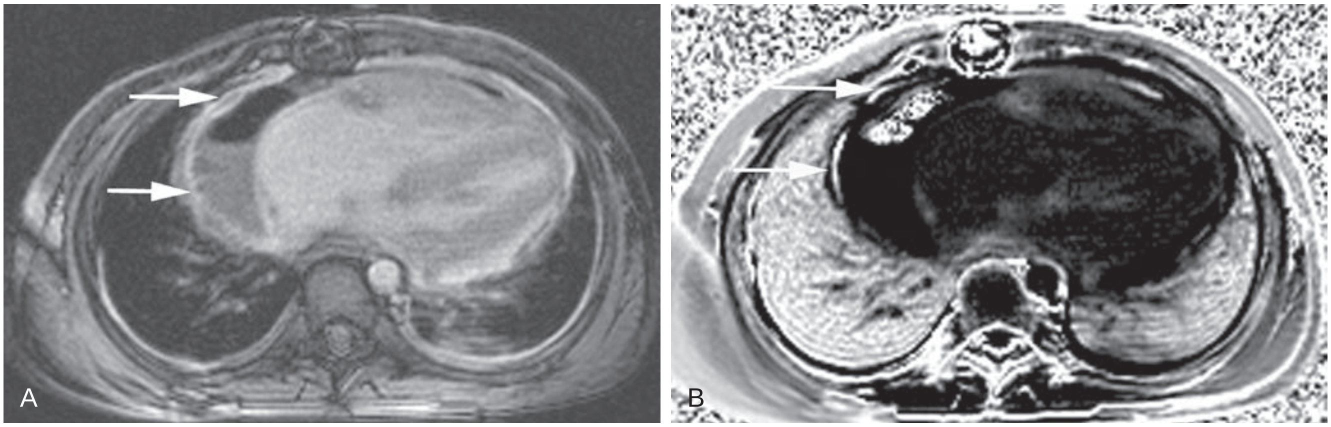

**Figure 79.12. Pericardial effusion.** Magnitude (A) and phase sensitive (B) axial LGE (late gadolinium enhancement) PSIR (phase-sensitive inversion recovery) images with optimized TI at 170 msec in a 14-year-old 3 weeks post heart transplant with recurrent hemorrhagic pericardial effusion status postdrainage. There is evidence for a large pericardial collection with air and complex fluid along the right atrium. Mild pericardial thickening and enhancement is also noted *(arrows),* likely reactive. No evidence of infection on microbiology exams.

## KEY POINTS

- Nearly two-thirds of pediatric cardiomyopathy cases are idiopathic. Of the cases of cardiomyopathy with an identified cause, 30% are infectious and 20% to 25% are familial.
- HCM is the most common genetic cardiovascular disease.
- Idiopathic dilated cardiomyopathy is the most common cause of congestive heart failure in children and the most frequent indication for heart transplantation.
- ARVC is a genetic desmosomal disorder with variable penetrance and characteristic MRI findings.
- Increased pericardial thickness (>4 mm) with calcifications, contrast enhancement on CT/MRI, and a tubular configuration of the compressed ventricles can help in differentiating constrictive pericarditis from restrictive cardiomyopathy.
- DMD is the most common of the muscular dystrophies affecting the heart.
- Iron deposition related cardiomyopathy is a potential serious consequence of repeated red blood cell transfusions.
- The radiologic visualization of the normal pericardium (<2 mm) depends on adjacent epicardial fat, usually more prominent along the right ventricle, and minimal along the left ventricular wall. Nonvisualization of the left pericardium should not be confused with pericardial absence/defect in the absence of additional imaging signs.
- Pneumopericardium should be differentiated from pneumomediastinum that may also surround the heart but usually extends more superiorly in the upper thorax above the roots of the great arteries.

# Cardiac and Pericardial Tumors

*Karen Lyons and S. Bruce Greenberg*

Primary cardiac tumors are rare in children, with a reported prevalence of up to 0.32%.[1] Use of echocardiography has resulted in more frequent detection of cardiac tumors in the fetus and neonate.[2] More than 90% of pediatric cardiac tumors are benign.[1] Symptoms are variable and usually depend on tumor location and size. Intracavitary cardiac tumors can cause cardiac valve obstruction or spread of tumor emboli, and present with heart failure, dyspnea, or neurologic symptoms. Myocardial tumors compress the cardiac lumen, leading to obstruction or heart failure, and can be associated with arrhythmias. Pericardial tumors are associated with pericardial effusions. Conventional radiographs may show cardiomegaly, an abnormal cardiac silhouette, or pulmonary edema (e-Fig. 80.1). Cardiac tumors in children can be associated with several syndromes (e-Table 80.1). Computed tomography (CT) and magnetic resonance imaging (MRI) findings help differentiate tumor types (Table 80.2).

## RHABDOMYOMA

***Pathophysiology and Clinical Presentation.*** Rhabdomyoma, the most common primary cardiac tumor of childhood, accounts for 60% to 79% of all cardiac tumors in infancy.[1,3] Rhabdomyomas are hamartomas that regress and have no potential for malignancy. Although greater than half of patients with rhabdomyoma are asymptomatic, presentations include nonimmune fetal hydrops, outflow tract obstruction, or arrhythmia. At least 50% of patients with rhabdomyoma have tuberous sclerosis, and rhabdomyomas can be the first manifestation.[3]

***Imaging.*** Rhabdomyomas are round, hyperechoic, solid masses on echocardiography (e-Fig. 80.2). They usually are multiple and occur most commonly in the ventricular tissue but also can arise from atrial walls.[4,5] Signal characteristics on T1- and T2-weighted MRI are similar to those of myocardium, making noncontrast MRI less sensitive than echocardiography.[6] They have increased attenuation compared with myocardium on noncontrast-enhanced CT scans, and decreased perfusion and variable postcontrast enhancement on MRI (Figs. 80.3 and 80.4).[7–9] Small fat globules may be detected.

## FIBROMA

***Pathophysiology and Clinical Presentation.*** Cardiac fibroma is the second most common and the most commonly resected primary cardiac tumor of childhood.[9–11] The tumors are frequently detected in infancy but can present throughout childhood. Fibromas are solitary tumors arising from myocardium composed of fibroblasts and collagen, and can be associated with Gorlin (basal cell nevus) syndrome.[10,11] Children can present with heart failure and arrhythmia.

***Imaging.*** Echocardiography reveals a heterogeneous, echogenic, solitary mass.[11] Cardiac fibromas are isointense to hypointense on T1-weighted MRI with variable T2 signal.[9,10,12] Classically, MRI shows decreased first pass perfusion and characteristic rim enhancement with decreased central enhancement on delayed imaging[9,13] (Video 80.1 and e-Fig. 80.5).[7,14] Calcifications are a frequent and differentiating finding compared with rhabdomyoma (e-Fig. 80.6).[1,11,15]

## MYXOMA

***Pathophysiology and Clinical Presentation.*** Myxoma, the most common cardiac tumor in adults, is rare in children.[1,3,10,11] Most myxomas are pedunculated, exophytic irregular masses attached to the atrial septum but can originate from other endocardial locations. Myxomas in children frequently are associated with Carney syndrome.[16] Compared with adults, they are more likely to be multiple and to recur. Clinical symptoms include obstructive cardiac symptoms, embolic phenomena, and constitutional symptoms.

***Imaging.*** Echocardiography identifies a pedunculated mass that often prolapses across the mitral or tricuspid valve.[6,11] On MRI, myxomas demonstrate heterogeneous signal and myxoid

## Abstract:

Primary pediatric cardiac tumors are rare. Use of echocardiography has resulted in more frequent detection of cardiac tumors in the fetus and neonate. More than 90% of pediatric cardiac tumors are benign. Symptoms are variable and usually depend on tumor location and size. Intracavitary cardiac tumors can cause cardiac valve obstruction or spread of tumor emboli, and present with heart failure, dyspnea, or neurologic symptoms. Myocardial tumors compress the cardiac lumen, leading to obstruction or heart failure, and can be associated with arrhythmias. Pericardial tumors are associated with pericardial effusions. Conventional radiographs may show cardiomegaly, an abnormal cardiac silhouette, or pulmonary edema. Cardiac tumors in children can be associated with several syndromes. Computed tomography (CT) and magnetic resonance imaging (MRI) findings help differentiate tumor types.
